4.1 Introduction

Particle accelerators were originally invented as enabling tools for physics research, for example, nuclear and elementary particle physics. Many, if not most, of the important concepts were invented for almost all accelerators and, in particular, linear accelerators (LINACs), around 1930. However, technological capabilities at that time did not permit anything but a proof of principle of LINAC operation. By using the term *LINAC*, we mean devices where, typically, the particle passes only once, on a straight trajectory through a possibly long structure to gain energy, and contrast this to ''circular'' devices such as synchrotrons and cyclotrons, where the particle passes a great number of times through the same accelerating structure. Accelerators such as microtrons and recirculating LINACs, where particles travel only a ''few'' times through the accelerating structure, show the limitations of such distinctions. With one or only a few passes of acceleration, LINACs typically provide the highest throughput of particles at a given energy.

After the development of high-power short-wave and microwave radiofrequency (RF) sources for radar, it was possible to undertake the construction of useful LINACs. Successive improvements pushed by continuous requests for still more energetic and powerful beams of better and better quality led from the initial crude machines to the very elaborate LINACs of today. In the past 20 years, the use of superconducting materials such as niobium has been a most significant innovation.

Besides being used in nuclear and particle physics research, LINACs are now also used as a source of energetic particles in equipment for medical, biological, and industrial applications, including industrial irradiation, radiotherapy, medical tool sterilization, food conservation, and baggage inspection, and provide intense beams of neutrons or photons for use as probes for condensed matter, materials, and in biological sciences. In the future, LINACs will enable methods to deal with radioactive waste and other societally important applications.

In this chapter, Section 4.2 explains the general principles of linear acceleration. A historical approach has been taken. Both the evolving goals and the difficulties encountered that have led to the sophisticated and complex designs of today's electron and proton LINACs are explored. Electron LINACs are described with some details of their components, limitations, application areas, and advanced research for the future. Proton LINACs are

described next, explaining in more detail the problems encountered at both low and high energies. Again, intensity and beam quality limitations are considered. Present and future applications are presented.

Heavy-ion LINACs, which have some special considerations and unique realizations, represent the final general category of LINACs.

The induction LINAC and alternating-phase-focused (APF) LINACs are covered briefly. The work being done on the search for new methods of acceleration aimed at reaching still higher energies in shorter distances for future generations of colliding beam machines for high energy physics and for tabletop devices for small laboratory research is described.

The final section, on engineering topics, covers the various aspects of LINAC construction: accelerating structures, magnetics, RF engineering, wideband electronics, instrumentation, automatic controls, and computers.

4.2
General Principles and Brief History

4.2.1
The Original LINACs

In the first part of the twentieth century, the development of nuclear physics and, later on, the discovery of induced radioactivity prompted the search for energetic projectiles to produce new nuclear reactions. The first particle accelerators were soon made from DC high-voltage generators, but source voltage and, therefore, particle energy were limited by electrical breakdown. To obtain more energetic projectiles, new methods had to be invented.

The proposal by Ising [1] that led to the development of LINACs called for an array of metallic tubes with an applied potential creating an electric field between tubes, but not inside them. Charged particles launched along the axis of the tubes were to be accelerated while traversing the gap between two adjacent tubes but drifted at constant velocity when inside a tube. Ising suggested that pulsed potentials be applied across the drift tubes at the time the charged particle bunches would enter the gap, and be switched off once they entered the tubes. Such a method, difficult to apply accurately enough then, is today the principle of the induction LINAC, mentioned in Section 4.6.1. Instead of using very accurately synchronized high-voltage pulses, Wideroe [2] proposed more simply to apply RF voltages on a succession of drift tubes, as shown in Figure 4.1. He tested a small device with two gaps and a single drift tube, and, with an RF peak voltage of 25 kV, accelerated Na^+ and K^+ ions produced by a heated filament to an energy of 50 keV.

Sloan and Lawrence [3] at Berkeley used 30 tubes of progressively increased length and a gap voltage of 42 kV at an RF frequency of 10 MHz to reach an energy of 1.25 MeV for Hg ions.

4.2.2
Phase Stability

To produce not only a few energetic particles but also a good useful beam, the following problems have to be resolved:

- how to obtain a large enough number of particles (*beam intensity*)?
- how to concentrate the particles – or focus them – into a thin enough beam (*beam quality*)?

Let us look further into this succession of accelerations between drift tubes at two

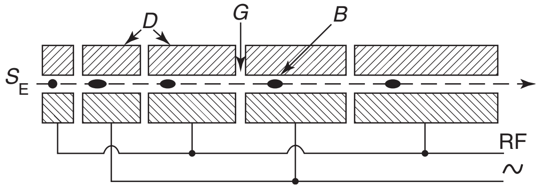

Figure 4.1 Principle of the Wideroe method of RF linear acceleration used in 1931 on the first machine of Sloan and Lawrence. *S* is a source of positive ions. *D* represents drift tubes alternatively connected to the two terminals of an RF voltage. The ion bunches *B* are accelerated in the gaps *G*. Because the velocity increases as the bunches are accelerated, the length of the drift tubes must increase along the machine.

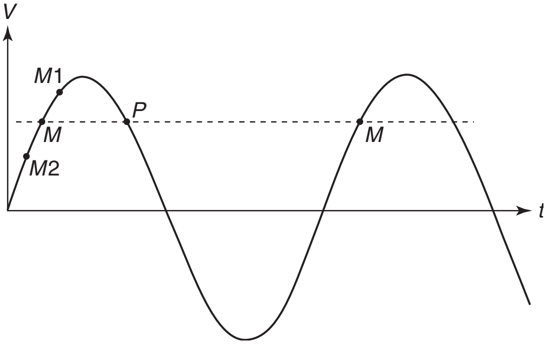

Figure 4.2 The voltage *V* in the gap *i* between the drift tubes has a sinusoidal variation with time *t*. To reach gap $i+1$ at the right time, the proper acceleration is necessary; the required amplitude occurs at two phases per period: *M* and *P*. While points *P* are unstable, points *M* are stable and particles form bunches around such phases.

consecutive gaps numbered i and $i+1$, where a sinusoidal RF voltage is applied (Figure 4.2). Suppose a particle arrives at gap i with the correct energy. The length of the drift tube between the gaps i and $i+1$ has been chosen for a given energy increase through gap i. Such a gain is produced according to Figure 4.2 at only two phases on the RF cycle: phases *M* and *P*. If particles crossing the gaps at these exact phases were the only ones that could be accelerated properly, the beam intensity would be extremely small. Let us examine, however, what happens around phase *M*, say at *M*1 and *M*2. A late particle at *M*1 is accelerated more and catches up with *M*. An early one at *M*2, on the contrary, is slower and also meets with *M*. It is said that there is phase stability around phase *M*. It can be seen that around *P* there would be instability. Thus, particles are caused to bunch around phases such as *M*, where the voltage is rising, and a more intense beam can be accelerated.

4.2.3
Focusing

Let us look now at focusing. Figure 4.3 sketches an electric field distribution in an accelerating gap; off-axis particles are focused at the gap input and defocused at the exit. For phase stability, however, at phase *M* (Figure 4.2), the field must be rising with time; defocusing is then larger than focusing. The overall effect of accelerating gaps is defocusing.

Additional focusing has to be provided, particularly for low-velocity particles [the velocity is small compared to the velocity of light: $v=\beta c$ (where $\beta \ll 1$)] that are nonrelativistic and are easily deflected by transverse electric fields. At the highest energies, focusing is introduced with

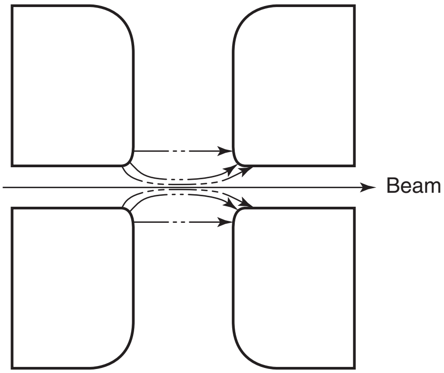

Figure 4.3 The electric field lines in the gaps terminate normally on the metallic surfaces of the drift tube holes. There is a focusing action at gap entrance and defocusing at gap exit if the gap is accelerating. If the voltage is increasing while particles cross a gap, the net effect is defocusing.

quadrupole magnets, typically in an alternate gradient configuration.

4.2.4
Electron Accelerators

In electron LINACs, the velocity rapidly approaches the velocity of light. The scheme of Wideroe is not easy to use; extremely high frequencies are needed, and the drift tubes become resonant antennas supporting very high currents with high losses (Section 4.4.3). Another method had to be invented. Using high-power microwave radar sources available in 1947, Ginzton *et al*. [4] designed an accelerating structure consisting of a stack of pillbox resonators with a central hole, called the *iris-loaded waveguide* (Figure 4.4). The holes provide a passage for the beam and also allow the electromagnetic energy to travel from resonator to resonator. The cavity array behaves as same as an RF filter of relatively narrow bandwidth; the phase relation between two successive cavities depends on the frequency. With a proper choice of the dimensions, at a given frequency, the field in successive cavities can be such that a traveling wave is generated with phase velocity equal to that of the electron beam: this synchronization ensures acceleration in every cell. The waveguide is interrupted at intervals to replenish the structure with energy and to install quadrupole magnets that provide the extra focusing needed for transverse stability.

Slater [5] at MIT, Walkinshaw in England, and others derived the theory of the iris-loaded waveguide and studied many other types of structures. Further developments at Stanford led to the longest electron LINAC to date; the 3 km long Stanford Linear Accelerator Center (SLAC) LINAC has accelerated electrons and positrons to 50 GeV.

In the 1980s, decades of work on superconducting accelerating structures came to fruition, with application to both circular [the CERN LEP (large electron–positron) collider] and the Continuous Electron Beam Accelerator Facility (CEBAF, now Jefferson Laboratory) recirculated LINAC [6]. For continually operating [continuous wave (c.w.)] or long-pulse LINACs of high Q, standing wave, multicell resonators rather than traveling wave structures are used. With the decision to use superconducting technology on the International Linear Collider (ILC) [7], free electron lasers (FELs) as optimal drivers [8], and energy recovery light sources [9], superconducting standing wave LINACs will likely become

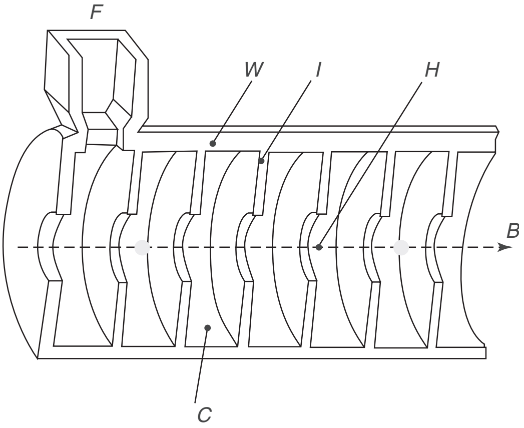

Figure 4.4 The cylindrical waveguide *W* is loaded by irises *I*; the holes *H* provide coupling between the cells *C* for electromagnetic energy transfer and beam passage along the axis *B*. The structure can also be considered as a stack of pillbox resonators *C* coupled through the axial holes *H*. Electromagnetic energy is fed at one end from a feeder *F*, through a ceramic window (not shown) to keep the interior of the structure under high vacuum.

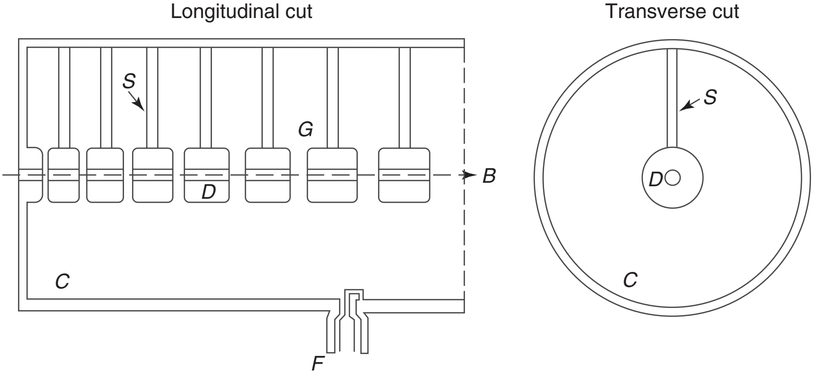

Figure 4.5 Alvarez structure. Drift tubes *D* supported by stems *S* are put along the axis of a cylindrical cavity *C*. The cavity is supplied with RF power from a coaxial line *F* (through a window not shown) by a coupling loop, and excited in a longitudinal mode such that the electric component of the electromagnetic field is directed along the axis and concentrated in the gaps *G*. The field varies sinusoidally with time but the drift tube lengths are chosen so that the beam is cumulatively accelerated along the axis *B*.

the dominant technology for large electron accelerators at the highest energies. Room-temperature standing wave structures (often of a side-coupled configuration) also have applications, especially as part of circular accelerators.

4.2.5
Proton Accelerators

For protons of low velocity, in 1947, Alvarez *et al.* [10] designed a 200 MHz structure at Berkeley, using surplus radar components. In a 12 m long, 1 m diameter resonant cavity, excited in a mode with uniform electric field on the axis, a succession of metallic drift tubes with axial holes provided cumulative acceleration of the beam (Figure 4.5). At first, additional focusing was provided with the help of flat foils or grids located at the exit of each gap (Figure 4.6). These devices suppressed the defocusing effect described in Figure 4.3, but stopped a nonnegligible fraction of

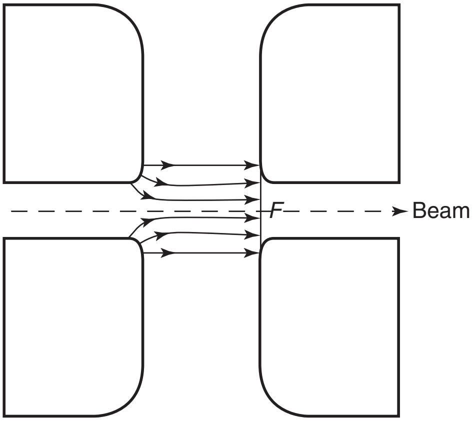

Figure 4.6 Foil (or grid) focusing. By closing the hole at the exit of the gap, the foil or grid suppresses the defocusing effect (Figure 4.3). The gaps are now focusing, but the beam is scattered and some particles are lost.

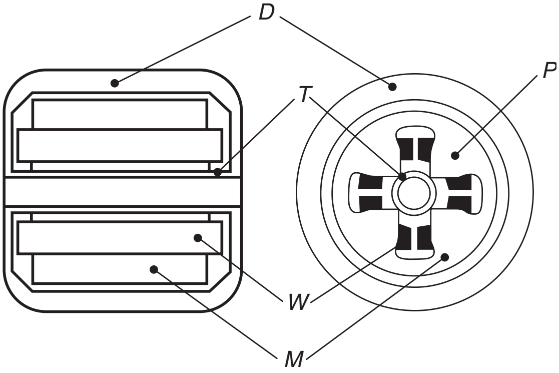

Figure 4.7 Magnetic quadrupole lens inside a drift tube. The windings *W* create a quadrupolar field between the four poles *P*. The magnetic flux returns through the magnet yoke *M*. The whole lens is encapsulated inside the drift tube *D* closed on the axis by a thin tube *T*.

the particles and deflected others in an irregular way, reducing the intensity and the beam quality.

It was then discovered by Courant *et al.* [11] that effective transverse focusing could be provided by a succession of focusing and defocusing quadrupole magnets, and Blewett [12] suggested installing such magnets inside the drift tubes. A four-pole magnet (Figure 4.7) constitutes a focusing lens in one transverse direction and a defocusing lens of equal strength in the orthogonal one. A succession of focusing and defocusing lenses, properly spaced, is globally focusing; with quadrupole magnets, one thus gets focusing in the two transverse directions [13]. This method is called *alternating-gradient* (AG) focusing.

The Alvarez structure, with various improvements, is used now for ion beam β values in the range 0.035–0.5; other types have been developed for lower and higher energies (Section 4.4.4).

As with electron accelerators, superconducting radiofrequency (SRF) LINACs have found important applications for protons and ions, with the Spallation Neutron Source (SNS) being the largest application to date [14]. A proposed rare isotope accelerator (RIA) using SRF is also under consideration to generate short-lived ion species.

4.3
Electron Linear Accelerators

4.3.1
Electron Source and Preacceleration (LINAC Injector)

Electrons are very light particles. According to Einstein's energy relation, one has $E = E_o + W = mc^2 = m_o c^2/\sqrt{1-\beta^2} = E_o/\sqrt{1-\beta^2}$, where the total energy E is the sum of the rest energy E_o (equal to $m_o c^2$) and kinetic energy W, where m is the total mass and m_o the rest mass; $\beta = v/c$ is the ratio of the velocity of the particle to the velocity of light. For electrons, $E_o = m_o c^2 = 511\,\text{keV}$. Table 4.1 shows how β changes with kinetic energy W.

As can be seen, with an energy gain in typical modern electron LINACs of $10\,\text{MeV}\,\text{m}^{-1}$ or more, the velocity is almost everywhere very close to the velocity of light, apart from a first section called *the injector*. A high-energy electron LINAC is then an injector followed by a number of identical sections of an accelerating structure, with the addition of some focusing. The simplest form of electron injector consists of a thermionic cathode emitting electrons into a DC voltage of 20–150 kV. A grid pulser modulates the beam to form "bunches" of adjustable length and amplitude in the range of microamperes to kiloamperes for certain applications. The conventional buncher section of an RF LINAC is an accelerating structure (Figure 4.8) with variable β bringing the energy to the order of 10 MeV and compressing the output bunches to 10° or less. Focusing is generally provided by magnetic solenoids.

Over the past few decades, electron injector technology has been revolutionized by the introduction of the laser-driven

Table 4.1 β as a function of W for electrons.

W (MeV)	0.020	0.05	0.10	0.20	0.50	1	2	5	10
β	0.272	0.413	0.548	0.695	0.863	0.941	0.979	0.996	0.999

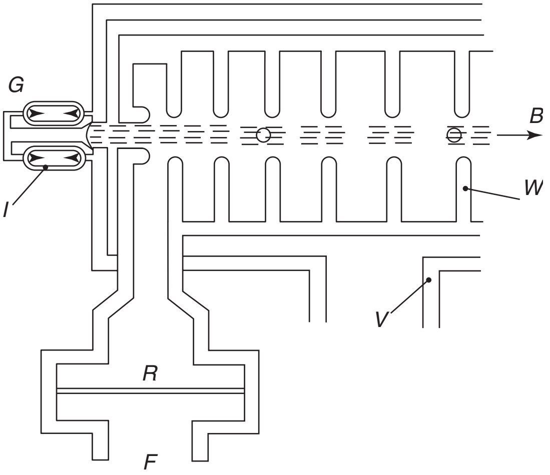

Figure 4.8 In this very schematic drawing of the bunching section of an electron LINAC, the gun *G*, at high voltage, is supported by an insulator *I*. The iris-loaded waveguide *W* is put inside a vacuum vessel *V* evacuated to high vacuum. A feeder *F* brings microwave power to the accelerating structure through the window *R*. The beam *B* is accelerated in the form of bunches. The details of the gun, the grid, and the chopper or prebuncher, as well as all the focusing elements, have been left out of this drawing.

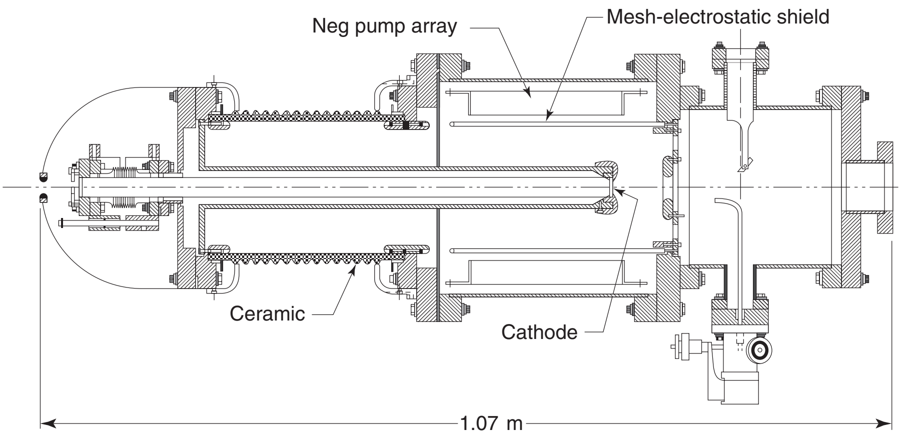

Figure 4.9 Schematic of Jefferson Laboratory polarized electron source. (Courtesy: Jefferson Laboratory.)

photocathode. This advancement has allowed the production of electron beams of significantly higher phase space density (smaller beam emittance) and shorter pulse lengths. For RF LINACs, the laser can be modulated to produce short electron bunches occupying only a narrow range about the proper RF phase. The photocathode is located at the entrance of an RF accelerating cell gap or a DC field (Figure 4.9). With high gradients, the electrons are accelerated very rapidly, helping to alleviate the effects of space–charge and preserve beam brightness. Bunch charges ranging from pico- to nanocoulombs can be obtained with normalized emittances below 10 μm at peak currents of tens of amperes. With the introduction of DC voltages approaching 1 MV or RF gradients of several tens of megavolts per meter, R&D is progressing toward submicrometer normalized emittances. The success of this effort will strongly impact the future of light sources such as FELs and energy recovery linear accelerators (ERLs).

Moreover, by using a photocathode and a laser, it is possible to produce longitudinally polarized electrons, which are of great interest in certain physics experiments. For example, circularly polarized near infrared (IR) light from a Ti:sapphire laser is projected onto a gallium arsenide (GaAs) cathode in the CEBAF polarized electron source [15].

4.3.2
Electron LINAC Characteristics

An RF electron LINAC consists of one or several sections of an accelerating structure, each generally several meters in length. Accelerating structures for short-pulse LINACs are of the iris-loaded waveguide, traveling wave type. They are usually operated in the microwave band around 10 cm wavelength (3 GHz). The shape of the cavities has been optimized to reduce (for a given accelerating gradient) both the peak electric field on the surfaces (to avoid the risk of electrical breakdown) and the RF power losses in the walls resulting from the finite conductivity of the material (usually copper). The SLAC cavities are pulsed for a few microseconds in a traveling wave mode, the first microsecond being used to fill the structure

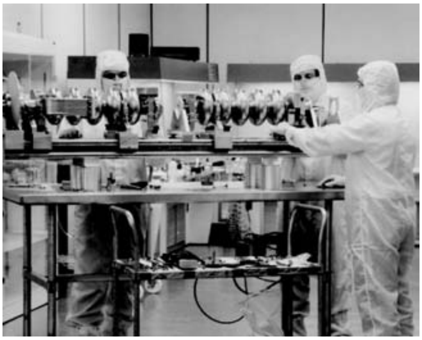

Figure 4.10 Assembly of CEBAF cavity in a clean room. (Courtesy: Jefferson Laboratory.)

from input to output (3 m). Only 1/10th or at most a few tenths of the power remains at the output, the rest being absorbed by losses in the walls or transferred to the beam. Electrons at relativistic velocity ride on the RF wave crest. As the RF cavity fields are raised by increasing the RF source power, the energy gain per unit length is raised accordingly.

For longer pulse and up to fully c.w. operation, RF LINACs are made with standing wave cavities. For optimal coupling to the electron beam, the side-coupled structure (Section 4.4.4) is typically chosen for normal conducting applications. The introduction of superconducting materials such as niobium has had a dramatic impact on standing wave LINAC technology. At RF, superconductors do still exhibit small losses, but resonators can offer *Q*s that approach 10^{10} at gradients of order $20\,\mathrm{MV\,m^{-1}}$. This is to be compared to a typical room-temperature copper structure where *Q*s of 10^4 are more typical. These low losses have enabled superconducting LINACs to be operated in a c.w. mode at these high gradients, which would be entirely impractical for room-temperature structures. True c.w. operation (and also the inherently high *Q*) provides at least an order of magnitude improvement in beam stability, which in turn has enabled applications that require smaller energy spread and beam temporal jitter. In fabricating superconducting cavities, much care must be taken to ensure the quality of the superconductor with minimization of imperfections in the material, meticulous assembly in clean-room environments, conditioning, and cool-down protocols (Figure 4.10).

Energy in big LINACs is mainly limited by cost considerations involving the length of the structure and the amount of RF power. In short-pulse machines such as SLAC, the energy can be increased economically by using a device called the *Stanford Linear Accelerator Center Energy Doubler* (SLED) [16, 17]. It makes use of high-*Q* resonant cavities that are filled with electromagnetic energy during the first part of the RF pulse. In the second part, the RF phase of the klystron is reversed and the cavities are automatically emptied, effectively resulting in pulse compression and a momentary reflected power increase by a factor of almost 3. With the help of 3 dB couplers, this power can be fed into the accelerating structures, and, over a very short pulse, can result in about 80% more acceleration.

4.3.3
Electron Beam Intensity Limitations

In applications such as high-energy LINACs for physics experiments or an

RF LINAC providing the driving beam for an FEL, beams of extremely good quality are required: very small transverse beam dimensions (measured in a tenth or hundredth of a millimeter or even in micrometers) and very small energy spread (0.1% or less). In these and other applications, beam intensity must also be as high as possible. Energy spread from the electron bunch phase width along the RF wave can be compensated using very short bunches and by ensuring that the bunches, on average, ride on the crest. However, to achieve the shortest bunch lengths, designs for FELs and colliders use bunch compression, which requires an energy chirp of the bunch that has passed through dispersive optics. The chirp is typically produced by off crest acceleration.

One limitation in short-pulse electron LINACs comes from beam loading. To be accelerated, the beam has to extract energy from the electromagnetic field, thus reducing the field strength in proportion to the beam intensity. As a result, under short-pulse operation, it is not easy to obtain a flat energy gain over the pulse. For long pulses or c.w., automatic control of the fields can be applied and then heavy beam loading (i.e., a large ratio of power supplied to the beam to that supplied to the accelerator structure losses) is used to raise the overall efficiency. In superconducting LINACs, for example, the structure losses are miniscule in comparison with the power transferred to the beam.

With the ever-decreasing bunch length and emittance and ever-increasing peak currents, wakefield phenomena and coherent synchrotron radiation (CSR) processes often limit the overall beam performance. As a generalization of beam loading, whenever a beam pulse passes through variations in its vacuum environment (e.g., the RF structure, bellows, and beam position monitors), the image charges change direction and radiate. The electromagnetic energy comes from the beam's kinetic and field energy. With a frequency content determined by the details of the environmental discontinuities, the electron bunch may find its momentum (both longitudinal and transverse) perturbed with a time variation. This is the basic notion of wakefield: the field generated by the beam, which is left behind and can act back on succeeding beam particles. A related but somewhat different notion is that of CSR. A single electron will radiate when it is accelerated, for example, on being steered along a curved path by a bending dipole magnet. If the electron is relativistic, this radiation has a very high frequency content (γ^3 of the typical revolution frequency), and the characteristic wavelength is typically much shorter than current modulations on the bunch or the bunch length itself. However, in the short bunch regimes typical of cutting-edge LINACs, the bunch length, in fact, is shorter than the characteristic wavelength of the radiation. The bunch can radiate as a single charge, with the radiation power enhanced by a factor corresponding to the number of electrons radiating in concert. Again, if the electron bunch is emitting energy, the beam energy must be diminished and will have a temporal variation. This is CSR.

The wakefields and CSR cause momentum changes that vary along the length of the electron bunch. This effectively increases the bunch energy spread and transverse emittance, which can destroy necessary resolution for spectroscopy and degrade performance of FELs. Moreover, the momentum variations can be exchanged for position variations in magnetic transport systems, yielding pulse lengthening, and spot size increases. Finally, beam instabilities can be generated, which can grossly degrade beam properties.

Another serious limitation comes from a class of phenomena called *beam breakup* (BBU), which results in beam deflection and eventual particle loss in the accelerator walls. The LINAC structure can be excited not only on the fundamental accelerating mode but, just the same way as an ordinary waveguide, in other modes, the most dangerous of which are transverse hybrid modes that deflect the beam. These modes can be excited by particles traveling off the cavity axis, or as a result of cavity asymmetries. Along a single accelerator section, the interaction of the beam with such a transverse mode can lead to uncontrollable beam deflection when the current is above a certain threshold. The deflected beam can couple its energy into the transverse mode, which has a longitudinal electric field component off axis. A feedback loop is generated, which can go unstable at high currents (effectively, high gain). This is called *regenerative BBU*. In a long accelerator, each cavity, although below the threshold of this unstable oscillation, can nevertheless behave as same as an amplifier. A long chain of such amplifiers, even if each gain is small, can eventually deflect the beam beyond the edge of the irises; this is called *cumulative BBU*. The wakefield effect discussed earlier leads to excitation of higher order deflecting modes, which can affect succeeding beam bunches. These wakefields can build as the chain of bunches get deflected and more strongly excite downstream cavity modes. Their integrated effect on particles passing through them can cause effective emittance growth that at least dilutes brightness, or may even cause beam loss. The transverse effects are combated by eliminating boundary discontinuities wherever possible, and by making geometrical changes in the accelerating cavities to prevent the beam from being synchronized with the offending modes. The effects in RF structures become more serious as the operating frequency is raised and the iris diameter becomes smaller, and this becomes a limitation in high brightness designs. In the design of c.w. LINACs using the latest generation of superconducting RF cavities, either cost optimization or energy recovery for high average currents favors configurations where the beam passes several times through the same accelerating structure. It was discovered during the commissioning of the Stanford Recyclotron that a new kind of instability, a hybrid between regenerative and cumulative BBU, can limit beam average currents. As in cumulative BBU, a series of marginally offset beam bunches can have their displacement amplified by a higher order mode (HOM) when passing through a long series of accelerating cavities. In addition, with recirculation, these offset bunches are allowed to pass through a given cavity for a second time, where the offset beam can excite the same HOM as happens in regenerative BBU. A closed feedback loop is formed, which can go unstable if the time delay is unfortunate and the beam current (which is equivalent to loop gain) is high enough. This ‘‘multipass BBU’’ is the principal limitation to average beam current in recirculated LINACs. Since superconducting cavity HOMs have relatively high Qs, prevention of BBU requires careful damping of the strongest modes with mode couplers. For applications in the milliampere range, this has proved to be sufficient to provide beam stability, for example, in the Jefferson Laboratory nuclear physics machine CEBAF. For ERLs to drive high-average-power FELs (e.g., the Jefferson Laboratory IR source) or for ERLs to generate incoherent synchrotron radiation (e.g., Cornell ERL) [9], average currents of order 100 mA are envisioned, and BBU and HOM damping must be monitored closely in cavity design and construction to ensure success.

4.3.4
Uses of Electron LINACs

Most of the pioneering electron LINACs in the world have been built for physics experiments. Table 4.2 lists four of the largest.

An important feature of large electron machines is the possibility of producing and accelerating positrons. Such particles are produced from the impact of high-energy (33 GeV at SLAC) electrons on a converter from which $e + e^-$ pairs emerge. Production efficiency is proportional to incident electron energy and is usually in the range of a small percent per incident gigaelectronvolt. Since the mid-1960s, energetic electrons and positrons from LINACs have been frequently used to fill collider rings (where counter-circulating beams collide, maximizing available energy) for physics experiments and to fill storage rings for the generation of synchrotron light.

In the early 1980s, the requirements for performing electron–nucleus coincidence experiments to look into the quark nature of the nuclear force and for very high resolution spectroscopy of nuclear states pointed out the need for high-duty factor electron accelerators. Although first conceived as a pulsed LINAC filling a pulse stretcher storage ring, it soon became clear that c.w. operation of a superconducting LINAC would offer the best, most upgradable solution. The CEBAF was designed as a multipass recirculated LINAC, with ultimately five beams of distinct energy being accelerated simultaneously through superconducting cavities originally designed for the Cornell electron positron storage ring (CESR) (Figure 4.11). Initially, the gradient in c.w. operation was specified at 5 MV m^{-1}. The electron beam (now from a photocathode polarized source) is sent up to 5 times through two antiparallel 400 MeV superconducting LINAC segments connected by beam lines to deliver a 4 GeV, 200 μA average current continuous beam as designed. The LINAC is constructed using 1.5 GHz, five-cell niobium cavities operating at a temperature of 2 K. Advances in SRF technology led almost immediately to operation at 6 GeV, and an upgrade to 12 GeV is planned for the near future, with average gradients nearing 20 MV m^{-1} for supplemental seven-cell cavity cryomodules. In addition, the technology was applied to smaller recirculated LINACs at Jefferson Laboratory, configured in an energy recovery mode, where the beam passes a second time through the accelerating structure 180°

out of phase with the field to deposit its kinetic energy for reuse. In this way, very high currents (approaching 10 mA) can be sustained for high-average-power FEL operation without making absurd demands on RF power. This notion of energy recovery is also of interest in the design of LINAC-based synchrotron light sources where fresh, low emittance electron bunches are sent through undulators, periodic arrays of magnets that coherently enhance the synchrotron radiation process.

After the initial findings of the large hadron collider (LHC) in the decade that followed, exploration of the high-energy frontier in detail will require a next generation of electron–positron colliders. Since 1980, high-energy physicists, seeking methods to collide electrons and positrons in the center-of-mass range of 100 GeV and higher, have reached the conclusion that above a certain energy level, linear colliders (two opposing LINACs whose beams collide at a target point) have an economic advantage over colliding rings. This advantage arises from the fact that a LINAC beam only loses a negligible amount of energy through synchrotron radiation because the particle trajectories are not bent in circles. Much R&D has gone into finding the best technology for linear colliders, and in the 1980s–1990s, work progressed on room-temperature short-pulsed, higher frequency copper LINACs, superconducting long-pulsed LINACs, and two-beam acceleration as potential approaches. In 2004, an international committee determined that long-pulsed superconducting RF technology was the most attractive candidate and an international collaboration has been created to bring this exciting idea to fruition.

The ILC is conceived as a positron–electron collider offering center-of-mass energies of 200–500 GeV, and upgradable to 1 TeV. Polarized electron beams are envisioned. In pulsed mode, the superconducting structures are expected to achieve gradients in excess of $35\,\mathrm{MV\,m^{-1}}$, with a theoretical limit of about $50\,\mathrm{MV\,m^{-1}}$.

Apart from physics experiments, many electron LINACs of lower energy are also now made for a host of applications. Medical or industrial irradiation, radiotherapy, industrial radiography, chemical reactions, or hardening processes of various materials induced by irradiation, medical sterilization, and conservation of agricultural products through ionization are some of the various applications that have been developed and are more and more extensively in use. Almost all hospital X-ray machines now in use contain small standing wave RF electron LINACs. For such applications, high power (several tens of kilowatts of beam power) and low energy (in most cases ≤10 MeV) are needed; beam quality is not critical, and the beam is scanned or widened to cover the needed irradiation area. The crucial parameter is average intensity, and costs are optimized in this respect. Sources based on laser Compton backscattering are also under development.

A special type of application of LINACs is flash or stroboscopic radiography; there, extremely intense but very short pulses (100 ns, for instance) are needed. Induction LINACs (Section 4.6.1) are used for this application, and RF LINACs can also be used. The Dual Axis Radiographic Hydro-Test (DARHT) Facility project at Los Alamos National Laboratory (LANL) represents the latest advance, with two induction LINACs producing 20 MeV electrons at 4 kA.

4.4
Proton Linear Accelerators

4.4.1
Injection into a Proton LINAC

Unlike electrons, protons need to have a very large kinetic energy to reach a velocity close to that of light. With a rest energy $E_o = 938\,\mathrm{MeV}$, the relation between β and W is shown in Table 4.3.

Even at the highest energy reached in proton LINACs today, the final velocity is <90% of the velocity of light. At injection, it is only a few hundredths of c, increasing along the machine at a typical accelerating gradient of around $2\,\mathrm{MeV\,m^{-1}}$ according to usual practice.

As explained in Section 4.2, protons, especially at low energy, are subject to a strong defocusing effect of the electric field, not at all compensated by the effect of the magnetic component. Furthermore, the magnetic field strength of static focusing lenses must increase as particle velocity decreases, and there is insufficient room in the drift tube to provide it. This led to the choice of at least 500 kV for the injection of protons in LINACs built before ~1980.

The source of protons, from a DC or RF discharge in hydrogen, was traditionally of the duoplasmatron type; that is, one in which the axial magnetic field is made to vanish at the extraction hole from an expansion cup. Such a source can produce a beam of very high quality with intensities of several hundred milliamperes of protons either pulsed or c.w. This source

Table 4.3 β as a function of W for protons.

W (MeV)	0.1	0.2	0.5	1	2	5	10	20	50	100	200	500	1000
β	0.015	0.021	0.033	0.046	0.065	0.103	0.145	0.203	0.314	0.428	0.566	0.758	0.875

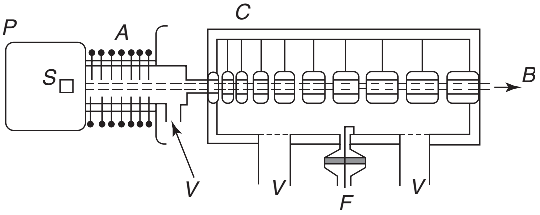

Figure 4.12 Schematic drawing of a proton LINAC with a high-voltage injector. The source *S* is placed on a high-voltage platform *P* and the beam is injected into the Alvarez structure (at ground potential) through a DC accelerating column *A*. was traditionally put on a high-voltage platform at ~750 kV DC, and the beam injected from it into a drift-tube accelerator through an evacuated accelerating column (Figure 4.12).

Modern ion sources of the electron cyclotron resonance (ECR), the electron beam ion source (EBIS), and other types are used to produce intense beams of H^+, H^-, D^+, and other ion species; research continues – for example, using laser-driven sources – on producing higher currents of high-charge-state beams.

4.4.2
RFQ Accelerators

The first practical device using the idea that the RF field could be used to produce both an accelerating field and the necessary transverse focusing field, avoiding the need for magnetic elements, was invented by Teplyakov [18] and tested in the USSR by 1968. Radiofrequency quadrupole (RFQ) accelerators have replaced high-voltage DC injectors and moved injection energy into the drift-tube-type accelerating structure up to a few megaelectronvolts. The RFQ can provide strong AG focusing at low energy [19]. With it, the space–charge limit (Section 4.4.5) is sufficiently increased so that protons or other ions can be injected at energies from around 20–100 keV depending on the intensity and accelerated to around 2 MeV for injection into a drift-tube-type LINAC. Very high percentages (95–97%) of the input beam can be captured and accelerated with minimal growth in emittance.

Using this principle, the first device built outside the USSR was tested in 1980 [20, 21, 17]. Figure 4.13 shows the sketch of a four-vane RFQ; when excited on the quadrupolar RF mode, the field on the axis is mainly quadrupolar in configuration but also contains, owing to the modulation of the pole tips, a longitudinal component that is accelerating. The fields in the RFQ are continuous, rather than intermittent as in the drift tube approach. The period of the modulation is synchronized with the ion velocity. The four-vane structure is currently used at or above about 200 MHz (Figure 4.13). A lower frequency variant is the four-rod RFQ structure (Figure 4.14). There the tip profile is materialized by minivanes properly supported to achieve the chosen resonant frequency and the whole system is put into a cavity; such a structure can be operated at a lower frequency without becoming too large in size [22].

The efficiency of RFQ structures for focusing at low velocity comes from

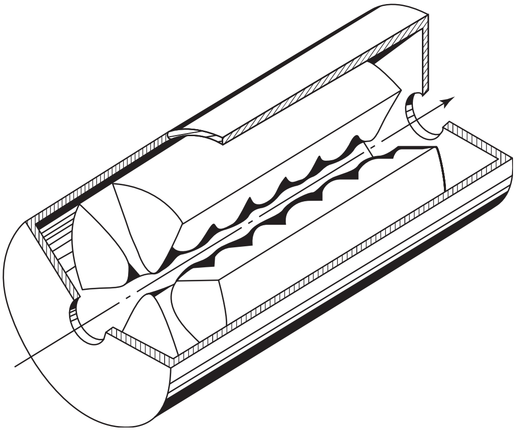

Figure 4.13 RFQ four-vane structure. The four vanes, in a quadrupolar arrangement, have their pole tips modulated; this produces a longitudinal RF field that allows the bunching and the acceleration of the beam.

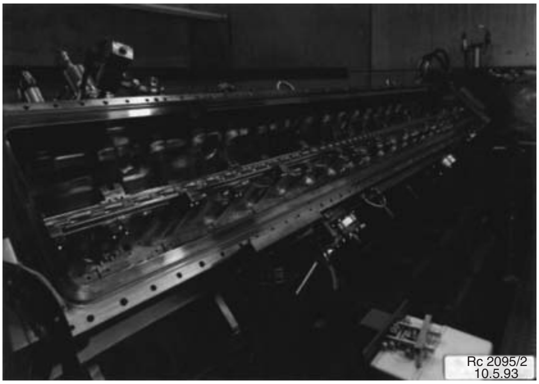

Figure 4.14 A four-rod-type RFQ built for GSI by Prof Dr A. Schempp, Institute for Applied Physics, Goethe University, Frankfurt.

the use of RF electric fields higher in strength than could be achieved with electrostatic fields and having a much larger focusing action than magnetic fields. RFQs are used to focus the beam emerging from the ion source to form bunches and accelerate them to an energy where adequate magnetic quadrupole focusing in the drift-tube-type structure can easily be provided (usually around 2 MeV). Because the RFQ has many cells in a reasonable length, the bunching and the acceleration characteristics can be slowly and carefully tailored. This nearly adiabatic process preserves the beam quality remarkably well and is a fundamental advantage of the RFQ with far-reaching consequences in modern high brightness proton and ion LINAC design.

4.4.3
Drift-Tube-Type LINACs

The RFQ loses efficiency as its cells become longer, necessitating a change in technique to accelerate to higher energies. The drift-tube principle is used.

The Alvarez type, with a focusing magnet located in every drift tube, provides the strongest and most uniform transverse focusing. The RF frequency of most of the large drift tube proton LINACs built in the 1970s is around 200 MHz, at which high-power triodes or tetrodes are available for long-pulse operation. New machines tend to use higher frequencies to achieve higher brightness. In a 200 MHz Alvarez structure, the length of a few tens of drift tubes varies from about 5 to 15 cm as the particles accelerate from 0.5 to 5 MeV.

Magnetic quadrupoles are enclosed in each drift tube, which, supported by stems, must be carefully aligned. Drift tubes are installed in long cylindrical cavities of typically a few meters; the cavity length is sized to match the power delivery capability of the amplifier units attached either singly or through multiple-feed ports.

The Alvarez structure is efficient for medium velocities: $0.05 < \beta < 0.3$. The large diameter drift tubes necessary to house the quadrupole focusing magnets require more RF power. The structure can be modified to save RF power. Groups of a few cells having small diameter drift tubes without magnets provide acceleration without focusing, interspersed with a group with larger drift tubes containing magnets. Thus this type of LINAC can be termed a *separated-function* LINAC; compared to the drift tube LINAC (DTL), where transverse focusing is provided in every cell, the separated-function LINAC uses a series of cells designed for high acceleration efficiency and low RF power consumption, with transverse focusing inserted periodically as needed. There are now many variations of this idea, including superconducting ones. The overall transverse focusing is weaker but often adequate, and the savings in RF power can be substantial.

4.4.4
LINACs for Higher Velocity Ions

Above ~100 MeV, for protons, the efficiency of these LINAC structures again becomes too low, and another structure is needed. The Los Alamos Meson Physics Facility (LAMPF) LINAC was the first high-intensity LINAC to push beyond ~100 MeV. The "separated-function" principle is used, and the side-coupled cavity structure [23] (Figure 4.15) was developed using the standing wave mode at an RF frequency that is an integer multiple of

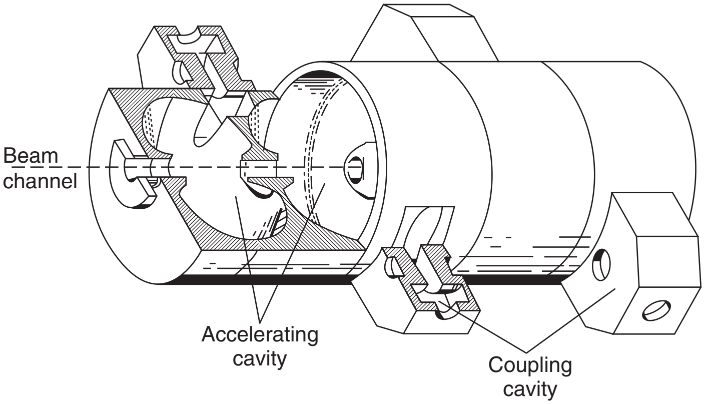

Figure 4.15 Side-coupled cavity structure. The on-axis accelerating cavities are designed with noses on the beam holes that prevent direct coupling and concentrate the accelerating field over a shorter length and time. The coupling between cavities is then made through lateral holes *H* via the side-coupling cavities.

2–4 times the frequency of the Alvarez section. In modern practice, this ''room-temperature'' structure type is used as a bridge between the structures of Section 4.4.3 to an energy at which a superconducting structure type becomes practical.

In Figure 4.15, one sees that the accelerating cells have noses on the beam holes in this structure. Such noses behave as same as drift tubes and concentrate the accelerating field over a shorter length, reducing the loss in acceleration resulting from the transit time through the gap. They also reduce the coupling between cells. The coupling necessary for the wave propagation is obtained through lateral cavities alternatively on one side and the other. There are two cells and two side-coupled cavities per wavelength. In a wavelength, there are two peaks and two nodes. The mode excited is such that the accelerating cells are at the peaks, that is, the field is high in them; the side cavities are on the nodes; so the RF losses are negligible in them. In this mode, the group velocity for energy propagation in the structure is high, and the cell fields are tightly synchronized – these features are very valuable in practice because the effect of errors is thereby reduced. The shaping of the cells optimizes the shunt impedance in room-temperature structures. In superconducting LINACs, the RF losses are low; so the cavity shape can be optimized on other criteria, and such structures can be used from below 100 MeV up to the velocity of light. The cell sequence is broken when it is necessary to place magnetic quadrupole lenses to provide focusing; special bridge coupler cells may couple RF power around the quadrupole.

Automatic control is applied to maintain the cavity field amplitude and phase constant by supplying extra drive when the beam is on. Because the required energy gain is fixed by the geometry, if beam loading were allowed to reduce the field, the trapping area in longitudinal phase space (called *acceptance*) would be smaller.

This side-coupled structure, with $\beta = 1$ for electrons, is presently used in most dental X-ray machines.

4.4.5
Beam Dynamics in Nonrelativistic LINACs

Almost all modern applications have to achieve an intensity as high as possible at the desired energy, along with a very good beam quality in terms of the beam confinement, aiming, or focusing. One figure of merit used is the beam brightness, defined as the *beam power* (or current, when the energy is fixed) divided by the phase space appropriate to the problem at hand. Phase space for the beam as a whole is six-dimensional, describing the physical size of the beam in x, y, and z, and the change in size with time or distance x', y', and z'; the area projected on one plane is called *emittance*.

Another figure of merit is to minimize the beam loss along the LINAC, and to concentrate any unavoidable beam loss to the lowest possible energies, as lost beam causes induced radioactivity in proportion to the lost particle energy.

The achievable beam intensity and quality are nonlinearly related, and raising the intensity tends to spoil the quality. Particle losses along the LINAC are to be strictly limited, as they would cause radioactivity buildup and complicate maintenance. The rule is that maintenance should be possible without remote manipulators. Achieving high brightness accelerated particle beams involves work on both the numerator and the denominator of the brightness equation – beam intensity divided by beam emittance.

The numerator can be raised by brute force, but the large power requirements and engineering problems that result can be formidable, and better system efficiency becomes a key issue. A given accelerator channel can accelerate only a certain amount of current, depending on the imposed constraints. If more current is desired, the constraints or basic parameters might be changed, or several accelerator channels or modules could be used. The latter approach would multiply the system power requirement directly; therefore, one would prefer to find a more efficient way to raise the current, if possible.

Decreasing the denominator of the brightness factor involves building low emittance (but also intense and, therefore, bright) particle sources and then preserving the source brightness through all the subsequent steps of beam transport and acceleration to the final energy and the beam target. Owing to basic beam dynamics, the minimum phase space volume anywhere in an accelerator is no smaller than that at the particle source.

The main problem at nonrelativistic velocities is space–charge effects. The beam particles must be charged to be accelerated, and all have the same sign; so they tend to repel each other. When the beam intensity is increased, the charge in the bunches becomes such that defocusing occurs. In a bunched beam of ellipsoidal shape, defocusing takes place in both transverse directions against the external focusing, and also in the longitudinal directions acting against the phase stability mechanism. Such effects mainly take place at low velocity when the particles are very sensitive to electric fields; the situation improves at higher velocity.

Simple but very effective design equations for nonrelativistic transported or accelerated beams can be obtained by writing general root-mean-square (RMS) envelope equations for the beam as it is constrained in the accelerator channel. The external channel-focusing forces are offset by the internal space–charge forces in the beam. For a beam that is matched to the machine and does not oscillate in shape, one finds then the following relations:

$$\varepsilon_\mathrm{t} = \frac{\sigma^\mathrm{t} a^2}{N\beta\lambda} \quad \text{and} \quad \varepsilon_\mathrm{l} = \frac{\sigma^\mathrm{l} b^2}{N\beta\lambda} \tag{4.1}$$

in terms of the transverse and longitudinal planes, where ε_t and ε_l are the transverse and longitudinal RMS emittance, a is the average transverse RMS beam radius, b is the physical RMS bunch length, and σ^t and σ^l are the phase advances of the oscillatory motion in phase space over the focusing period $N\beta\lambda$. Each of the σ terms can be expanded into two terms, one containing the machine parameters and the other containing the beam current and also the beam sizes a and b, explicitly. It is necessary to solve both parts of Eq. (4.1) simultaneously; the result is a beam that is ‘‘matched’’ to the RMS shape factors of the machine acceptance phase space. We know that RMS matching minimizes the growth of the effective emittances. It is important to note that these equations apply locally; thus, they should be applied not only as initial conditions at the entrance point of various sections of a machine but also with care to ensure that they remain true at every point.

In space-charge-dominated beam/accelerator systems, effective emittance growth could occur if the average energy in each of the coupled degrees of freedom is unequal [24, 25]. Requiring equality produces another set of equations:

$$\frac{\varepsilon_l \sigma^l}{\varepsilon_t \sigma^t} = 1, \text{ which also requires}$$
$$\frac{\varepsilon_l}{\varepsilon_t} = \frac{\sigma^t}{\sigma^l} = b/a \tag{4.2}$$

If Eqs. (4.1) and (4.2) is not satisfied, the effective emittance will shift between the degrees of freedom (with conservation in six dimensions). The physical mechanisms for the redistribution have been clarified as a charge density distribution occurring at an abrupt parameter change within about one-quarter of the plasma oscillation period of the system, and in a smooth channel, a slower kinetic exchange toward the equipartitioned state. Systems satisfying Eqs. (4.1) and (4.2) are both matched and ''equipartitioned.'' Again, the condition can be applied locally and may be applied at injection and all along the machine to ensure minimum emittance growth.

Another problem can be the formation of a diffuse halo of particles around the beam bunch. Halos are to be avoided, as these particles may strike the walls of the LINAC. A halo forms when single particles interact with resonant driving forces in the channel [26]. If Eq. (4.1) is not satisfied, the beam is ''mismatched'' and this is a prime source of a halo.

A primary design requirement is to maintain matching and to avoid resonances between the beam and the accelerator structure parameters that can cause emittance growth and particle loss. The equilibrium, equipartitioned beam has no free energy to drive a resonance; so, even if a resonance is traversed, the growth rate will be zero. Although the equilibrium condition is desirable, as with all LINAC parameters, it may be relaxed or abandoned in favor of a particular objective; in this case, if a resonance area is encountered in the LINAC, it should be crossed quickly to avoid excessive emittance growth.

From these equations, many of the tradeoffs and scalings in machine design can be explored to first order. For example, an important result is that if high brightness is the goal, the maximum current achievable for a fixed transverse emittance strongly favors higher frequency LINACs. As a practical example, the low-β section of a modern 100 mA average current proton LINAC would operate at a frequency around 400 MHz. Fortunately, there are also other factors that are advantageous at higher frequencies, such as smaller size, ability to withstand higher electric fields without breakdown, and reduction in the amount of energy that must be stored in a resonant structure. Engineering factors such as heat removal in high duty factor or c.w. applications, on the other hand, argue for lower frequency; so a balance must be struck. Optimization for low and minimum energy beam loss is much more difficult, still not expressible in compact form, but considerably aided using the equipartitioned equilibrium and resonance avoidance.

Thus, in the final design for an application, many factors constrain the brightness that can be achieved. However, in summary, a few key requirements and procedures have been postulated that have major effects on achieving lower beam loss and/or higher brightness. These include using higher frequencies for ion LINACs, maintaining external focusing fields as high as possible, maintaining local matching per Eq. (4.1), the use of beam equilibrium and resonance avoidance locally per the simultaneous solution of Eqs. (4.1) and (4.2), and the important techniques for initial acceleration from the source as embodied in the RFQ LINAC for ions. Further research is required to fully understand and exploit

these constraints, especially for controlling particles that tend to form a low-density ‘‘halo’’ around the beam and are likely to be scraped off, causing radioactivity problems for machine maintenance if their energy is above a few megaelectronvolts and to incorporate optimization algorithms.

4.4.6
Proton LINAC Applications

The LAMPF in New Mexico, producing an energy of 800 MeV with an average current of 1 mA of protons for medium-energy physics experiments, was completed in 1972; its energy is approximately 10 times and beam intensity 1000 times higher than any previous operational LINAC. Its length is close to a kilometer. It contains both 201.25 MHz Alvarez and 805 MHz side-coupled cavity structures. The SNS LINAC at Oak Ridge National Laboratory (ORNL), put into operation in 2005, has similar charge per bunch, and includes 402.5 MHz RFQ and DTL, and 805 MHz coupled cavity LINAC (CCL) and superconducting LINAC structures (SNSs, 2006) (Figure 4.16).

Ion LINACs are frequently used as injectors for storage rings or circular accelerators of higher energy. Frequently, H^- ions are accelerated for injection into a circular machine (e.g., SNS); a thin foil strips the two electrons, leaving the protons to circulate. An H^- LINAC just differs from a proton LINAC by the source and the sign of its extraction voltage.

Proton LINAC applications include drivers for intense neutron sources for physics and materials research such as the SNS, and the planned International Fusion Materials Irradiation Facility (IFMIF) for fusion-related materials development. Smaller proton and heavy-ion (mainly carbon) LINACs are being used for cancer therapy machines. Major new ideas were proposed at Los Alamos in 1990 [27] for closing of the fission power cycle by treatment of radioactive wastes, and for practical implementation of the thorium fuel cycle, using a high-intensity proton LINAC to drive a subcritical nuclear reactor. These proposals were extended to the international community [28], and an active program EUROTRANS [29] is in progress to construct an R&D facility. The initial accelerator would be able to accelerate up to ∼20 mA protons to 600–800 MeV; superconducting structures are ideal for a major part of the accelerator because a continuous beam is required. For such machines, the major design concerns are the minimization of beam losses at energies above a few megaelectronvolts, and strict prevention of sudden beam turn-off (discussed later).

More recently, advances in superconducting RF technology have been applied to the construction of proton LINACs. The main application is the SNS at the US ORNL [14]. The SNS is a second-generation pulsed neutron source, with a LINAC delivering 1 GeV protons at 1.4 MW average power to a liquid mercury target for neutron spallation with applications to the study of the structure of materials. The bulk of the LINAC is superconducting RF (0.812 GeV out of 1 GeV). In addition to greater efficiency and higher gradients for shorter lengths, the larger apertures allowable with SRF reduce beam loss, which is a critical concern because of activation. The superconducting LINAC utilizes two cavity types, for β of 0.61 and 0.81.

4.5
Heavy-Ion Linear Accelerators

4.5.1
Special Difficulties Relative to Ions

Under the term heavy ions, it is common practice to include all ionized atoms heavier than deuterons; accelerated ions usually range from lithium or carbon up to uranium.

Much of heavy-ion physics has been done in the past with the help of circular machines, usually cyclotrons, but there have also been several LINAC facilities, for instance, the heavy-ion linear accelerator (HILAC) at Berkeley – a big low-frequency Alvarez LINAC, later converted as an injector for the Lawrence Berkeley Laboratory Bevatron/Bevalac Facility (BEVALAC), a large heavy-ion synchrotron.

A center for heavy-ion physics was created at the Gesellschaft für Schwerionenforschung (GSI) laboratory in Darmstadt, Germany, and a heavy-ion LINAC complex called the universal linear accelerator (UNILAC) [30] was built. It is made of a Wideroe section, an Alvarez section, and an independent cavity section; more developments, such as special RFQs and H-type interdigital structure sections, have been added later, and the facility remains very active.

From this short description, it appears that a heavy-ion LINAC may be rather complex and differ appreciably from the proton machines.

A fundamental difference comes from the experimental requirements for a wide variety of ions with different masses and charge states. The charge-to-mass ratio (q/m) then differs from one ion to another and is always smaller than 1/2 (compared to the proton case) and often much smaller. In a given LINAC, where the geometry is fixed and only certain adjustments of the phase and amplitude of the accelerating fields are possible, only some combinations of q/m can be accelerated. For this reason, short, separately adjustable resonators are preferred to afford retuning for each separate ion beam.

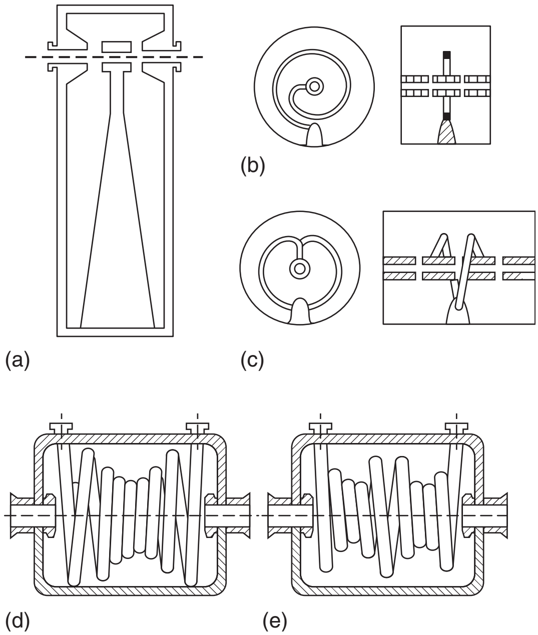

Figure 4.17 Superconducting cavities for heavy ions. (a) Quarter wave cavity: in this sort of coaxial resonator, the open end supports a drift tube and acceleration takes place across the gap. (b) Spiral ring resonator: to reduce the size, the resonant quarter wave line has been curved into a spiral. (c) Split ring resonator: to increase the energy gain, two spirals are put together; the gain should be doubled (in practice less), but the band width in velocity is reduced. (d) Half wave helix: the construction is easy, but there is a risk of mechanical vibrations and the field axis is not well defined. (e) Full wave helix: the rigidity is better, but the velocity bandwidth is smaller. Such cavities currently deliver >0.5 MV to the beam.

4.5.2
Accelerating Structures – Normal and Superconducting

Lower frequencies (20–100 MHz) offer more space for focusing; so structures such as the Wideroe structure (Section 4.2), or a variety of so-called H-type interdigital structures are used, some of which are represented in Figure 4.17. Independent short superconducting cavities are ideally suited, as they can be phased independently, affording complete flexibility in the velocity program. Fifty or one hundred cavities designed to have an optimum acceleration in several velocity steps (but with usable acceleration over a velocity range about a factor of 2 around the optimum) are arranged in succession. Their amplitude and phase are adjusted and controlled for the best possible acceleration of a chosen ion. The first machine of this type was made at Argonne near Chicago and is called *ATLAS* (Argonne tandem LINAC accelerator system). Its length has been progressively increased. Initially, as with the other machines of this type, it was used as a booster after an electrostatic tandem. Now, with proper low-β cavities ($\beta < 0.01$), beams from ECR sources at a relatively low voltage can be accepted directly [31].

4.5.3
Application

Heavy-ion accelerators have been mainly constructed for nuclear physics experiments; one of the largest facilities is the GSI in Darmstadt, Germany. More and more nonnuclear applications are appearing (solid-state physics, materials research, etc.), however, as also more and more industrial uses (implantation, surface treatments, ultrafiltration, etc.). An ambitious project that would reach the limits of the LINAC technology is a heavy-ion LINAC for inertial fusion. Fusion reaction could be induced in a small deuterium pellet if bombarded by a short and extremely intense bunch of energetic heavy ions (10 GeV, several kiloamperes with a 10 ns pulse length). It is clear that a special type of accelerator would be needed to reach that goal (Section 4.6).

4.6
Other Types of Linear Accelerators and New Methods of Acceleration

4.6.1
Induction LINAC

The induction LINAC is a candidate for short-pulse applications. Long induction LINACs are built up from a series of modules of the type shown in Figure 4.18. They behave as same as pulse transformers with the beam as one winding, and are accurately phased to produce acceleration (and possibly bunching) exactly at the time a bunch of particles crosses the gaps. The method is, in fact, the modern version of the original Ising proposal (Section 4.2). Induction LINACs are inherently pulsed devices of pulse length ∼50 ns. Longer pulses are limited by the energy that can be stored in the pulser cores. Repetition rates of up to a few kilohertz are being developed using special magnetic modulators. This device can accelerate extremely high intensities. The largest electron induction LINAC built is the Advanced Test Accelerator at Livermore, a 50 MeV machine that has accelerated up to 10 kA in 50 ns pulses [32]. The induction LINAC is also well suited for the heavy-ion fusion project [33] mentioned in the previous section (its length would be several kilometers).

4.6.2
Alternating-Phase-Focused LINACs

As noted in Section 4.4.2, the RF field can be used for both an accelerating and the transverse focusing field, avoiding the need for expensive magnetic elements. Except for the RFQ, it has been very difficult in general to design such LINACs, but recently a new practical method has been found [34].

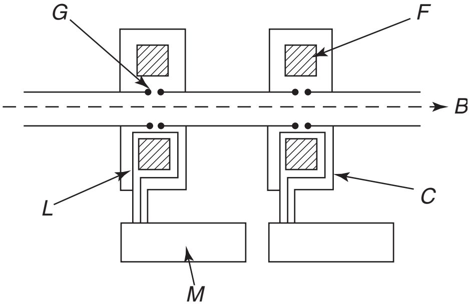

Figure 4.18 Induction LINAC modules. Along the beam path *B*, a succession of cylindrical cavities *C* are installed with an accelerating gap *G*. Inside these cavities, toroidal ferrite cores *F* are excited via a coupling loop *L* by the pulse-forming networks of the modulators *M*. The cavities behave as same as a transformer and the pulse voltage applied on the loop appears on the accelerating gap. Timing of the modulators must be accurately controlled so that the pulses are applied very correctly at the time the bunch crosses the gaps.

4.6.3
New Methods of Acceleration

Even in pulsed mode, microwave structures are limited to gradients of the order of 100 $\mathrm{MV\,m^{-1}}$, and as the need for higher energy beams and compact sources has grown, strong interest has developed in using the intense fields generated by lasers or plasma waves to accelerate beams. For example, plasma perturbations can yield field gradients of order 100 $\mathrm{GV\,m^{-1}}$. A device based on this technology could shrink the length of LINACs by three orders of magnitude! To generate these plasma waves, either a high-powered laser or a particle beam would be used to set up the plasma oscillation (laser wakefield or plasma wakefield concept). An alternative approach would use gratings, ministructures such as photonic bandgaps, or exotic materials (e.g., active or negative index of refraction) to couple a laser beam to a particle beam. Also, a particle beam passing through the alternating fields of an undulator can couple to a copropagating laser beam for acceleration in a device called an *inverse FEL*. Limitations of these ideas include structure damage, plasma instabilities, accelerating high currents, and beam quality maintenance. However, there have been significant experimental advances that hold the promise for future applications. See [35] for more details and references on these new methods of acceleration.

4.7
Engineering Aspects

The full spectrum of engineering disciplines is applied to accelerator technology; a close, multidisciplinary approach with the physical, mathematical, material, and computer sciences and technologies is essential. Deciding on trade-offs between the possibilities and constraints of the many aspects constitute a large part of the design, construction, and operation of accelerators. Broad engineering categories applied to most accelerator systems are described in the following sections.

4.7.1
Accelerator Structure Design

The structures in which beams are accelerated must efficiently provide precisely the correct fields and are mechanically complicated vacuum vessels that must be thermally stabilized, structurally rigid, extremely clean for sustaining high electromagnetic fields, precisely aligned, and maintainable. They must be structurally stiff to hold their shape under vacuum and component loading. RF accelerating structures are copper clad or copper plated, or of special material such as niobium if superconducting. Structures and beamlines must be constructed of materials that are hard-vacuum compatible because they must maintain a vacuum quality typically 10^{-6} to 10^{-9} Torr. Fabrication techniques used in accelerators are diverse. High-precision machining is done on numerically controlled milling machines and by other specialized fabrication techniques such as electron discharge machining (EDM). Specialized joining and forming techniques include brazing, electron beam and laser welding, explosive bonding of dissimilar metals, and explosive hydroforming. Very good mechanical tolerances and cooling systems are needed. Complex brazing is used in the latest vane-type RFQs (Figure 4.19) and side-coupled LINACs (Figure 4.20). The highest power RFQ built to date, the

(a) (b)

Figure 4.20 (a) A side-coupled LINAC cell before brazing, and (b) a section of a 2400 MHz c.w. side-coupled LINAC.

Los Alamos Low-Energy Demonstration Accelerator (LEDA) c.w. 100 mA, 6.7 MeV proton LINAC (Figure 4.21), almost disappears in its support structure, which contains RF power, water-cooling, and vacuum connections.

Rapid advances in the performance of superconducting cavities have made RF superconductivity a key technology for accelerators. They are especially suitable for applications that require c.w. or long-pulse accelerating fields of many megavolts per meter. The RF surface resistance of an SRF cavity is many orders of magnitude less than copper, and even allowing for the inefficiencies of heat removal at cryogenic temperatures, a net gain in efficiency of 100 can be easily obtained. (Since superconducting Cooper pairs exhibit inertial effects in AC fields, they do not completely cancel the electric fields in a superconducting material. Nonsuperconducting electrons from ''ionized'' cooper pairs or impurities above absolute zero can respond to these residual fields and dissipate small amounts of energy.) Gradients of up to 20 MV m^{-1} and Qs approaching 10^{10} are practical today, and further improvement can be expected. SRF structures are

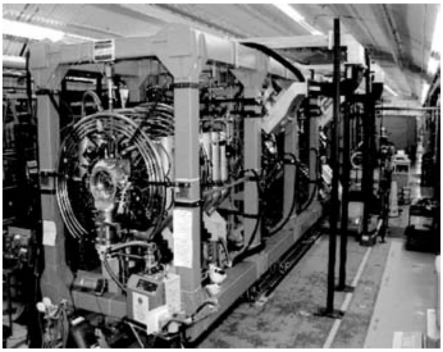

Figure 4.21 Low-Energy Demonstration Accelerator (LEDA) RFQ at Los Alamos.

shaped to control resonant electron effects (multipactoring). Control of contamination by macroparticles by assembly in clean rooms and careful surface preparation has eased the limits of field emission and thermal breakdown.

4.7.2
Magnetics

Complex magnet systems provide magnetic steering and focusing elements that control the position, size, and transport characteristics of particle beams. Modern transport systems use and control magnetic properties as high as fifth order in the optics. Many of the magnets used in accelerator systems are physically short because of packaging constraints or must deviate from ideal geometry because of the field coils. The fields must be measured, often to an accuracy of better than 1 part in 10^4, using magnetic mappers supported by sophisticated instrumentation and computers. Radiation-hardened magnets are also required.

Permanent magnets are quite applicable to high-frequency DTLs and considerably simplify the drift-tube design because they require no power or cooling. Small, accurate quadrupoles (with 1.2 cm bores operating at 18.33 kg cm^{-1} gradients) have been built and tested. They too can be built to a size appropriate for a beam-transport line. New design techniques can be used for adjustable-field multipole magnets and for magnets in which permanent magnets and normal-magnet steels are mixed. Recent experimental results on rare-earth cobalt materials show, however, that serious demagnetization occurs in some designs at 10^9 rad dose levels. Thus, although permanent-magnet technology grows rapidly in its own range of application, use in high radiation environments is precluded at present.

4.7.3
Radiofrequency Engineering

The complex electromagnetic requirements of the accelerator structures must be met, and high-power RF driver systems provided for them. Radiofrequency power systems typically use gridded tubes to frequencies of around 200 MHz, with solid-state amplifiers, klystrons, and inductive output tubes (IOTs) at higher frequencies. The power requirements can be very large; for example, a 40 MeV, 125 mA IFMIF RF LINAC requires 5 MW just for the beam. LINACs are divided into sections sized to the power sources; this ranges from single cells to tanks containing many cells. To maintain synchronism, all the sections must be tightly controlled to within typically 1% in amplitude and synchronized to ±1° in phase, by the automatic control of a reference oscillator. Bunch compression scenarios can demand more stringent RF control by up to a factor of 100. Development of efficient RF power sources is an urgent requirement for future applications.

4.7.4
Availability and Maintainability

LINACs for physics research machines have almost always been cutting-edge technology, always breaking new ground, and on a very tight budget. Usually a loss of beam for some period, from missing pulses to some hours, could be tolerated without any problem by the experiments. Thus, accelerator facilities to date have considered availability only as ''best-practice'' and not as a top-level specification. The users of research facilities such as SNS may come for short periods of a few days; so their productivity must be ensured; SNS has availability goals built into its development schedule over the next decade. For IFMIF, the question of beam trips resulted in the choice of building at least two parallel LINACs, in modules of 125 mA each, greatly increasing the probability that at least one would always be operating. Also, the material samples would not be damaged because the thermal cooling could be adjusted quickly. For transmutation, however, a beam trip would induce thermal stress on the subcritical core, and the number of unwanted ''beam trips'' should not exceed a few per year, a requirement that is several orders of magnitude above usual performance. For these and other future facilities, availability becomes a top-level specification and a major design challenge, as accelerators contain thousands of components, and often the failure of one will require the beam to be shut off.

4.7.5
Computers

Accelerators, in general, have long provided a major impetus for the development of advanced computer systems. Design teams and facilities use the full panorama of computers, from supercomputers to simulate particle motion and electromagnetic fields in the accelerator and magnet systems and on-line real-time computer control systems with distributed processing, to personal computer tools. Modern, fully integrated computer control using instrumentation and automatic control bring accelerator commissioning and operation under strict and very effective management, as witnessed by the recent commissioning of the SNS.

4.7.6
Wide-Bandwidth Electronics and Instrumentation

The pulsed nature of particle beams requires wide-bandwidth electronics, some at higher power, and various diagnostic instrumentation to monitor machine- and beam-operating parameters and control them. Most of these tasks can now be handled digitally.

An example of high-power, high-bandwidth electronics is the pulsed beam chopper shown in Figure 4.22. This device deflects part or all of a 750 keV H^- beam in the LAMPF injector transport line. A pulse rise time of <5 ns and pulse lengths from 15 ns to 750 μs are required at repetition rates up to 4.7 MHz. Chopping is accomplished by launching along this structure a pulse that propagates at the ion velocity of the beam, $1.2\,\mathrm{cm\,ns^{-1}}$. The very

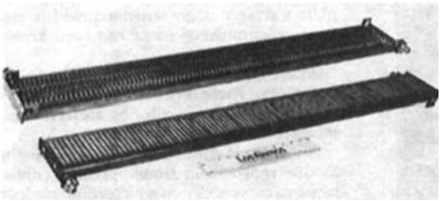

Figure 4.22 Deflector plate assemblies for a beam chopper.

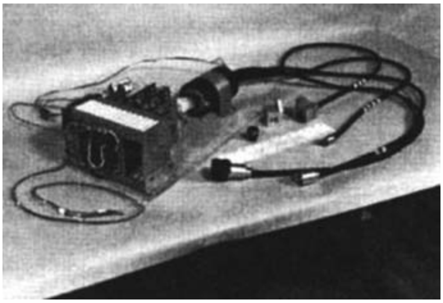

Figure 4.23 Four-armed fiber optics beam-sensing system.

fast high-power electronics uses planar triodes and vertical metal-oxide semiconductor fields-effect transistors (VMOS FETS) in a parallel cascade arrangement to deliver both positive and negative 600 V pulses to the opposing coaxial plate structures.

Diagnostic instruments must often measure beam parameters without intercepting the beam. This is essential with high-intensity beams, which would destroy intercepting materials. Beam parameters of interest include current, energy, density distribution, emittance, and centroid position. Beam density distribution is sometimes measured by optical sensors that view through optical ports the light generated by beam scattering from residual background gas. The optical system uses four-armed fiber-optic image scopes (Figure 4.23) to transmit four-beam profiles from a given beam tube/optical-port array to a microchannel light intensifier and then onto a pair of linear photodiode arrays, from which the light intensity is digitized. The use of a number of these ports distributed along the beam tube allows beam size and trajectory information to be reconstructed into beam emittance. The emittance reconstruction codes are executed in a microcomputer along with beam-transport dynamics codes and several display routines. Longitudinal beam phasing and shape information may be sensed using a variety of high bandwidth capacitive pickups, such as shown in Figure 4.24.

4.7.7
Automatic Controls

Automatic controls are used widely in accelerator technology. Examples include the following:

- control of parameters in complex subsystems such as the injector;
- cooling-system temperature control;
- RF amplitude and phase control;
- beam trajectory control.

Control of water temperature is fundamental to high-power accelerator tasks because operating temperature affords a vernier adjustment to the structure's RF.

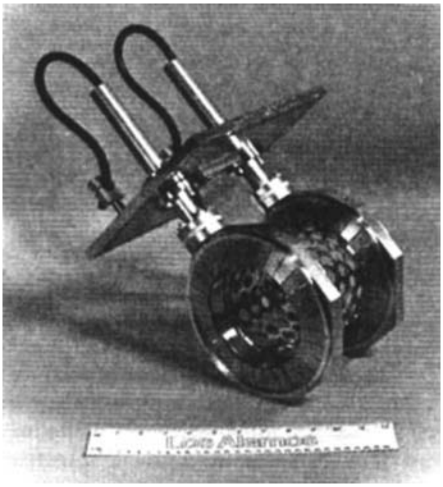

Figure 4.24 Capacitive pickup probes for time-of-flight measurement.

The proper RF field phase and amplitude are crucial to operation and must be controlled to within ±1° and ±1%, typically, under all possible transient and steady-state conditions. In some cases, multiple amplifiers drive a single structure; field control of these complex systems has been accomplished.

Many types of errors can affect the beam trajectory. These must be found and corrected or compensated for by correction elements located along the beamline.

A variety of controllers are used, covering a wide range from simple process control loops, to complex loops with feed forward, domain switching depending on system state, and adaptive and nonlinear systems; modern implementation is digital with computer processing. Work is currently being done using expert system and neural network techniques.

4.7.8
Civil Engineering

The accelerating structures and magnets defining the beam trajectory must be aligned relative to each other to exquisite tolerances (a few mils; down to micrometers for linear colliders) and also absolutely over the whole facility, again to mil-level tolerances. The alignment must be maintained over the lifetime of the facility. Civil engineering procedures must therefore take many factors into account, such as thermal cycling on stresses in the buildings, placement and rearrangement of heavy shielding, vibrations from utilities, and replacement procedures when accelerator parts are maintained. The surveying techniques incorporate the latest laser- and computer-supported techniques.

4.8
Concluding Remarks

Details on current developments can be found in the proceedings of the biannual US Particle Accelerator Conferences (PACs) published for many years as part of the IEEE Transactions on Nuclear Science, and recently as IEEE Conference Proceedings. Also biannually, LINAC Conferences have been held with proceedings published by a host laboratory. A third biannual conference series is "Application of Accelerators in Research and Industry." A

European Particle Accelerator Conference (EPAC) series started in 1988, and is now a triannual feature, rotating with the Asian Particle Accelerator Conference (APAC). Many of these proceedings are available at [36]. Russia also has a long-standing biannual particle accelerator conference series. These conference proceedings constitute the bulk of the accelerator technology literature, along with many laboratory internal reports and workshop proceedings (a number of these have been published as AIP Conference Proceedings, e.g., 156, 177, 184, 193, and 480). There is an active USPAC particle accelerator school and the CERN Accelerator School series. Since the previous (2007) edition, when conferences were almost the only source of accelerator literature, the American Physics Society has established its Division of Physics of Beams, and the Physical Review has a special topic component on Accelerators and Beams – PRSTAB.

Glossary

Acceptance: The maximum beam emittance that can be accepted without loss, through a transport-focusing channel or an accelerating system, determined by machine parameters, independent of the actual beam.

AG focusing (alternating-gradient focusing): A beam-focusing system made of a succession of focusing and defocusing lenses, normally of quadrupole type. Such a system provides net focusing.

Alvarez structure: An accelerating structure for protons, of the drift-tube type, invented by Luis Alvarez.

BBU (beam breakup): Intensity-dependent transverse phenomena in relativistic linear accelerators that limit the current in intense machines (Section 4.3.3).

Beam loading: Power absorption in RF accelerating cavities by the accelerated beam compensated by the application of RF power and control of the accelerator fields.

Bunch: The group of particles accelerated per RF period.

Disk-loaded structure: See Iris-loaded structure.

Drift tube: A tube connected to an RF voltage, through which the beam can drift. When a beam bunch is inside a drift tube, it drifts without being submitted to any RF field.

DTL (drift-tube LINAC): LINAC structure based on the use of drift tubes, for example, the Alvarez type.

Emittance: The positions of individual particles in an accelerated bunch can be expressed by three physical coordinates and their conjugate momenta. The areas occupied by the projections in the three-phase planes (see **Phase space**) are called the *beam emittances*; there are two transverse emittances (often equal in LINACs and expressed in terms of divergence angle rather than in terms of transverse momentum), and a longitudinal emittance (often expressed in terms of energy spread and time duration).

Equipartition: A balanced division of field energy between the three emittances of the beam that guarantees the best stability; the term is used similarly in the case of thermal equilibrium in a gas.

Focusing: The action of concentrating particles to form a beam, similar to focusing of light in optics.

GSI: Gesellschaft für Schwerionenforschung, Darmstadt, Germany.

Gap, accelerating gap: Interval between drift tubes where a strong RF field is concentrated, accelerating the particles of a bunch at the time they cross the gap.

IFMIF: International Fusion Materials Irradiation Facility, a complex of two 125 mA, 40 MeV, c.w. deuteron LINACs providing beams to a molten Li target, generating neutrons with a fusionlike spectrum for development of neutron-resistant materials for fusion reactors.

Iris-loaded structure (or disk-loaded): An accelerating structure for relativistic particles made of a circular waveguide loaded by irises to slow down the phase velocity of the RF wave, making it synchronous with the beam.

LAMPF: Los Alamos Meson Physics Facility, commissioned 1972, with 800 MeV, 1 mA average current proton LINAC, later known as LANSCE, Los Alamos Neutron Science Center.

LINAC: Linear accelerator.

Matching: The machine parameters define a preferred region in phase space (acceptance) for transport or acceleration. If the beam particle phase space distribution has a congruent orientation, called *matched*, beam passage will be smooth, without oscillations. A *mismatched* beam will oscillate in position or shape, which may cause loss of quality or actual particle loss.

Phase space: The six-dimensional space of physical coordinates and conjugate momenta.

Photocathode: A photocathode is a negatively charged electrode, often with a coating to improve emission, that generates electrons through photoemission when struck by a laser beam.

Quadrupole lens: Lenses, usually magnetic, with four poles around the beam: two of N polarity diametrically, and two S in between. Such a lens focuses in one transverse direction and defocuses in the other.

RFQ (radiofrequency quadrupole): An accelerating structure for low-velocity particles where the electrodes produce an RF field that is the sum of a transverse, quadrupolar, AG focusing field and an accelerating field.

SCL (side-coupled LINAC): A normal-conducting, standing wave LINAC structure used for accelerating electrons and protons when the RF pulse length is longer than a few microseconds, or for c.w. operation. The coupling between successive cells is arranged to take place through side cavities alternately on one side and then the other. The accelerating and side cavities resonate at the same frequency, resulting in a $\pi/2$ mode operation having maximum group velocity and field stability.

SNS: Spallation Neutron Source, Oak Ridge National Laboratory, USA, commissioned in 2006 [37].

Space–charge effects: Nonrelativistic particles in a bunch, all charged with the same sign, repel each other, tending to force the dimensions to grow, and requiring more focusing. This also leads to possible instabilities and couplings, and to the formation of a halo of particles around the bunches (Section 4.4.5).

Standing wave cavity: A hollow structure bounded by a conductive wall that supports a resonant electromagnetic mode when excited by an external RF source. The mode pattern is typically designed to accelerate a charged particle passing along the axis, although deflecting modes are also used in some accelerator applications.

Unit of energy: The energy of particles is expressed in electronvolts (eV), energy given to a unit charge (charge of the electron) through a potential difference of 1 V. Higher energies are expressed in kiloelectronvolts, megaelectronvolts, gigaelectronvolts, and teraelectronvolts.

Wakefield: The electromagnetic field left by a charged particle when it passes a discontinuity in its environment. For example, such discontinuities may be resonators or gaps, bellows, or steps in a conductive wall boundary. Resistive wall boundaries can also generate wakefields, which describe the loss of beam energy as image currents are driven in the wall.

INTRODUCTION

Potential-drop accelerators were the first to open nuclear physics to extensive experimentation. After more than half a century, they continue to play an important, and in many respects dominant, role in nuclear physics.

Basic research in nuclear and atomic physics was virtually the sole application of potential-drop accelerators until the 1980s, when their uses for applied physics began to expand rapidly in many fields. They became the new tools for the new techniques required for analysis and production in many emerging fields, especially in microelectronics and molecular biology. Advances in the designs and construction of potential-drop accelerators, which are described in Sec. 1, have given them the precision, reliability, simplicity, and versatility needed for broader application. Their unique capabilities, developed during decades of use in basic research, are now available to apply previously untapped knowledge and techniques.

The widespread and varied applied uses of potential-drop accelerators, described in Sec. 2, include ion implantation in the manufacture of semiconductor devices, age determination of samples thousands and even millions of years old, and nondestructive analysis to characterize computer chips, analyze biomedical specimens, monitor pollution, and locate oil. High power electron beams are used for enhancing insulation on wire, producing shrink tubing, and sterilizing dis-

posable medical products, and for tunable, microwave lasers.

1. DESCRIPTION OF POTENTIAL-DROP ACCELERATORS

A potential-drop accelerator consists of a high-voltage terminal supported by an insulating column, a means of generating the high voltage, a source of charged particles, and an evacuated acceleration tube through which the particles are accelerated. The potential drop from the high-voltage terminal to ground potential accelerates the charged particles to an energy equal to the charge on the particle times the terminal voltage ($E = qV$).

Potential-drop accelerators that operate above 10^6 V (1 MV) are usually enclosed in a steel pressure vessel. The vessel contains electrically insulating gas at high pressure, which significantly reduces the size of these accelerators and is required for reliable operation above about 1 MV. SF_6 is the most widely used insulating gas for accelerators. Its dielectric strength is 2.7 times that of air at 1 atm (101 kPa) and rises approximately linearly with pressure to 7 atm, where SF_6 sustains fields of about 200 kV/cm.

For stable operation at high voltages, the insulators of the accelerator support structure and the acceleration tube must be subdivided by metal electrodes which are connected to a resistive voltage divider for voltage grading from the terminal to ground.

1.1 Types of Potential-Drop Accelerators

Potential-drop accelerators are often identified with the type of high voltage generator they use. Some systems generate high voltage by rectifying ac voltage. Others use electrostatic charging, in which a mechanical system carries the charge to the terminal.

Each type of accelerator described below has advantages for specific applications, and each is serving needs in the growing range of applied uses of accelerators. For analytical precision and for voltages above 5 MV, the electrostatic accelerator is far superior. For certain neutron-induced reactions, ion implantation to a few hundred keV, and electron beam applications, the Cockcroft–Walton or symmetric cascade rectifier accelerator may be the most convenient. Needs for very intense positive ion or electron beams of a few MeV energy are most easily met by the insulating core transformer (ICT) and Dynamitron accelerators.

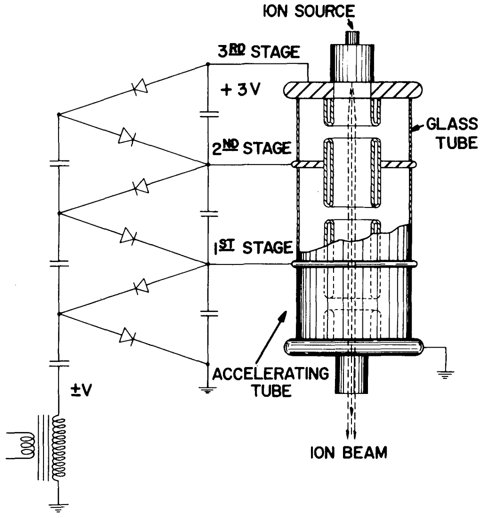

FIG. 1. Schematic of a Cockcroft–Walton accelerator with three voltage multiplier stages.

1.1.1 Cockcroft–Walton Voltage Multiplier Accelerator. This accelerator was the first to be used successfully for nuclear transmutation and gained wide recognition when results were published in 1932. It employs a circuit developed by H. Greinacher in 1920, which uses two stacks of series-connected capacitors as illustrated in Fig. 1. One capacitor stack is connected at one end to ground and at the other to the load, which in this case is an acceleration tube. The voltage across each capacitor in this stack is constant except for voltage ripple.

One terminal of the second capacitor stack is connected to a transformer giving peak voltages of ± V. Voltages at all points along this capacitor stack oscillate over a range of $2V$. Series-connected rectifiers link the two capacitor stacks. As voltages on the transformer-driven stack oscillate, charge is transferred stepwise through the rectifiers from ground to the terminal. Except for ripple from power drain and stray capacitance, the terminal voltage is constant and approximately equal to $2VN$, where N is the number of stages.

The terminal voltage accelerates charged particles from the ion (or electron) source

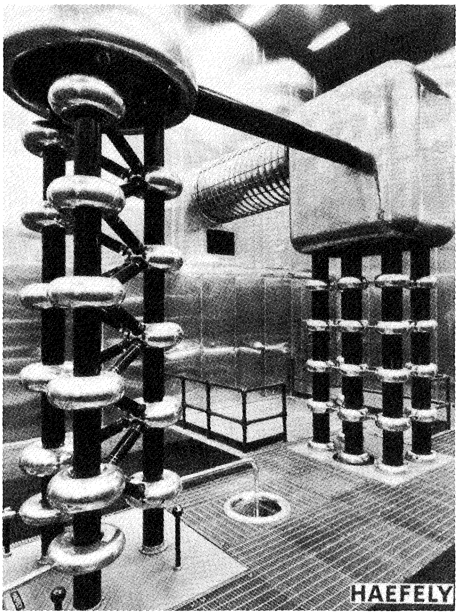

FIG. 2. 850-keV Haefely accelerator for injection of pulses of hydrogen ions into a linear accelerator at the Los Alamos National Laboratory (photo courtesy of Emile Haefely & Co., Ltd.).

through the acceleration tube, which is continually pumped. The acceleration tube sections may be connected to the power supply stages as in Fig. 1 or may be equipped with resistors for potential grading from high voltage to ground.

Cockcroft–Walton accelerators are in widespread use throughout the world and are especially advantageous for applications requiring beam currents of a few milliamperes in the voltage range of a few hundred kilovolts. Many are used to accelerate deuterons to bombard targets containing deuterium or tritium to yield neutrons, e.g., for neutron activation analysis. Neutron generators are available commercially from a number of manufacturers.

Cockcroft–Walton accelerators operating in open air near 1 MV are large and require a very large room to avoid voltage flashover. Figure 2 shows an 850-keV accelerator of this type. It generates pulsed hydrogen ion beams for injection into the high-intensity linear accelerator at the Los Alamos National Laboratory for production of intense meson beams. Air-insulated accelerators with Cockcroft–Walton charging have been manufactured by Emile Haefely & Co. Ltd. and N. V. Philips Gloeilampenfabrieken.

1.1.2 Symmetric Cascaded Voltage Multiplier Accelerator. G. Reinhold of Haefely has shown that, up to a few hundred kV, voltages developed by cascade voltage multipliers using the circuit of Fig. 1 do not depart greatly from $2VN$. Above about 500 kV, however, voltages achieved fall substantially below the value from this simple expression, because of stray capacitance and other effects. He developed a circuit called a symmetrical cascade rectifier, which eliminates most shortcomings of the circuit of Fig. 1. It employs two transformers and two capacitor stacks that oscillate in voltage. Both oscillating stacks feed one fixed-voltage capacitor stack. Using this symmetric system, Haefely built an open-air voltage generator without an acceleration tube that operated to 2.5 MV. Nearly all commercially available high voltage power supplies now use the symmetrical cascade rectifier circuit.

High Voltage Engineering–Europa and National Electrostatics Corp. build open-air accelerator systems with symmetric circuit charging to 500 kV for ion implantation and ion beam analysis. Air-insulated accelerators ranging from20 kV to over 500 kV are utilized as injectors for almost all MeV and GeV accelerators. Figure 9 shows the open-air 500-kV injector for the 25-MV tandem accelerator at the Oak Ridge National Laboratory.

Size and space requirements for open air systems increase rapidly with voltage and appear to set a practical upper limit of about 1.5 MV. Using high pressure gas for insulation greatly reduces the size of higher voltage accelerators. Haefely built accelerators insulated by gases such as SF_6 or a mixture of N_2 and CO_2 ranging in voltage from about 1 MV up to 4 MV. Nissin–High Voltage Co. builds SF_6-insulated Cockcroft–Walton accelerators from 500 kV to 3 MV for their industrial electron beam processing systems.

1.1.3 Dynamitron® Accelerator. Cleland invented a cascaded rectifier system called the Dynamitron, in which the rectifiers are driven in parallel (Fig. 3). Rectifiers connected in series between ground and the high voltage terminal are in two rows on opposite sides of the acceleration tube of the Dynamitron. The high voltage column is enclosed

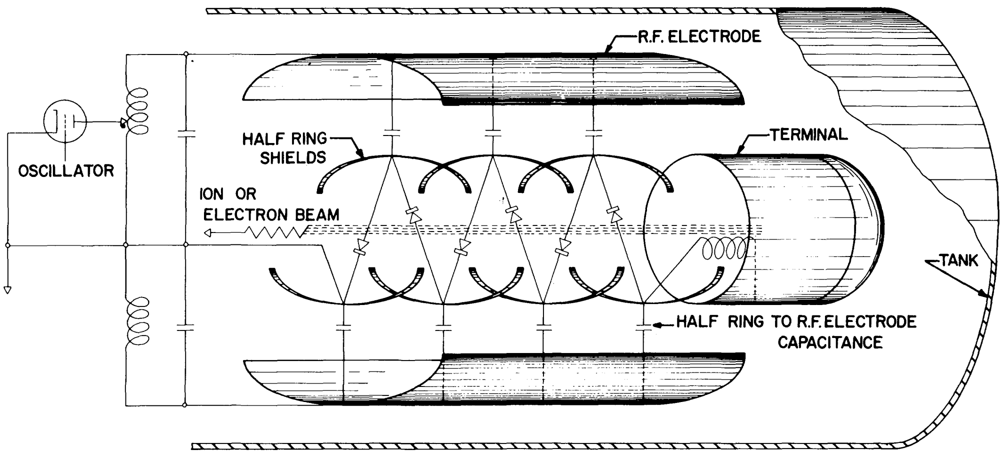

FIG. 3. Schematic of a Dynamitron accelerator in a pressure tank.

by half rings with smooth exterior surfaces to inhibit corona and spark discharge. Large, semicylindrical rf electrodes, mounted near the wall of the tank, surround the accelerator column. As indicated in Fig. 3, the half rings on the column provide capacitive coupling between the rectifiers and the large rf electrodes. The rf electrodes form the tuning capacitance of an *LC* resonant circuit driven by a separate high frequency (~100 kHz) power supply.

Since ac power is fed in parallel to each of the rectifiers, the large storage capacitors that are between successive stages in other cascaded rectifier systems are not required. This reduces stored energy in Dynamitrons to levels comparable with accelerators using electrostatic charging. Minimizing stored energy is important, especially in multimegavolt accelerators, because high stored energy released in a discharge can damage capacitors, rectifiers, column components, and acceleration tubes.

Dynamitrons are built by Radiation Dynamics, Inc. RDI has manufactured single-stage and two-stage Dynamitrons up to 4 MV for research applications requiring high current ion beams. Figure 4 shows a 4 MV positive ion Dynamitron accelerator. The tank for SF_6 insulating gas is open to show the accelerator column.

Most Dynamitrons are built to accelerate electrons for industrial polymerization and sterilization. These applications require electron energies up to a few MeV and high beam power. Systems built by Radiation Dynamics range from a 0.5 MV model with beam power of 50 kW and a model for 75 kW of 1.5 MeV electrons to a 5-MV Dynamitron with electron beam power of 200 kW.

1.1.4 ICT (Insulating Core Transformer) Accelerator. The High Voltage Engineering Corporation developed the ICT circuit for high-current electron beam applications. Rectifiers in the ICT power supply are on modular, flat, circular decks which are stacked one above the other. Nominal 460 V, three phase, 50 or 60 Hz line power drives the primary coil of the power supply transformer. Input power is magnetically coupled to secondary coils (three per deck) by a laminated three phase iron core which is electrically insulated between each deck. The secondary coils on each deck energize the rectifier circuit on the

deck. This minimizes electrical stresses within the stack. HVEC builds ICT electron accelerators for energies from 0.3 to 3 MeV and beam power up to 100 kW, primarily for their industrial electron beam processing systems.

1.1.5 Van de Graaff Accelerator. Accelerators that use an insulating belt to carry charge to the high voltage terminal are named for Robert Van de Graaff, who first successfully demonstrated high voltage generation with belt charging in 1929.

In this device, illustrated in Fig. 5, electric charge is deposited on the insulating belt at the ground end. The motor-driven belt carries the charge to the smooth, well-rounded metal terminal, shown as a sphere in the figure.

To charge the belt, a corona discharge is maintained between a series of points or a fine wire on one side of the belt and the grounded lower pulley or a well-rounded, grounded plate on the other side of the belt. If the corona needles are at a positive potential, the belt intercepts positive ions moving from the needles toward the grounded pulley. The belt carries the positive charge into the sphere, where another array of needle points removes the charge, which passes to the outer surface of the sphere. The positive voltage on the terminal rises until discharged by a spark to ground or limited by corona or an electrical load, such as a resistor string along the insulating support or an ion current through an acceleration tube. Operating the needles at negative voltage produces a negative terminal voltage.

Charging electrodes must be well shielded from the electric field of the terminal, and charge must be carried well within the terminal before removal is attempted. Charging current is then independent of the voltage on the terminal.

The first use of a Van de Graaff voltage generator to accelerate ions was in 1932 at the Department of Terrestrial Magnetism of the Carnegie Institution, Washington, D.C. By 1934 this institution had built a second such accelerator, which was used extensively for nuclear physics research at energies to 1.2 MeV and is now on display at the Smithsonian Institute in Washington, D.C. Other belt-type accelerators built for 2–3 MV in open air were very large (to over 12 m high).

Compact belt-charged accelerators in steel tanks containing high pressure insulating gas were developed at the University of Wisconsin in the 1930s under the direction of Herb. Many basic design features of potential-drop accelerators, still applicable today, were determined in these early machines at Wisconsin. In 1940, Wisconsin completed a 4.5-MeV accelerator, which was used for precise nuclear physics measurements. It was the highest energy potential-drop accelerator for over a decade.

In 1947, High Voltage Engineering Corporation began commercially manufacturing belt-charged accelerators insulated by high pressure gas for electrons and positive ions to 4 MeV.

1.1.5.1 Two-Stage (Tandem) Accelerators. In 1958, High Voltage Engineering Corporation completed a potential-drop accelerator to produce high energy beams by accelerating ions twice. In this two-stage or "tandem" accelerator, illustrated in Fig. 6, injected negative ions are accelerated from ground potential to a positively charged high voltage terminal. In the terminal, a thin gas (or foil) target strips electrons from the ions. The resulting positively charged ions are accelerated a second time, away from the terminal, back to ground potential.

Tandems accelerate protons to an energy of $2eV$, where e is the electron charge and V is the terminal voltage. Heavier ions, which can be stripped to multiple positive charge states, are accelerated to even higher energies. For example, negative oxygen ions injected into a tandem operating at 10 MV are first accelerated to an energy of 10 MeV. If they are stripped of all electrons, the oxygen ions emerge from the terminal with a charge of $+8e$ and gain 80 MeV in the second acceleration for a total energy of 90 MeV.

The tandem principle was originally patented in 1935 by Bennett of Ohio State University, and Peter independently demonstrated keV protons from a tandem with negative-to-positive charge change at the Giessen University in 1936.

HVEC built many single-stage and tandem accelerators, which are in operation in laboratories around the world. The largest reach terminal voltages of over16 MV. Many are used for applied physics applications.

In 1988, Vivirad Corporation purchased the Accelerator Division of High Voltage Engineering Corporation to build accelerators for research and materials analysis. High Voltage Engineering–Europa also manufactures Van de Graaff accelerators to about 2 MV, primarily for ion implantation. Nissin–High Voltage Company manufactures single-stage and tandem accelerators with belt charging to 3 MV for basic research and materials modification and analysis.

1.1.6 Tandetron® Accelerator. In 1980, Purser designed the Tandetron line of compact tandem accelerators for materials analysis, accelerator mass spectrometry, MeV ion implantation (Fig. 7), and basic research. The high voltage generator is a Dynamitron-type parallel-driven cascade rectifier circuit with silicon rectifiers and a 50-kHz driver. It delivers several milliamperes of charging current at up to 3 MV with high stability. For accessibility, the high voltage stack is at right angles to the accelerator column. SF_6 at about 5 atm insulates the accelerator and power supply.

General Ionex Corporation manufactured Tandetrons, many with specialized accessories that they developed for materials analysis, until 1988, when Genus Corporation purchased General Ionex. In 1989 Genus sold the materials analysis line to High Voltage Engineering–Europa, retaining the line of ion implantation equipment.

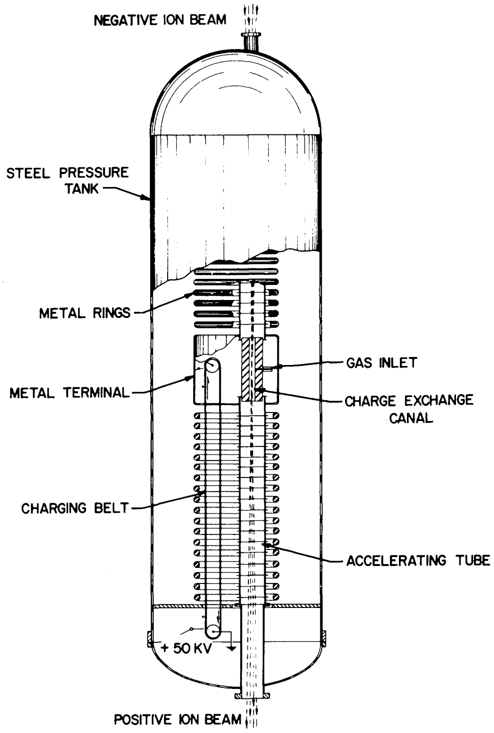

FIG. 6. Schematic of a two-stage (tandem) electrostatic accelerator in a pressure tank.

1.1.7 Pelletron® Accelerator. Pelletron accelerators use a charging chain, rather than a belt or rectifier stack, to generate high voltage on the accelerator terminal. The chain (Fig. 8) consists of steel cylinders (pellets) joined by links of solid insulating material such as nylon. The chain is intrinsically spark protected (undamaged in test sparks at 30 MV). Pellet charging current is adjustable and highly uniform, so that terminal voltages are easily maintained at very precise values with very little voltage ripple. This high charging stability is important and in some cases required for applied uses of accelerators. Many belt-charged accelerators have been converted to Pelletron charging.

The pellets are charged inductively. There is no contact with the charging electrodes (inductors) and no electrical discharge between the pellets and inductors. For positive terminal voltage, the charging inductor is at negative voltage (to -60 kV) to induce positive charge on the pellets at a motor-driven, grounded pulley.

The pellets carry the charge into the terminal, where the charge is removed at another pulley. The pellets are then negatively

charged in the terminal, so that the up-going and down-going runs of the chain contribute equally to charging. Reversing inductor voltage polarities gives a negative terminal voltage.

Acceleration tubes in Pelletrons are unique. Their ceramic insulators and titanium electrodes are bonded together with a metal. Flanges are vacuum sealed with thin metal gaskets. These tubes are bakable for organic-free, ultra-high vacuum operation. This is important for reliability at high voltages and for contaminant-free vacuum applications. Earlier tube designs use organic glues to bond glass insulators to metal electrodes.

Pelletron accelerators were developed by the National Electrostatics Corporation in the 1960s. NEC manufactures single-stage and tandem Pelletron systems from 1 MV up to 25 MV for industries and laboratories around the world.

Most Pelletrons above 4 MV are vertically oriented for simplicity of support. The insu-

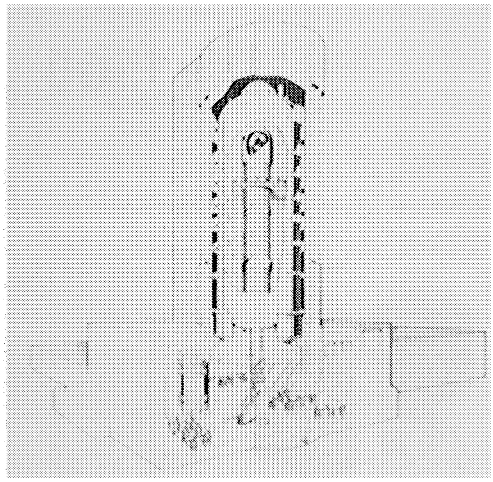

FIG. 9. Drawing of the 25 MV folded tandem at the Oak Ridge National Laboratory, showing 180° magnet in the high voltage terminal and raised service platform around the insulating support column. Multiple target stations are below accelerator. Cylinder (lower left) is a 500 keV ion injector (drawing courtesy of National Electrostatics Corp.).

lating support column is an assembly of standard column modules, each module holding 1 MV. The insulating column supports are posts of alumina ceramic and titanium.

The highest voltage potential-drop accelerator, the 25 MV tandem accelerator at the Oak Ridge National Laboratory (Fig. 9), utilizes this modular column design. It is also one of the few "folded" tandems. In the folded design, both acceleration tubes are mounted in a single insulating support column. Ions are accelerated up to the terminal, where a 180° magnet, shown in the cutaway in Fig. 9, reverses the beam direction for the second acceleration down to the target locations. The magnet completely filters ions from the stripper before the second acceleration, so there is no extra beam loading, and ion transmission is straightforward. Also shown in the figure is a service platform in a raised position in the tank for access to the high voltage column. The folded design, first successfully used by Naylor in New Zealand, conveniently locates both ion source and sample chamber near the system control panel. For very large tandems (20 MV and higher), it reduces the size and costs for the building, insulating gas, and pressure vessel.

Larger potential-drop accelerators (above ~8 MV) are used for basic research, not applied physics, because simpler, smaller cyclotrons and linacs are adequate for high energy beam applications like medical radiation therapy. In the 1990s, applied uses for large potential-drop accelerators may well be developed, e.g., for high-mass accelerator mass spectrometry (AMS) (Sec. 2.5) and shorter wavelength free electron lasers (FELs) (Sec. 2.7).

National Electrostatics also manufactures the S-Series line of small, simplified Pelletrons, mainly for applied physics uses. These accelerators have an inexpensive, cast acrylic support column. They range from 1-MV light-ion systems for materials analysis to heavy ion models to 4 MV, some with over 1 mA of charging current for high current industrial MeV ion implantation. Figure 10 shows a 3-MV tandem S-Series system with dual ion

sources and high resolution beam handling in use for materials modification and characterization.

Pelletrons with computer-automated, multisample end stations are used for production ion implantation, automated materials analysis, accelerator mass spectrometry, and biomedical analysis. Figure 11 shows a computer-automated Pelletron system used by a materials analysis service company.

2. APPLICATIONS OF POTENTIAL-DROP ACCELERATORS

From their beginnings in the early 1930s until well into the 1970s, the emphasis, development, and prolific construction of potential-drop accelerators centered around basic research in nuclear and atomic physics. In the 1980s a broad range of new applications of accelerators rapidly expanded their use into many fields, as illustrated in the examples below. By the end of the 1980s, nearly all new potential-drop accelerators were being built for applied physics uses. Many older accelerators, originally built for basic physics research, were also being converted for use for applied physics.

2.1 Ion Implantation to Produce Semiconductor Devices

Ion implantation is a process used to add specific "impurities" to bulk semiconductor materials to produce microscopic electronic circuits. In ion implantation, a beam of accelerated ions is scanned uniformly across the semiconductor material, e.g., a silicon wafer. The ions penetrate (are implanted) into the wafer. Photoresist is used to limit implantation to specific regions. Typical implant doses are from 10^{13} to 10^{16} ions/cm^2.

Since before 1970, manufacturers have made increasing use of ion implantation in the production of electronic devices. Implanters for energies from 20 to 200 keV are commonplace for creating *p*-type and *n*-type regions near the surface of the wafer. As manufacturers developed microchip circuits with more complex structures, higher energies were needed for deeper implants. Today many implanters are in use for implants at energies up to 400 keV. Most systems for implant energies to 400 keV use an air-insulated, positive voltage single-stage accelerator with a symmetrical cascade rectifier circuit power supply to generate the acceleration voltage. Eaton/Nova, Varian Extrion, Applied Materials, and other companies manufacture ion implanters operating at energies to a few hundred keV.

MeV implanters produce ion beams at energies from a few hundred keV to over 1 MeV. At these higher energies, ions penetrate deeper into the wafer. Deeper implants permit higher density circuits and can create conducting or insulating layers below surface circuitry to inhibit effects from stray charges, e.g., in computer memory chips. Multiple implants at different energies to over 1 MeV are used to produce deep complementary metal-oxide semiconductor (CMOS) wells, with economic and performance advantages over wells produced by slower, energy-consumptive thermal diffusion. MeV ion implantation in III–V materials (GaAs, etc.) produces very high speed switching circuits and light-emitting and light-sensitive solid state devices. MeV implants can program logic circuits late in their production cycle and enhance circuit resistance to radiofrequency and radiation interference.

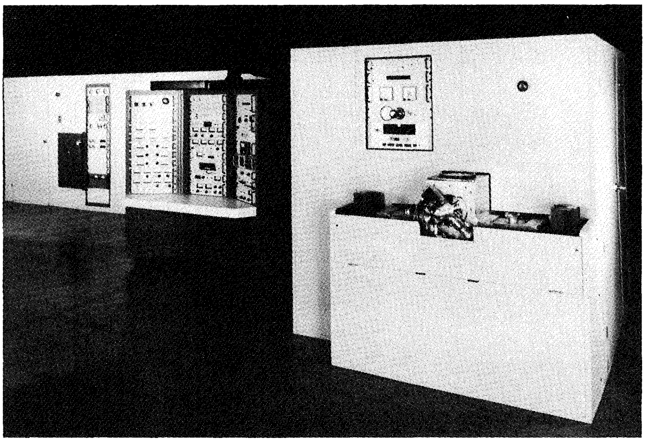

FIG. 12. MeV ion implanter of the type used for semiconductor device production since 1983. A 1-MV tandem accelerator produces ion beams for implantation at energies from 200 keV to over 3 MeV. Microcomputer-controlled cassette-to-cassette wafer handler is in right foreground (National Electrostatics Corp. photo).

Production use of ion implantation at energies of 1 to 3 MeV began in 1983 (see Fig. 12), and more than a dozen MeV implanters were installed in production lines during the next five years. National Electrostatics Corp., Genus Corporation, High Voltage Engineering–Europa, and Nissin–High Voltage Co. manufacture MeV implanters which use potential-drop accelerators for microelectronic device production applications.

2.2 Ion Beam Processing for Reduced Corrosion and Wear

Ion implantation is used to modify mechanical and chemical properties of surfaces to increase their resistance to wear or chemical corrosion. Implanting nitrogen into low carbon steel increases surface hardness for improved resistance to abrasive wear. Implanting titanium into steel reduces the coefficient of friction. Implants of such elements as Cr, Ta, Pd, P, and B into metals can reduce the chemical reactivity of the metals, e.g., for longer component lifetime in chemical processing systems.

These applications generally use high implant doses ($>10^{17}$ ions/cm^2) over large surface areas. This requires very high-current ion beams (10's of milliamps), but beam purity and energy dispersion are much less critical than in implants for electronic devices.

Harwell Laboratory in England has made notable contributions to the techniques and understanding of this applied use of accelerators.

2.3 Materials Analysis with Ion Beams

Materials analysis is a rapidly expanding application of potential-drop accelerators. These nondestructive techniques use MeV ion beams to identify elements and measure their concentrations in a wide range of materials.

2.3.1 PIXE (Particle Induced X-Ray Emission). PIXE identifies elements and their relative abundances from the energy spectrum of characteristic x rays emitted by atoms in the sample, which are excited by an incident MeV ion beam, usually protons. Compared to using electrons to excite the atoms, PIXE generates very little background, making it sensitive to trace concentrations ($<10^{-6}$ for elements of $Z \geqslant 10$).

PIXE was originally developed at the Lund Institute of Technology in Sweden in the 1970s. It is now used worldwide to measure trace elements in biomedical samples, ceramics, petroleum, polymers, and crystals, and on the surfaces of metals and semiconductor materials. PIXE analysis of air samples is used to monitor aerosol pollution. With a scanning proton microprobe (Sec. 2.4), PIXE provides high-resolution lateral mapping of trace element distributions in organic tissues, minerals, etc.

PIXE analysis uses standard equipment developed for atomic and nuclear physics research. Simple accelerator systems easily produce the few microamperes of beam at energies of a few MeV needed for most PIXE applications. Figure 13 shows a typical sample chamber with a multiple-sample holder for batch analysis. The metal block at an angle to

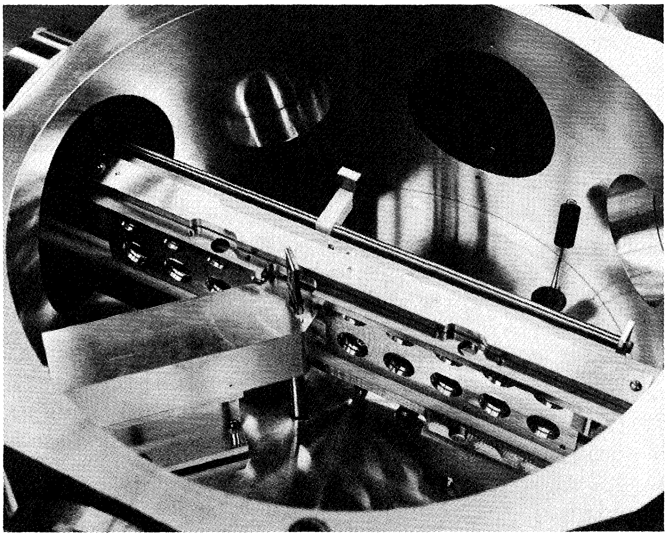

FIG. 13. PIXE target chamber with multiple-sample holder and Si(Li) detector housing with remotely selectable filters.

the sample changer houses a Si(Li) x-ray detector, positioned near the samples for detection efficiency. Selectable filters absorb background x rays to increase sensitivity.

For objects not compatible with analysis in a high vacuum chamber, PIXE is done outside the vacuum by directing MeV-energy protons through a thin foil "window" into the atmosphere. For example, the ALGAE accelerator facility at the Louvre Museum in Paris uses in-air PIXE to analyze art and archaeological objects.

2.3.2 RBS (Rutherford Backscattering) Analysis. RBS analysis measures depth and density profiles of elements at and near the surface of samples. Nuclei in the sample elastically scatter incident MeV helium ions, which are measured at a backward angle for increased sensitivity.

Rutherford scattering is simply elastic scattering due to the electrostatic repulsion of the positively charged incident and target nuclei. Kinematics and absolute cross sections can be calculated from first principles. For a given incident beam, the energy of the scattered ions increases with increasing target mass. Cross sections are proportional to the square of [the target atomic number (Z) divided by the incident energy]. From the calculated cross section and the measured incident beam current, RBS can measure elemental concentrations directly. Calibration standards are not required. RBS is, therefore, often used to measure concentrations of known target elements, e.g., in surface layers created by vapor deposition or ion implantation.

Figure 14 shows a RBS spectrum for bulk silicon with a thin insulating SiO_2 layer and a coating of tungsten silicide. The heaviest element (W in Fig. 14) gives the highest energy backscattered ions. Using known rates of energy loss in the materials, layer thicknesses are determined from peak widths. The area under each peak is converted to an elemental concentration profile, using the measured incident beam current and calculated cross sections.

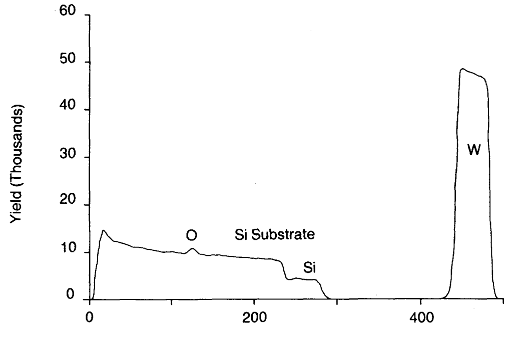

FIG. 14. RBS spectrum of 29% W, 71% Si layer (240 nm thick) over SiO_2 layer (50 nm) on bulk Si substrate, at 160° with 2.275 MeV incident helium ions. RBS measures silicide layer thickness, W/Si ratio, and impurities. (Spectrum from Charles Evans & Assoc., Inc.)

The fast, simple, quantitative, and nondestructive nature of RBS analysis has opened many applications, of which the following are but a few. RBS measures depth profiles of B, P, and As in silicon for electronics. Thin film analysis, a major use of RBS, characterizes metal silicide layers in very large scale integrated (VLSI) devices, measures thicknesses of laminated layers, measures relative concentrations, e.g., of the constituents in YBaCuO high temperature superconducting films, and analyzes nitride layers used as oxidation barriers and in surface hardening. RBS also measures the elemental composition at the interfaces between layers to clarify diffusion and reaction rates, catalytic effects, and adhesion and alloying processes.

RBS systems typically use small tandem accelerators, which produce microampere helium beams over a wide range of selectable energies. Lower energy beams increase depth resolution in thin films. Higher energies probe deeper and improve mass resolution for heavy elements, as in GaAs samples.

Charles Evans & Associates, Inc. and Universal Energy Services are two of the companies that use potential-drop accelerators to provide materials analysis services to industrial and research customers. Charles Evans & Assoc. utilizes the RBS spectrometer shown in Fig. 11 for automatic analysis of up to 100 samples per batch by RBS and related techniques, including elastic recoil detection (ERD), nuclear reaction analysis (NRA), and channeling.

2.3.3 Channeling. Channeling, an effect seen in RBS analysis of crystals, decreases backscatter yields by as much as 98% when the beam is aligned with a crystal axis. Ions incident parallel to the axis (within about 1°) are steered by correlated small-angle deflections along the axis, preventing the close approach to lattice atoms required for large angle scattering, except at imperfections and impurities in the crystal.

Channeling is used, especially in the semiconductor industry, to measure crystal perfection, amount and depth of lattice disorder, locations of substitutional and interstitial impurities, and lattice damage from ion implantation in silicon and subsequent crystal regrowth after annealing. Surface defects and amorphous surface layers increase the angular divergence of the beam, so that some of the beam cannot be channeled by the crystal below the surface. This effect is used to measure thickness and crystallinity in surface layers. Channeling improves RBS sensitivity to surface impurities by reducing backscatter from the substrate and permits deeper analysis with PIXE and NRA in crystals.

Most RBS systems can include channeling measurements by adding a goniometer for accurate sample orientation and collimators to limit the angular spread of the beam.

2.3.4 ERD (Elastic Recoil Detection). ERD is like RBS analysis, but ERD measures the recoiling target ions at forward angles. In most applications, the incident beam and detector are at grazing angles to the sample. Thin foil samples use transmission analysis with the beam at normal incidence and the detector at 0°, where recoil cross sections are largest. Absorbing filters in front of the detector suppress the (heavier) ions from the beam and other interfering recoils.

ERD is sensitive to light elements in heavy substrates and is used to profile hydrogen in metals and semiconductors. Nuclear reaction analysis gives better depth resolution, but ERD is faster and easy to analyze.

2.3.5 Resonance Scattering. Resonances increase the scattering cross section at particular energies and angles. Proton backscattering from carbon, resonant at 1.73 MeV, is used to measure photoresist thickness on wafers coated with a metal, such as gold. With helium RBS, the high background of backscatter from the Au obscures the carbon signal.

To measure elemental concentrations with resonance scattering, the detection system must be calibrated using standard targets of known concentrations.

2.3.6 NRA (Nuclear Reaction Analysis). As beam energy increases, the use of nuclear reactions becomes possible. The reaction ^{1}H(^{15}N, $\alpha\gamma$) is resonant at 6.4 MeV and provides good depth resolution for profiling hydrogen in metals, semiconductors, and glass. Unlike ions, gamma rays do not suffer energy loss in the material. Using channeled beams to induce gamma-emitting reactions, NRA locates impurities deep within a crystal. The sensitivity of reactions to specific isotopes is useful for analyses in several fields, including mineralogy and biomedicine.

2.3.7 Activation Analysis. Particle-induced nuclear reactions are used to generate trace quantities (10^{-10}) of radioactive isotopes at the surface of objects like gears or inside a pipe. Decreases in radioactivity in excess of natural decay measure the rate of surface wear or erosion.

Neutron activation analysis is used to locate underground oil deposits. Accelerators to generate the neutrons operate at about 100 kV and are small in diameter (to <45 mm) to fit into drill holes. Neutrons are also used to detect explosives in airplane cargo.

2.4 Microprobe: The Ion Beam Microscope

Typical MeV ion beams are about 1 cm in diameter. While ideal for many applications, this is too large for measuring lateral distributions of elements.

The microprobe produces a beam spot of from 10 to 20 μm down to less than 300 nm diameter for measurements with spatial resolution of a few microns or better. It uses energy-analyzed beams from an accelerator and includes a beam collimator, strong focusing lens, chamber with sample holder, detectors, and a means of scanning the beam across the sample. Data are collected at points in a line along the sample or over a grid of from 10×10 to 1000×1000 or more points. Microprobes mainly use MeV proton beams and PIXE analysis, primarily for biomedical studies, but also for archaeology, mechanical engineering, mineralogy, and solid state.

For high lateral resolution, microprobes require beams with very little angular divergence. The emittance (a measure of beam divergence in position-momentum phase space) of ion beams from accelerators is far too high for the microprobe. Reducing emittance requires a collimator to remove the more divergent ions, which also reduces beam current. Better accelerator voltage stability improves beam emittance for higher microprobe currents.

To focus the collimated beam, most systems use a quadrupole lens with micrometer adjustments to translate and rotate lens elements to minimize or eliminate aberrations. Magnetic or electrostatic scanning of the focused beam spot across the sample is generally used, because it is easier to control and less sensitive to beam current variations than mechanically moving the sample across a fixed beam. A computer is essential for data acquisition, storage of spectra from each grid point, and data reduction for each element detected. Color graphics displays show the variations in elemental concentrations within the microstructure (Plate 1).

In the 1980s over 30 laboratories built microprobe beamlines for their accelerators. The Universities of Oxford and Melbourne manufacture microprobe components and systems for sale to other laboratories.

2.5 AMS (Accelerator Mass Spectrometry)

AMS measures isotopic concentrations down to 10^{-16} with high precision using only milligram samples. Naturally occurring radioisotope concentrations are measured to date art and archaeological objects, ground water, lunar samples, and meteors and to study glacier and sediment formation and ocean mixing. AMS of tracer isotopes is used in hydrological and atmospheric studies.

The samples analyzed by AMS are not in a target chamber, but in the ion source, which creates ion beams from the sample. The ions are accelerated to MeV energies for high resolution isotopic analysis.

Carbon dating, the primary use of AMS, determines the age of samples from the concentration of ^{14}C, whose half-life is 5.73 ka (a=year). The beam from the ion source contains ^{12}C, ^{13}C, and ^{14}C ions in the same relative abundances as in the sample. The isotopes are accelerated to the same energy (~ 12 MeV), so that the electrostatic and magnetic analyzers following the accelerator give maximum mass resolution and eliminate all interference. Several of the over 30 AMS laboratories have automated their carbon-dating systems. Ages to10 ka require only 15 min for 1% accuracy, compared to 12 h for decay counting techniques, and ages to 50 ka can be measured.

Tandem accelerators are best suited to most AMS applications, because they can transport all of the isotopes without intermediate adjustments and accelerate them to high energy for high resolution. Molecular isobaric interferences, a common problem for other mass spectrometers, are eliminated in tandems, because the stripper dissociates molecules, and the fragments are easily resolved. The use of negative ions, required for tandems, eliminates potential interference from ^{14}N (much more abundant than ^{14}C) in carbon dating, because N^- ions cannot be created.

Other isotopes used in AMS measurements include ^{10}Be (1.6 Ma half-life) to measure ages to 15 Ma in polar ice core samples and ocean sediments, ^{26}Al (720 ka) for hydrology and cosmology, ^{36}Cl (310 ka) to map ocean currents and date ground water, ^{129}I (16 Ma) to study petroleum deposit formation, and ^{41}Ca (130 ka) for paleoanthropological studies.

AMS also measures traces of stable isotopes, e.g., $^{3}He/^{4}He$ ratios in geological samples. Impurity concentrations below 10^{-10} are measured by using a secondary ion mass spectrometer (SIMS) as the ion source for a tandem AMS system (Super-SIMS).

The first AMS measurements with tandem accelerators were at McMaster University (Canada) and the University of Rochester (New York). Dedicated systems, like those at the Universities of Toronto and Arizona, offer AMS service. ETH in Zurich, Switzerland, uses a 6 MV tandem for their AMS facility, which is unsurpassed in performance (over 2500 samples per year with 1% to 5% precision).

2.6 Electron Beam Processing

Industrial plants use electron beams from accelerators or gamma rays from ^{60}Co to induce physical and chemical changes to enhance the properties of materials. High throughput of thin materials favors electron beam (EB) processing, because of its high beam power and processing efficiency. Gamma rays are used for bulky items, e.g., sterilization of shipping cartons of medical disposables, because gamma rays penetrate deeper into materials than electrons.

Cross-linking of polymers, the primary industrial EB application, improves the resistance to heat and solvents of insulation on wires and cables and is vital to the production of heat shrinkable tubing and film. EB is used for polymerization to cure thin coatings and improve adhesives, for sterilization of single-item medical disposables, and for crystal modification for permanent color in glass and gems. Potential EB applications include the irradiation of food products for sterilization and preservation, treatment of drinking water, disinfection of municipal sewage, and treatment of SO_2 and NO_x in industrial smokestack exhausts.

High Voltage Engineering Corp. and Nissin–High Voltage manufacture potential-drop accelerators for EB processing systems at energies from 0.3 to 3 MeV with electron beam power up to 100 kW. They use electron beam scanning to process sheet material or multiple runs of wires or tubing.

Radiation Dynamics, Inc. has built many Dynamitron accelerators from 1.5 to 4.5 MV with electron beam power to 150 kW for EB facilities worldwide. They have also completed a Dynamitron which produces 200 kW of 5 MeV electrons. In addition to providing more power for electron processing, this system can generate x rays of intensities competitive with large gamma ray facilities (1–2 MCi of ^{60}Co) for processing bulky items.

2.7 FEL (Free Electron Laser)

The free electron laser (FEL) uses a high power MeV electron beam in an undulatory magnetic field (wiggler) to amplify electromagnetic radiation to produce high power, coherent "light" at wavelengths from millimeters to the visible region. Since the FEL is not restricted to atomic energy level transitions, laser frequencies are continuously tunable.

Electrostatic potential-drop accelerators produce electron beams with very low energy dispersion, which improves amplification efficiency in FELs. Electrostatic accelerators are also capable of dc electron currents. Linacs and electron storage rings, also used for FELs, produce electrons in short pulses.

The first facility for FEL applications was developed by Elias at the University of California, Santa Barbara (1984). It is used for studies in molecular biology, solid state, and atomic physics. The FEL utilizes a 6 MV electrostatic accelerator designed for recirculated electron beams. In this design, after the 6 MeV electron beam passes through the wigglers in the FEL system, the beam is directed back to the 6 MV terminal. By recollecting well over 90% of the beam in the terminal, beam currents in the ampere range are achieved with less than1 mA of charging current. Facilities are being designed with free electron lasers to provide shorter wavelengths, using higher energy electrostatic accelerators.

2.8 Electron Cooling

Electrons are used to increase the phase space density of beams from sources for high energy (GeV) accelerators. In the preacceleration storage ring, the beam repeatedly passes through a region of cool (low energy spread) electrons which have the same velocity as the beam. Collisions transfer momentum to the electrons, which are then extracted, until the energy spread of the beam has been reduced to that of the electrons.

To increase antiparticle beam intensities, higher antiparticle production energies are used. This increases to several MeV the electron energy required for cooling. Suitable electron beams were demonstrated in tests with an electrostatic accelerator at National Electrostatics Corp. in collaboration with the University of California, Los Angeles, and the Fermi National Accelerator Laboratory (supported by the U.S. Department of Energy). Using the circulated electron beam technique described for free electron lasers, the accelerator produced over 100 mA of 2 MeV electrons with 99.99% of the electrons recollected in the accelerator terminal.

2.9 Electron Microscope

Electron microscopes are like optical microscopes but use electrons at energies from tens of keV to several MeV to illuminate samples. The electron image is observed on a fluorescent screen, directed onto a photographic plate, or analyzed electrically. Scanning electron microscopes, which provide lateral imaging of samples, are in widespread and routine use in industry, biomedicine, and applied and basic research. A separate article in this *Encyclopedia* (ELECTRON MICROSCOPY) describes the significance and vast range of applications of this very important applied use of potential-drop accelerators.

3. SUMMARY

Potential-drop accelerators have emerged as reliable tools for an expanding range of applied uses in many industrial and applied science fields. The variety of potential-drop accelerators provides a spectrum of capabilities for high efficiency and high precision applications. The routine use of potential-drop accelerators continues to grow rapidly, often providing the only solution to meet existing needs.

GLOSSARY

Beam: A directed stream of energetic electrons or atomic or molecular particles.

Charge State: The net charge on an ion divided by the absolute value of e (electron charge), i.e., the atomic number (Z) minus the number of electrons.

Charging: Pertaining to the means used to generate high voltage, as in charging system, charging current, etc.

Ion: A charged atomic particle, including charged molecular particles (radicals).

Stripping: The removal of electrons from energetic ions during their passage through a low density medium (foil, poor vacuum, etc.). Although stripping is generally undesirable in potential-drop accelerators, tandem accelerators utilize stripping in the terminal to advantage to achieve higher ion energies.

Terminal: A metal shell or frame with smooth, rounded exterior surfaces to prevent corona and flashover, supported by insulators, and operated at the high acceleration voltage. May also refer to the assembly of components housed in the terminal shell.

Voltage Grading: The controlled distribution of voltage along the acceleration tube and insulating support column, in most cases for a uniform voltage gradient, using a resistive voltage divider from the high voltage terminal to ground.

Voltage Flashover: A high voltage spark across the surface of an insulator.

INTRODUCTION

The propagation of sound waves in fluid media has considerable practical and fundamental significance. The most widespread application of sound in liquids is underwater, or ocean, acoustics. Because seawater is electrically conducting, it is a poor medium for the propagation of electromagnetic waves and, as a result, sound waves are the best choice for long-range underwater detection and imaging. Another major application for sound-wave technology applied to a (mostly) liquid medium is medical diagnosis. Ultrasonic images complement those obtained with x rays, magnetic resonance, or positron emission and have the advantage of relatively low cost and low risk.

Knowledge of the acoustic properties of liquids is essential, not only because of the practical applications, but because sound provides a way to investigate some of the fundamental properties of condensed matter. In this article we will discuss the propagation of sound in a wide variety of liquids, in each case with anemphasis on what this reveals about the basic properties of the material. Sound waves are a gentle probe, varying the local temperature and pressure as they pass by. This energy can couple to internal degrees of freedom by, for example, altering the equilibrium distribution of the system among internal energy levels. A common theme, then, that occurs in all but the simplest liquids, is the relaxation of perturbed distributions towards equilibrium and the dissipation of acoustic energy that ensues. A secondary theme will be the type of relaxation that occurs at critical phase transitions—the dissipation of fluctuations of the parameter that specifies the degree of order of the ordered phase. We will be concerned throughout only with small-amplitude, linear sound waves;

finite-amplitude effects are discussed in ACOUSTICS, NONLINEAR.

1. ABSORPTION AND DISPERSION OF SOUND IN LIQUIDS

1.1 Propagation of Sound in Lossless Fluids

The propagation of acoustic waves in fluids is governed by the principles of fluid mechanics and thermodynamics. When expressed as conservation equations, these are given by

$$\dot{\rho} = -\frac{\partial g_i}{\partial x_i} \quad \text{(mass conservation)}, \tag{1}$$

$$\dot{g}_i = -\frac{\partial \sigma_{ij}}{\partial x_j} \quad \text{(momentum conservation)}, \tag{2}$$

$$\dot{\epsilon} = -\frac{\partial q_i}{\partial x_i} \quad \text{(energy conservation)}, \tag{3}$$

where ρ is the fluid density, $g_i = \rho v_i$ is the mass current or momentum density, v_i is the particle velocity, σ_{ij} is the stress tensor, ϵ is the energy density, and q_i is the energy flux. Here we use the notation that repeated indices are summed over and i, $j = 1,2,3$ represent the x,y,z axes.

In a lossless fluid, we can ignore the energy conservation equation by assuming that the process is completely adiabatic. In an isotropic fluid without dissipation, the stress tensor is given by

$$\sigma_{ij} = P\delta_{ij} + \rho v_i v_j, \tag{4}$$

where P is the pressure of the fluid and δ_{ij} is the Kronecker delta. The pressure and density changes are in phase so that, to first order, the pressure is given by

$$P = P_0 + \left(\frac{\partial P}{\partial \rho}\right)_S (\rho - \rho_0), \tag{5}$$

where the derivative at constant entropy indicates an adiabatic process. If attention is limited to small-amplitude, longitudinal motion in the x direction, Eqs. (1), (2), (4), and (5) can be combined to form the one-dimensional acoustic wave equation, given by

$$\frac{\partial^2 v_1}{\partial x_1^2} - \frac{1}{c^2}\frac{\partial^2 v_1}{\partial t^2} = 0, \tag{6}$$

which has harmonic solutions for the acoustic variables of particle displacement and velocity and excess pressure and density. The particle velocity in the x direction, v_1, for example, is given by

$$v_1 = v_0 \exp[i(\omega t - kx)], \tag{7}$$

where the phase velocity is a constant, real number given by

$$c = \frac{\omega}{k} = \left(\frac{\partial P}{\partial \rho}\right)_S^{1/2}. \tag{8}$$

1.2 Viscosity and Thermal Conductivity

For a viscous liquid, a dissipative term must be added to the stress tensor in Eq. (4), in the form:

$$\sigma_{ij}^D = -2\eta A_{ij} - (\eta' - \tfrac{2}{3}\eta)\delta_{ij} A_{kk}, \tag{9}$$

where

$$A_{ij} = \frac{1}{2}\left(\frac{\partial v_i}{\partial x_j} + \frac{\partial v_j}{\partial x_i}\right) \tag{10}$$

is the strain-rate tensor. The coefficient η is the shear viscosity, while η' is the volume viscosity coefficient associated with pure, shearless compressions. A finite volume viscosity means that, if the fluid is subject to a sudden pure compression, the density will not respond immediately, but will relax towards its new equilibrium value. There are a number of molecular and structural sources of this delay that will be discussed below. In fact, it is just the coupling of these internal processes to the sound wave through the volume viscosity that has made acoustic spectroscopy so useful in the study of the properties of liquids.

We will limit ourselves now to the effect of shear viscosity and will set $\eta' = 0$. Combination of the linearized, one-dimensional versions of Eqs. (1), (2), and (4) with Eq. (9) included will then yield the damped wave equation, given by

$$\rho_0 \frac{\partial^2 v_1}{\partial t^2} - \rho_0 \left(\frac{\partial P}{\partial \rho}\right)_S \frac{\partial^2 v_1}{\partial x^2} - \frac{4}{3}\eta \frac{\partial^3 v_1}{\partial x^2 \partial t} = 0. \tag{11}$$

We now assume a harmonic wave solution,

$$v_i = v_0 \exp[i(\omega t - k^* x)], \tag{12}$$

where the complex wave number is given by $k^* = k - i\alpha$, where α is the amplitude absorption coefficient. If $\alpha \ll k$, then one finds, to first order in α/k, that

$$c=\left(\frac{\partial P}{\partial \rho}\right)_S^{1/2} \tag{13}$$

and

$$\alpha=\frac{2\eta}{3\rho_0 c^3}\,\omega^2. \tag{14}$$

Conduction of heat from the compressed, warmer parts of a sound wave to the cooler, expanded parts dissipates acoustic energy and contributes a term to the absorption coefficient. The conservation of energy, Eq. (3), including thermal conductivity in the energy flux term, must be combined with the conservation of mass and momentum to yield the acoustic wave equation with a heat-conduction damping term. One finds that the acoustic absorption coefficient due to heat conductivity has the form

$$\alpha=\frac{(\gamma-1)}{2C_p\,\rho_0 c^3}\,\kappa\omega^2, \tag{15}$$

where κ is the thermal conductivity coefficient, C_p is the specific heat at constant pressure, and γ is the ratio of specific heats. Except for highly conducting fluids, such as liquid metals, the sound absorption due to heat conduction is generally negligible compared to that due to shear viscosity.

When simply added together, the combination of the shear viscosity and heat conductivity terms of sound absorption is called the classical sound absorption. The forms given in Eqs. (14) and (15) were developed in the 19th century by Stokes and Kirchhoff, respectively.

1.3 Relaxation Processes

All but the simplest liquids can be characterized by certain internal degrees of freedom that may consist, as we shall see below, of vibrational states, various structural configurations, dimerization, and a number of other possibilities. They have in common the ability to be described in thermal equilibrium by a distribution function, in which a certain fraction of the liquid is associated with one or another of the multiple states of the system. When the equilibrium conditions are perturbed, the distribution generally does not respond instantaneously, but relaxes more or less slowly towards its new equilibrium distribution. If the equilibrium conditions are changing sinusoidally, under the influence of a sound wave, the distribution lags in phase, continually trying to catch up with the changing equilibrium conditions. This phase lag results in a dissipation of energy and an attenuation of the sound wave.

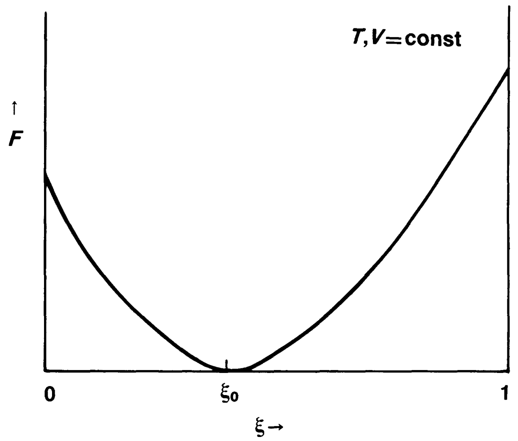

FIG. 1. Helmholtz free energy vs degree of reaction. The minimum at $\xi=\xi_0$ represents equilibrium.

A phenomenological description of this process can be obtained using the methods of irreversible thermodynamics (see THERMODYNAMICS, NONEQUILIBRIUM). A new thermodynamic variable must be introduced, called the order parameter or the degree of reaction, that describes the extent to which the internal degrees of freedom have approached their equilibrium distribution. The change of the Helmholtz free energy can then be expressed as

$$dF=-S\,dT-P\,dV-A\,d\xi, \tag{16}$$

where S, T, P, and V are the entropy, temperature, pressure, and volume, respectively, and where ξ is the degree of reaction and $A=-(\partial F/\partial \xi)_{T,V}$ is called the affinity. The free energy as a function of ξ for constant T and V will have the general form shown in Fig. 1, where ξ_0 represents the equilibrium distribution. When a sound wave perturbs the system, the new values of temperature and density result in a slightly changed curve with a new position of the minimum. It is assumed that the rate of change of ξ as it approaches its new equilibrium position is proportional to the negative slope of the curve, i.e., that

$$\frac{d\xi}{dt}=aA. \tag{17}$$

To find an expression for the relaxation time for this process, we can expand the affinity in terms of any three independent variables. A convenient choice for sound wave excitation is the combination of pressure, entropy, and degree of reaction. This expansion is given by

$$A(P,S,\xi)=\left(\frac{\partial A}{\partial \xi}\right)_{P,S}(\xi-\xi_0)+\left(\frac{\partial A}{\partial P}\right)_{S,\xi}\times(P-P_0)+\left(\frac{\partial A}{\partial S}\right)_{P,\xi}(S-S_0), \tag{18}$$

which can be written as

$$A(P,S,\xi)=\left(\frac{\partial A}{\partial \xi}\right)_{P,S}[\xi-\bar{\xi}\,(P,S)], \tag{19}$$

where

$$\bar{\xi}\,(P,S)=\xi_0+\left(\frac{\partial \xi}{\partial P}\right)_{A,S}(P-P_0)+\left(\frac{\partial \xi}{\partial S}\right)_{A,P}(S-S_0) \tag{20}$$

is the equilibrium value of ξ for given P,S. If we use this expression for A in Eq. (17), then we find that, for constant pressure and entropy, the relaxation time is given by

$$\tau_{P,S}=-\frac{1}{a}\left(\frac{\partial \xi}{\partial A}\right)_{P,S}. \tag{21}$$

This relaxation behavior can now be combined with thermodynamics (see, e.g., Beyer and Letcher, 1969) to provide an acoustic equation of state, given by

$$\tau_{P,S}\dot{\rho}+(\rho-\rho_0)=\frac{\tau_{P,S}}{c_\infty^2}\dot{P}+\frac{1}{c_0^2}(P-P_0). \tag{22}$$

Here

$$\frac{1}{c_\infty^2}=\left(\frac{\partial \rho}{\partial P}\right)_{\xi,S},\quad \frac{1}{c_0^2}=\left(\frac{\partial \rho}{\partial P}\right)_{A,S}. \tag{23}$$

This notation utilizes the fact that constant ξ, which refers to no reaction, occurs at very high frequencies and that constant (in this case, zero) A, which refers to equilibrium, occurs at very low frequencies.

When the acoustic equation of state is combined with the equations of mass and momentum conservation, one obtains a damped acoustic wave equation. Finally, if the absorption is much smaller than the wave number, one can find the velocity dispersion and the absorption to be given by

$$\frac{c^2}{c_0^2}=\frac{1+\omega^2\tau_{P,S}^2}{1+(c_0^2/c_\infty^2)\omega^2\tau_{P,S}^2} \tag{24}$$

and

$$\alpha\lambda=\frac{c^2}{c_0^2}\frac{\pi\epsilon\omega\tau_{P,S}}{1+\omega^2\tau_{P,S}^2}, \tag{25}$$

where $\epsilon=(c_\infty^2-c_0^2)/c_\infty^2$ is known as the relaxation strength. Generally, the dispersion is very small and one can let $c^2/c_0^2=1$ in Eq. (25). For a single relaxation process, the frequency dependence of the total absorption can be expressed as

$$\frac{\alpha}{f^2}=\frac{A}{1+f^2/f_r^2}+B, \tag{26}$$

where the first term is due to the relaxation process with relaxation frequency $f_r=(2\pi\,\tau_{P,S})^{-1}$ and the second term represents the background consisting of the classical absorption and any high-frequency relaxations. Three ways in which the absorption expression can be usefully plotted are shown in Fig. 2.

The properties of a particular liquid can be related to the acoustic absorption through the relaxation strength by noting that the sound velocity is given by $c=(\rho_0\kappa_s)^{-1/2}$. The adiabatic compressibility κ_s and other relaxing thermodynamic coefficients can be expressed as the sum of two terms—an instantaneous, constant ξ, part and a relaxing part. Then the relaxation strength can be written as

$$\epsilon=(\kappa_s^0-\kappa_s^\infty)/\kappa_s^0. \tag{27}$$

After considerable thermodynamic manipulation (see, e.g., Bauer, 1965 or Lamb, 1965), the relaxation strength can be put in the form

$$\epsilon=(\gamma-1)\frac{\delta C_P}{C_P^\infty}\left[1-\frac{\Delta V}{\Delta H}\frac{C_P}{V\beta}\right]^2, \tag{28}$$

where $C_p=C_p^\infty+\delta C_p$ is the specific heat at constant pressure, expressed in terms of its instantaneous and relaxing parts, β is the thermal expansion coefficient, and ΔV and ΔH are, respectively, the changes of the volume and enthalpy per unit change of the degree of reaction during the relaxation process at constant P and T.

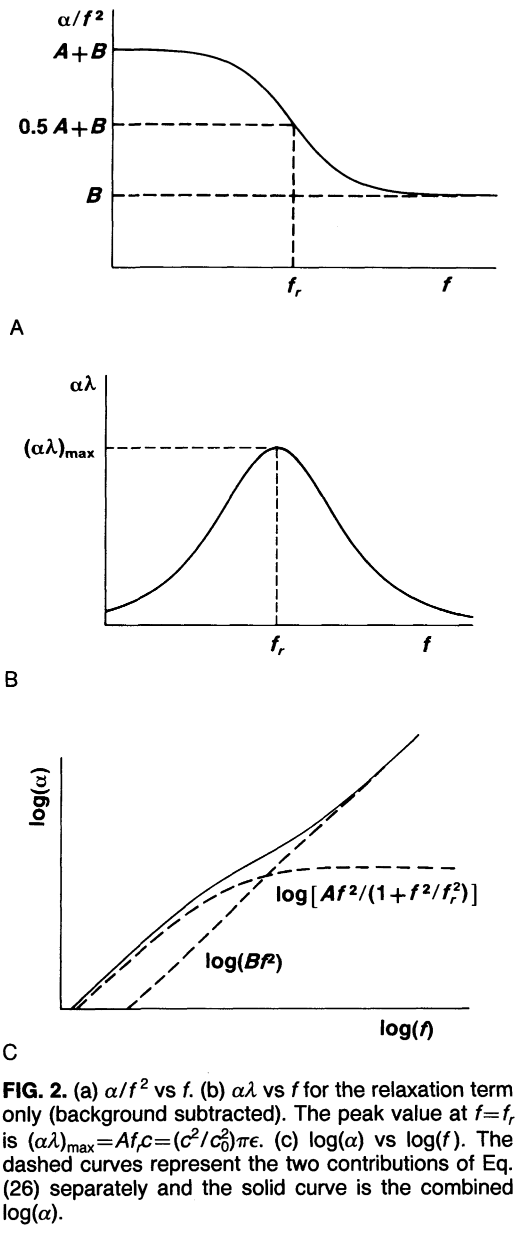

FIG. 2. (a) α/f^2 vs f. (b) $\alpha\lambda$ vs f for the relaxation term only (background subtracted). The peak value at $f=f_r$ is $(\alpha\lambda)_{\max}=Af_rc=(c^2/c_0^2)\pi\epsilon$. (c) log($\alpha$) vs log($f$). The dashed curves represent the two contributions of Eq. (26) separately and the solid curve is the combined log(α).

Equation (28) describes a relaxation process that is induced by either the pressure changes or the temperature changes of the sound wave. These are generally treated separately and are called structural and thermal relaxation processes, respectively. Structural processes occur most notably in water and alcohols and will be discussed further in Sec. 3.2. In temperature-induced relaxation process, ΔV in Eq. (28) may be negligible and the interpretation of the relaxation strength becomes a problem of finding an expression for $\delta C_p/C_p^\infty$ that describes a particular process.

For the relatively simple case of the two-state reaction illustrated in Fig. 3, Lamb (1965) has shown that the peak value of $\alpha\lambda$ [see Fig. 2(b)] is given by

$$(\alpha\lambda)_{\max}=\frac{\pi}{2}\frac{\gamma-1}{C_p}R\left(\frac{\Delta H}{RT}\right)^2 \times\exp\left[-\frac{\Delta H}{RT}\right]\exp\left[\frac{\Delta S}{RT}\right]. \tag{29}$$

Thus, sound absorption measurements can provide values for ΔH and ΔS, the differences of enthalpy and entropy between the two states of the reaction. Similarly, the relaxation frequency f_r provides values of ΔH_1 and ΔS_1, specifying the energy barrier between the two states.

1.4 Sound Propagation Near a Critical Point

General properties of critical phenomena are discussed in the article entitled CRITICAL PHENOMENA. A critical point marks the onset of a degree of long-range order, which is represented by an order parameter. The order parameter is finite in the ordered state and goes smoothly and continuously to zero at the critical temperature T_c. Local fluctuations of the order parameter have a characteristic size that diverges as $|T-T_c|$ goes to zero. Along with light scattering and thermodynamic measurements, propagation of ultrasound is a powerful way to study the nature of critical phase transitions. Near the critical point, the sound velocity generally has a frequency-dependent dip, but the most dramatic effect is

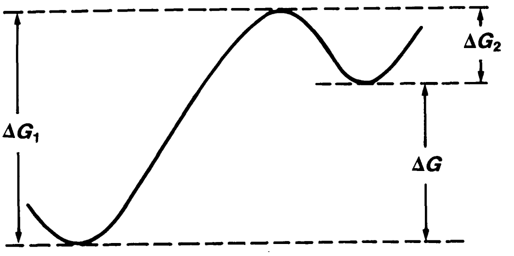

FIG. 3. Two-state energy diagram. ΔG is the difference in the Gibbs free energy between the two equilibrium states and ΔG_1 is the activation energy. The horizontal axis depends on the particular process considered.

a large increase in the absorption. The sound wave couples to the order-parameter fluctuations and the absorption can be calculated from the complex, frequency-dependent volume viscosity or specific heat that arises from the dissipation of the fluctuations. Ordinarily the relaxation time for the dissipation of fluctuations is very short, but the critical slowing down that occurs as T approaches T_c produces times that are accessible to ultrasound.

Early theoretical developments and experimental results (including those at the liquid-vapor critical point, which are not included in this article) have been discussed by Garland (1970). Recent theories have been based on mode-mode coupling and renormalization group theory. Theories for the case of binary mixture phase separation have been actively developed and have been summarized and compared by Tanaka and Wada (1985).

In addition to the coupling of the sound to fluctuations of the order parameter, which occurs on both sides of T_c, an additional source of absorption exists in the ordered phase near T_c. The value of the order parameter is strongly temperature dependent and the variation of temperature associated with the sound wave modulates the equilibrium condition. This is exactly the condition for a thermal relaxation process described in Sec. 1.3. In this context, it is referred to as the Landau–Khalatnikov mechanism.

2. EXPERIMENTAL TECHNIQUES

Techniques for measuring the velocity and absorption of sound waves in liquids will be mentioned here only briefly. For further details, see ACOUSTICAL INSTRUMENTATION, ULTRASONICS, and FILTERS AND RESONATORS, ACOUSTIC. A number of standard techniques exist, each with a range of frequencies over which it is reliable. To study the broad relaxation processes described below, it is convenient to have access to more than one technique.

At high frequencies (1–10 GHz), Brillouin scattering can be used. Laser light is scattering from thermally excited density fluctuations (phonons) and measurement of the frequency shift and the width of the resonance peaks provides the velocity and absorption of sound. At intermediate frequencies (1–1000 MHz), pulse methods are widely used. The absorption and velocity of the sound pulse are obtained from the decrease of amplitude and the time of flight over known distances. Phase-sensitive detection methods measure fractional changes of sound velocity of 10^{-4} to 10^{-6}. The pulse method is limited at high frequencies by the very large damping ($\alpha \sim f^2$) and at low frequencies by diffraction losses that overwhelm the very low absorption losses. At low frequencies (0.01–20 MHz), continuous-wave resonance techniques are used. The width of the resonance peak of a resonating system has a contribution from the absorption coefficient of the liquid sample. Parallel-plate resonators have been effective down to about 150 kHz. At lower frequencies, spherical or cylindrical resonant modes are used.

3. MATERIALS

3.1 Simple Liquids

From an acoustical point of view, simple liquids can be defined as those in which the speed of sound and α/f^2 exhibit no frequency dependence and for which α/f^2 has nearly the classical value.

3.1.1 Liquefied Gases. The acoustical properties of a few liquefied gases are given in Table 1. In each case, the absorption is slightly above the calculated classical value and is dominated by the viscous absorption. The small, positive $\alpha_{\text{meas}} - \alpha_{\text{classical}}$ suggests the existence of a relaxation process at high frequencies, perhaps a structural relaxation, but no frequency dependence of the absorption has been observed.

The superfluid properties of liquid helium disqualify it from being considered as a simple liquid; it will be considered separately in Sec. 3.8.

3.1.2 Liquid Metals. For a general description, see LIQUID METALS, STRUCTURE OF. The acoustic properties of a few liquid metals are included in Table 1. They share with liquefied gases the characteristic that α/f^2 is slightly (5%–30%) above classical and is frequency independent, but in this case the absorption is dominated by thermal conductivity. The excess absorption and the lack of observable frequency dependence again suggest

Table 1. Acoustic properties of some simple liquids.

Liquid	T (K)	c (m s^{-1})	dc/dT (m s^{-1} K^{-1})	$10^{15}\times\alpha/f^2$ (s^2 m^{-1}) Exp.	Classical
Ar	87	848	−8.7	14.5	11.5
N_2	70	925	−10.	14.5	10.4
O_2	70	1066	−7.9	11.6	7.6
Na	371	2531	−0.54	11.5	9.55
Sn	505	2474	−0.27	5.6	4.3
Pb	601	1820	−0.28	9.4	7.6

a form of structural relaxation with relaxation frequency above 100 MHz. Beyer and Ring (1972) analyzed the experimental results in a number of liquid metals and concluded that the uncertainty in the experimental results for sound absorption and for the thermophysical properties that appear in the classical absorption [Eqs. (14) and (15)] render the validation of any theory of the excess absorption extremely difficult.

The electrical conductivity of liquid metals leads to interesting magnetohydrodynamic effects when sound propagation is observed in the presence of an external magnetic field. When the sound is propagated perpendicular to the magnetic field, a linear, damped sound wave exhibits dispersion and a magnetically induced relaxation of the absorption, given by (Beyer and Letcher, 1969)

$$c=\left[c_\infty^2+\frac{\mu H_0^2/\rho}{1+f^2/f_m^2}\right]^{1/2}, \tag{30}$$

$$\alpha_m=\frac{\sigma B_0^2}{1+f^2/f_m^2}, \tag{31}$$

where σ is the electrical conductivity, μ is the magnetic susceptibility, H_0 is the applied magnetic field intensity, $f_m=\mu\sigma c_0^2/2\pi$, and $B_0=\mu H_0$. At low frequencies ($f\ll f_m$), the magnetic field lines are "frozen in" and cause a stiffening of the fluid and an increase in the sound velocity. At high frequencies ($f\gg f_m$), the fluid moves relative to the field lines and the induced currents and associated Joule heat losses produce an increase in sound absorption. At high frequencies, the sound velocity has its normal value. The relaxation frequency f_m is about 10 MHz for liquid alkali metals and 0.5 MHz for mercury.

3.2 Water and Associated Liquids

In water the absorption of sound is about three times greater than predicted by shear viscosity, but no frequency dependence of α/f^2 is observed at frequencies up into the gigahertz range. This suggests that a relaxation process is taking place with a very high relaxation frequency. This excess absorption persists even at 4 °C where the compression due to the sound wave causes no temperature change. This rules out a thermal relaxation as defined above; the excess absorption must be due to the pressure or volume changes associated with the sound wave. Furthermore, the ratio of the measured to classical absorption and, therefore, the ratio of volume viscosity to shear viscosity are nearly independent of temperature and pressure suggesting that the two processes originate in similar mechanisms. This is true even though the hydrogen bonding of water leads to the peculiar property that both viscosity coefficients have a minimum as a function of pressure at low temperatures (see Davis and Jarzynski, 1972).

Water and the alcohols are in the class called associated liquids, which have a strong tendency to form bonded aggregates even in the liquid state. The distribution of molecules in aggregates is pertubed by the pressure changes of a sound wave, resulting in a structural relaxation. Hall (1948) presented a two-state theory in which water is assumed to have two different arrangements of the molecules. In one state, the molecules are in the hydrogen-bonded, rather open, low density structure characteristic of the crystalline solid and in the other state the molecules are more closely packed. Hall assumed that the close-packed structure had a higher energy and that the states were separated by an energy barrier, as depicted in Fig. 3. The energy barrier is taken to be the same as that encountered in theories of shear viscosity, since in each case it is the breaking of hydrogen bonds that is the effective mechanism. The observed pressure dependence of the absorption and velocity of sound, on the other hand, requires that the icelike structure be assigned the higher free energy in the two-state model.

The two-state model has provided a very useful picture of structural relaxation processes, but the project of fitting this concept into a general model of the structure of water is still in progress. Application of such a model to the primary alcohols, which have similar acoustic properties as water, has been less successful.

3.3 Seawater and Electrolytic Solutions

The propagation of sound in the ocean, including the topics of scattering, refraction, the existence of sound channels, etc., is discussed in the article entitled ACOUSTICS, UNDERWATER. In this section, we will restrict our attention to the mechanisms for the absorption of sound in seawater.

When an electrolyte is dissolved in a polar solvent like water, the Coulomb attraction of the ions toward the solvent dipoles tends to disturb the short-range, crystallinelike order of the solvent and to replace it with a structure in which a relatively tightly bound sheath of solvent molecules surrounds each dissolved ion. In water, this results in a decrease in volume and in compressibility, which, for most electrolytes, results in an increase of sound velocity as the solute concentration increases. The sound absorption is changed rather little by the addition of electrolytes except in a few important cases.

The frequency dependence of the absorption of sound in seawater has traditionally been displayed in a log-log plot, as in Fig. 2(c), and is shown schematically in Fig. 4. At frequencies above a few hundred kilohertz, the absorption is proportional to the square of the frequency and has the value for pure water, due primarily to high-frequency structural relaxation and shear viscosity. The low-frequency absorption is increased substantially by a relaxation process involving magnesium sulfate ions with a relaxation frequency of 130 kHz. At lower frequencies another relaxation process occurs with a relaxation frequency of 1 kHz, which has recently been shown to be due to the minute concentration of boric acid present in seawater. Each of these processes has the general form described in Sec. 1.3, in which the equilibrium chemical distribution is perturbed by the volume changes induced by the sound wave, but they are both multistep processes that are more difficult to analyze.

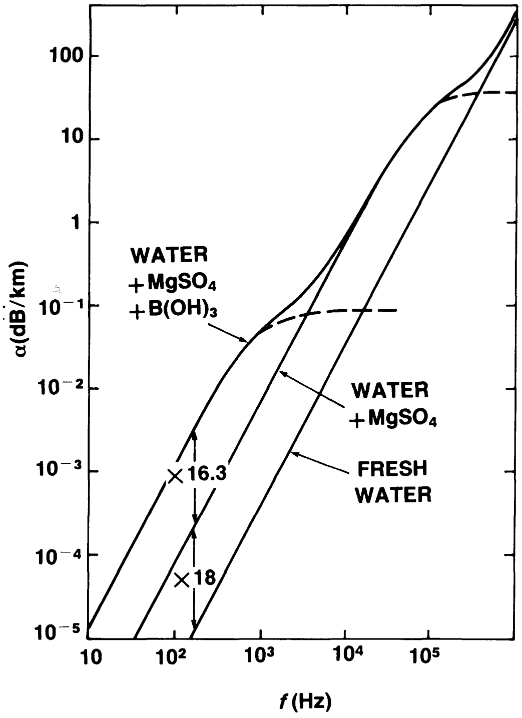

FIG. 4. Schematic representation of the absorption of sound in seawater. The top curve represents the total absorption, which is due to the fresh-water background (lowest curve) and the two independent relaxation processes (dashed curves). From Fisher and Simmons (1977).

The model for the magnesium sulfate relaxation and, by extension, that of other 2-2 electrolytes, is described in detail by Steuhr and Yeager (1965). It is based on the association of the Mg^{2+} and $(SO_4)^{2-}$ ions in a way that necessitates the displacement of water molecules from the hydration sheaths that surround each ion. Four different states in the process are identified: ions far removed from each other, ions approaching each other as close as intact hydration sheaths will allow, removal of one water molecule so that the remaining intervening molecule is shared by the two hydration sheaths, and, finally, direct ionic interaction following removal of

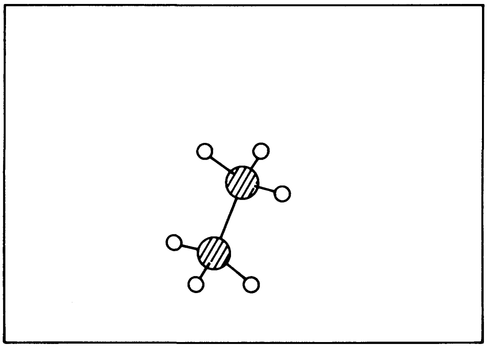

FIG. 5. Ethane molecule: carbon, ●; hydrogen, ○.

the last intervening water molecule. Each step of this process involves a volume change and takes some time, producing a relaxation effect. The final step in the $MgSO_4$ process is the slowest step that creates the relaxation at 130 kHz.

The source of the 1-kHz relaxation in seawater was much more difficult to establish. First of all, it was difficult to be certain that there was an effect. The absorption at 1 kHz is extremely small and the wavelength is 1.5 m, making laboratory acoustical experiments difficult. Only careful analysis of ocean data taken over long ranges produced definite evidence of the relaxation. A review of these ocean experiments has been provided by Waton and Candau (1983). The role of boric acid, which has a concentration in seawater of only 0.43 mmol L^{-1}, was identified by using temperature-jump experiments. Although the details of the process are still somewhat ambiguous, the general outline is now clear. Detailed discussion can be found in the reviews by Mellen *et al.* (1987) and Mallo *et al.* (1985). The dissociation of boric acid provides the correct relaxation time, but the sound absorption is negligible unless it takes place in the presence of magnesium carbonate or calcium carbonate. One is left, then, with a complex coupled exchange reaction involving this combination of components.

3.4 Organic Liquids

We are concerned here with liquids that are unassociated and that have a large relaxing sound absorption caused by the temperature variations of the sound wave. These are sometimes called Kneser liquids after Kneser (1938), who proposed that thermal relaxation is responsible for the excess absorption in liquids just as it is in gases (see ATMOSPHERIC ACOUSTICS). Initial observations of thermal relaxation in liquids were made in the 1930s; our current understanding owes much to the detailed measurements of Lamb and his colleagues and has been reviewed by Lamb (1965).

Several different molecular degrees of freedom can couple to the sound wave resulting in a relaxation process. Here we mention some examples of each.

3.4.1 Rotational Isomerism. A number of liquids are composed of molecules that can exist in two or more isomeric forms. If these forms have different energies, sound energy can be absorbed when the distribution among the isomeric forms is perturbed. A simple example is 1,1,2-trichloroethane. The ethane molecule is shown in Fig. 5. The two ends of the molecule can rotate relative to each other, but the rotation is not entirely free. The energy has local maxima and minima as a function of rotation angle, but in ethane, since all of the minima have the same energy, no acoustic energy is transferred. 1,1,2-trichloroethane, which is ethane with two hydrogens at one end of the molecule and one at the other replaced by chlorine, has the energy diagram shown in Fig. 6. In this case, sound energy is dissipated as the distribution is perturbed. The relaxing part of the absorption is shown in Fig. 7. From the temperature dependence of the maximum value of $\alpha\lambda$, one can find ΔH and from the relaxation time, the excitation energy ΔH_1. The results for 1,1,2-

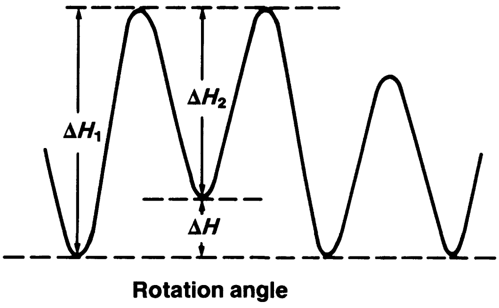

FIG. 6. Energy diagram for the rotational states of 1,1,2-trichloroethane. The higher-energy equilibrium corresponds to the three chlorines being on the same side of the molecular axis.

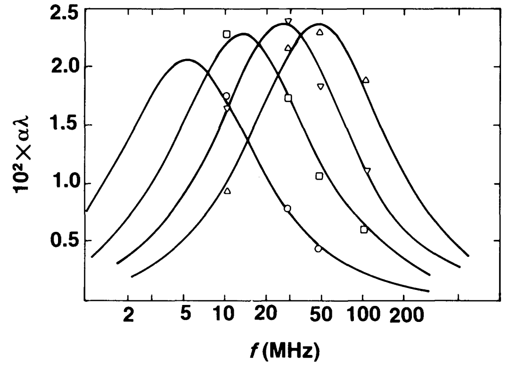

FIG. 7. Ultrasonic absorption due to rotational isomerism in 1,1,2-trichloroethane. Temperatures of the measurements are 0 (○), 20 (□), 40 (▽), and 60 °C (△). From Lamb (1965).

trichloroethane and a few other thermally relaxing liquids are shown in Table 2.

Various esters, aldehydes, and ketones also exhibit strong relaxation effects that can be attributed to hindered rotation about C–O or C–C bonds. Triethylamine and substituted cyclohexanes, which also have different isomeric forms, are other examples of this type of thermal relaxation.

3.4.2 Monomer-Dimer Reaction. Acetic acid shows a remarkably strong thermal relaxation. At 25 °C, the value of α/f^2 rises from 140×10^{-15} $s^2\,m^{-1}$ at frequencies well above the relaxation frequency of 725 kHz to $132\,000\times10^{-15}$ $s^2\,m^{-1}$ at low frequencies. Propionic acid and other carboxylic acids exhibit similar behavior.

Carboxylic acids tend to form dimers in which a molecule's O and OH group form double hydrogen bonds with a neighboring molecule. The equilibrium distribution of the monomer-dimer system is perturbed by the temperature variations of the sound wave. Analysis of the temperature dependence of the peak value of yields a value for the energy difference between the two states.

Table 2. Ultrasonic relaxation parameters for some thermally relaxing liquids.

Liquid	T (°C)	f_r (MHz)	$(\alpha\lambda)_{\max}$
1,1,2-trichloroethane	20	14	0.023
Corotonaldehyde	25	30	0.013
Acetic acid	25	0.725	0.0525
Carbon disulfide	25	78	0.26

3.4.3 Vibrational Relaxation. This process does not necessarily involve organic liquids, but is included here as another example of thermal relaxation. A large number of polyatomic liquids have been studied in which excess sound absorption and associated dispersion exist due to the transfer of energy between the translational and vibrational degrees of freedom of the molecules. For most liquids, the relaxation frequencies occur well above the typical range of measurements. Carbon disulfide is an exception with a relaxation frequency of about 80 MHz at room temperature. Results for CS_2 as well as for carbon dioxide, sulfur hexafluoride, cyclopropane, and a number of others are consistent with a picture of the excess sound absorption being due to the relaxation of the total vibrational specific heat with a single relaxation time. The relationship of the relaxation time to the collision rates in various theories of liquids is given by Herzfeld and Litovitz (1959).

3.5 Binary Mixtures

3.5.1 Nonassociated Liquids. When two thermally relaxing, but nonassociating, liquids are dissolved in one another, the absorption generally does not vary linearly with concentration. As is discussed by Sette (1961), this is due to the difference in the efficiency of collisions of like and unlike molecules in creating the transitions associated with relaxation. Two examples of absorption data and their fit by a theory based on this idea are shown in Fig. 8. A compilation of a large amount of early data is provided by Schaafs (1967).

3.5.2 Critical Phase Separation. Many binary mixtures of liquids display a critical phase separation. They are mutually soluble over only a certain range of concentration and temperature, but, for the critical concentration, a critical temperature exists, called the consolute point or T_c, at which the mixture separates in a second-order phase transition into two solutions with distinctly different concentrations. The order parameter, which is the difference in concentration of the two separated phases, changes continuously from zero at $T=T_c$. The critical behavior is similar to (in the same universality class

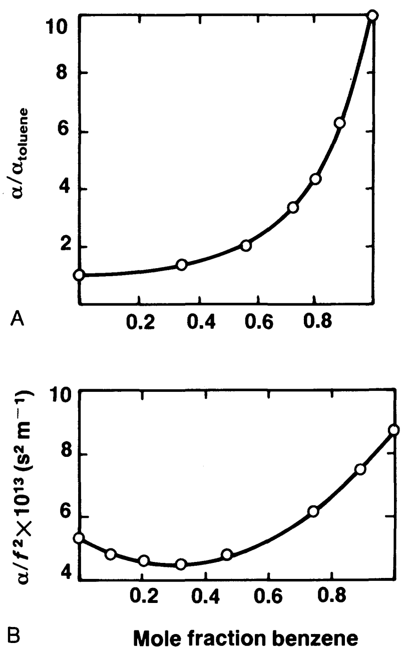

FIG. 8. Comparison of theoretical and experimental values of the absorption coefficient in binary liquid mixtures: (a) toluene-benzene; (b) carbon tetrachloride-benzene at 25 °C. From Sette (1961).

as) the liquid-vapor critical point. A few of the mixtures that exhibit this behavior are listed in Table 3.

As the temperature approaches T_c in a critical binary mixture, sound propagation is marked by velocity dispersion and by a frequency-dependent peak in the absorption. As in other critical phenomena, this is due to the adiabatic temperature changes of the sound wave coupling to the order-parameter (in this case, the concentration) fluctuations. As a case study of this type of behavior, we consider the application of the theory of Ferrell and Bhattacharjee (1985) [FB] to the data of Garland and Sanchez (1983) on the system of 3-methylpentane-nitroethane. The total absorption over a distance of one wavelength $\alpha\lambda$ is shown in Fig. 9 for the critical concentration as a function of temperature. The critical absorption at low MHz frequencies rises to values several times greater than the background absorption. The theory of FB uses dynamic scaling to calculate the dynamic specific heat associated with the dissipative relaxation of the concentration fluctuations. An approximate expression for the predicted temperature dependence of the absorption is given by

$$\left[\frac{\alpha_c(T)\lambda}{\alpha_c(T_c)\lambda}\right]^{1/2} \approx 1+\frac{0.414\Delta T}{\Delta T_{1/2}}, \tag{32}$$

where $\alpha_c(T)$ is the critical part (background subtracted) of the absorption, $\Delta T = T - T_c$, and $\Delta T_{1/2}$ is the value of ΔT for which $\alpha_c(T) = \alpha_c(T_c)/2$. The linear plot, shown in Fig. 10, is consistent with this prediction.

3.5.3 Associated Liquids.

It has been known for a long time, as indicated by Sette (1961), that water-alcohol mixtures have anomalously large attenuation that has frequency-dependent peaks as a function of concentration. Some examples are shown in Fig. 11. Although this behavior is similar to that displayed by critical mixtures, water-alcohol systems do not have a critical phase separation.

The exact source of the absorption in water-alcohol mixtures is still under discussion. Generally the absorption can be fitted by two separate relaxation processes and these have been attributed to reactions involving a liquid clathrate structure. The hydrophobic part of the alcohol molecule induces the water molecules to rearrange their hydrogen bonds to form a cell structure in which an alcohol molecule is trapped. Interaction of these structures or exchange of an alcohol molecule can produce a relaxation. On the other hand, the system water-propanol has been studied over a very large frequency range by Madigosky and Warfield (1987), who find good agree-

Table 3. Some binary mixtures whose critical phase separations have been studied acoustically.

Mixture	Critical concentration (mole fraction of a)	T_c (K)
a. Nitroethane b. Cyclohexane	0.453	296.3
a. Nitrobenzene b. *n*-heptane	0.470	293.7
a. *n*-amyl alcohol b. Nitromethane	0.385	301.1
a. Nitroethane b. 3-methylpentane	0.500	299.6

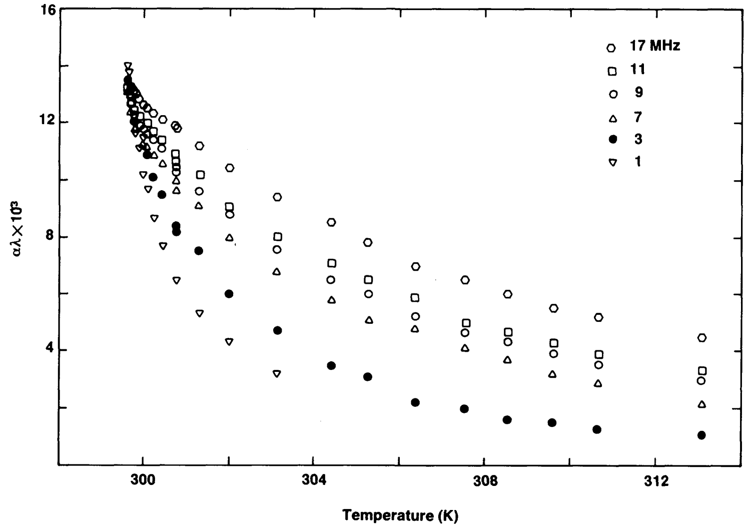

FIG. 9. Temperature and frequency dependence of the absorption per wavelength in a critical mixture of 3-methylpentane and nitroethane. From Garland and Sanchez (1983).

ment with the concentration-fluctuation theory of FB that is used for critical phenomena. They find that the pressure changes, rather than the temperature changes, of the sound wave couple to the concentration fluctuations and that a correlation length of 2.5 nm at room temperature suggests the formation of associated clusters.

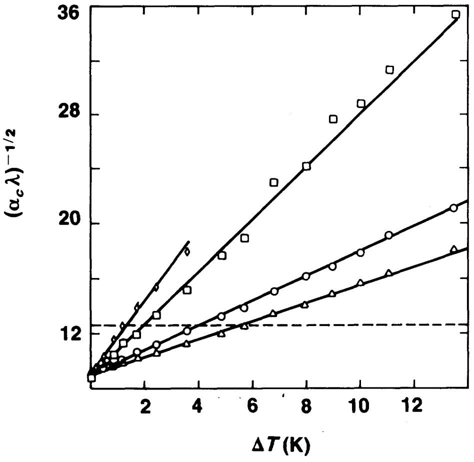

FIG. 10. Critical part of the absorption per wavelength vs ΔT for 3-methylpentane-nitroethane at the critical concentration for several frequencies: 1(△), 3 (○), 9(□), and 17 MHz (◇). The dashed line represents $\alpha_c(T)=\alpha_c(T_c)/2$. From Ferrell and Bhattacharjee (1985).

3.6 Liquid Crystals

The liquid crystalline phases are states of matter intermediate between the crytalline solid and the isotropic liquid that occur for a large number of organic materials. A liquid crystal has lost some or all of the solid crystal's long-range positional order, but it retains

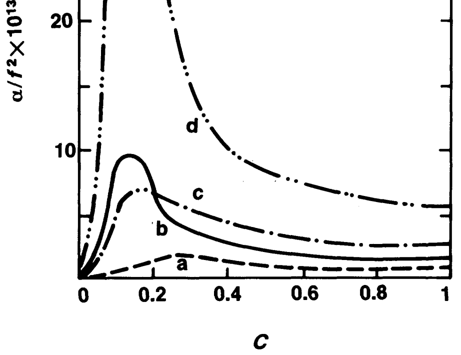

FIG. 11. Absorption as a function of concentration c for several water-alcohol mixtures: (a) ethanol; (b) n-propanol; (c) isopropanol; (d) tert-butanol. From Burton (1948).

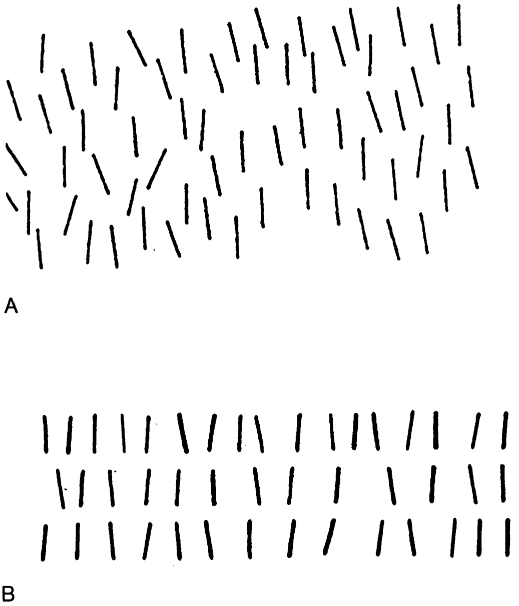

FIG. 12. Molecular arrangement in the (a) nematic phase and (b) smectic-A phase.

the long-range orientational order of its long, thin molecules. It is, thus, a liquid whose physical properties, including its acoustic properties, are anisotropic. Further acoustical interest derives from the behavior at the phase transitions between the liquid crystal states and the neighboring states and from intramolecular thermal relaxations.

For a description of the structure and properties of the variety of liquid crystalline phases that exist, see LIQUID CRYSTALS, STRUCTURE OF. Here we will mention only the acoustical properties of nematic and smectic-A phases. The molecular structures of these two phases are represented in Fig. 12. In the nematic phase, the molecules align parallel to one another, but otherwise have no long-range order. The smectic-A phase is characterized by one-dimensional positional ordering; the molecules lie in planes with the molecular axes aligned parallel to the plane normals.

3.6.1 Intramolecular Relaxations. Liquid crystal molecules generally contain rigid phenyl rings and long flexible end chains. The end groups can exist in various conformations that have different free energies, and thus are subject to rotational isomeric thermal relaxation processes, as discussed in Sec. 3.4.1. An example is the case of *p*-methoxy-*p*′-methylazoxybenzene (MBAB), which has been discussed by Natale (1978) and Candau and Letcher (1978). The frequency dependence of absorption can be fitted by a single relaxation with a relaxation frequency of about 15 MHz. The temperature dependence of the relaxation frequency gives values of the activation enthalpy and entropy. Comparison with pentane, which has the same hydrocarbon chain, shows a comparable activation enthalpy; on the other hand, the activation entropy of MBAB is much larger, which is consistent with the high degree of ordering of the end chains in nematic liquid crystals.

3.6.2 Acoustic Anisotropy. The hydrodynamics of ordered systems, including liquid crystals, has been presented by Martin *et al.* (1972) and reviewed by Miyano and Ketterson (1979). The dissipative part of the stress tensor, Eq. (9), must be expanded to reflect the symmetry. For a uniaxial system, such as nematic and smectic-A liquid crystals, five viscosity coefficients are required. From the revised hydrodynamic equations, one can derive the acoustic wave equation from which the sound absorption is found to have the form

$$\begin{aligned}\frac{\alpha}{\omega^2}\,2\rho_0c^3 &= (\nu_2+\nu_1)\sin^2\theta\\ &\quad+(2\nu_1+\nu_2-\nu_4+2\nu_5)\cos^2\theta\\ &\quad+(4\nu_3-2\nu_1-2\nu_2)\sin^2\theta\,\cos^2\theta, \qquad (33)\end{aligned}$$

where θ is the angle between the direction of propagation of the sound wave and the preferred direction of orientation of the molecules. The coefficients ν_1, ν_2, and ν_3 are shear viscosities and ν_5 and $\nu_4-\nu_2$ are volume viscosities. Thermal conductivity, which is also anisotropic, makes negligible contribution to the absorption.

In the hydrodynamic (low frequency) limit, the sound velocity in nematics is isotropic. In smectic phases, due to the ordering of the molecules in planes, the sound velocity is anisotropic and propagating shear modes can exist.

The anisotropy of absorption in the nematic phase is shown in Fig. 13, which shows the angular dependence of $\alpha(\theta)-\alpha(\pi/2)$. The solid curves are two-parameter fits of the angular dependence of the form of Eq. (33). In

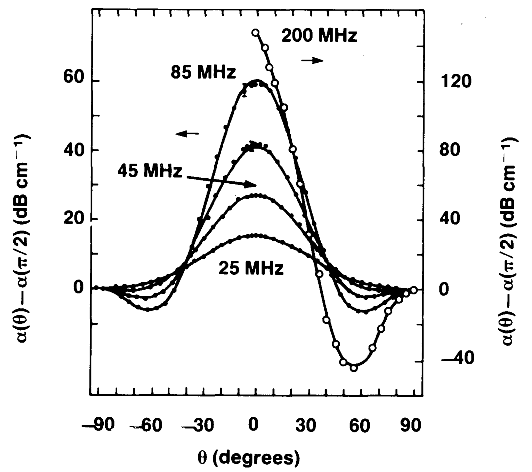

FIG. 13. Frequency dependence of the absorption anisotropy in the nematic phase of MBBA. Data in closed circles are from Wetsel *et al.* (1972); open circles, Bacri (1974). Figure from Miyano and Ketterson (1979).

all nematics studied the absorption anisotropy conforms to the hydrodynamic model, but with viscosity coefficients that can vary dramatically with temperature and frequency.

In the absence of intramolecular relaxations, one would expect that the viscosity coefficients are independent of frequency and then Eq. (33) states that the absorption coefficient in smectics and nematics is proportional to f^2. This is observed in all nematics after relaxation processes have been accounted for. Mazenko *et al.* (1983), however, have shown that, in smectics, anharmonic terms in the fluctuations of the compression and undulation modes of the layers lead to a $1/f$ divergence of some viscosities at low frequencies. This predicts a frequency dependence of sound absorption of the form $\alpha/f^2 = a(\theta) + b(\theta)/f$, where $a(\theta)$ is given by Eq. (33) and $b(\theta)$ contains elastic and viscous constants. Collin *et al.* (1986) have shown that this behavior is observable in the megahertz range only if the elastic constant for planar compression is sufficiently large compared to that for planar bending.

Measurements of sound velocity in the megahertz frequency range in both nematics and smectics show anisotropy, with the velocity for propagation parallel to the preferred molecular orientation greater than for normal propagation direction. This is illustrated in Fig. 14 for cyanobenzylidene octyloxyaniline (CBOOA), which can exist in both the nematic and smectic-A phases. In the low frequency limit, the anisotropy in the nematic phase vanishes and that in the smectic phase remains finite, in accordance with the hydrodynamic theory.

3.6.3 Relaxation Processes at Phase Transitions. Liquid crystals offer a wide array of liquid-liquid phase transitions for study by acoustic means. Here we will mention briefly only the nematic to isotropic liquid (NI) transition.

The NI transition is a weak first-order transition in the sense that the nematic order parameter changes discontinuously at T_{NI}, but the discontinuity is small. As a result of this weak first-order behavior, critical phenomena are still evident, but with a virtual critical temperature less than T_{NI}. The sound absorption has a frequency-dependent peak just below T_{NI} that, at low frequencies, dominates the absorption for five or ten degrees on either side of T_{NI}. The sources for this absorption are, for the most part, analogous to those that occur at the binary liquid phase separation (Sec. 3.5.2). In the isotropic and nematic phases, the sound couples to thermal fluctua-

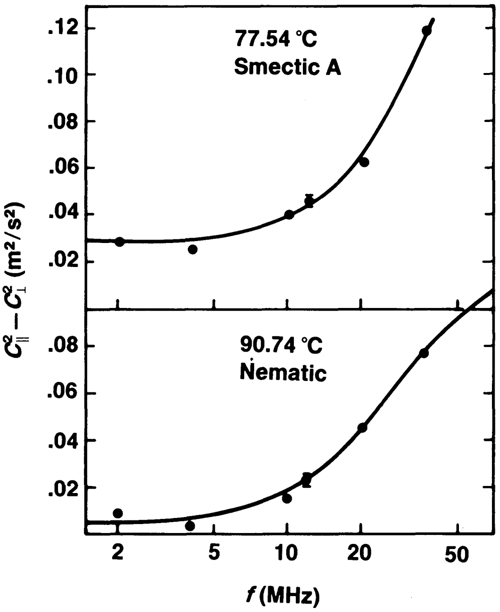

FIG. 14. Frequency dependence of the velocity anisotropy in the smectic-A (top) and nematic (bottom) phases of CBOOA. From Miyano and Ketterson (1975).

tions of the nematic order parameter and, in the nematic phase, the Landau–Khalatnikov mechanism (thermal relaxation of the acoustically perturbed nematic order parameter) is also present. In the nematic phase near the transition temperature, a third absorption mechanism has been identified that is due to fluctuations of the director that specifies the orientation direction.

3.6.4 Acousto-Optic Effect in Liquid Crystals. The combination of acoustic and optic anisotropy of liquid crystals suggests the possibility of a device that would allow the visualization and mapping of ultrasonic fields. This would be particularly useful in the fields of nondestructive evaluation and medical diagnosis. Consider a cell that consists of a thin layer of uniaxially birefringent nematic with the long molecular axes attached normal to the containing glass surfaces. The optic axis is then everywhere normal to the surfaces and, when the material is placed between crossed polaroids, incident light is blocked. If ultrasonic waves are incident on this cell, they exert a torque on the molecules and, at high enough intensity, induce streaming. Each of these effects will tilt the optic axis and allow light to pass through. One can thus map the sound field and, with a little more sophistication, form images of objects irradiated by the sound. Although only intensity, not phase, information is detected, this method has the advantage that a full two-dimensional picture of the sound field is observed in real time. This field was reviewed by Candau and Letcher (1978) and by Kapustina (1984).

3.7 Amphiphilic Aggregates in Solution

Amphiphilic, or surfactant, molecules have a polar head group that is attracted to water and a hydrocarbon tail that is hydrophobic. When dissolved in water, they tend to arrange themselves in structures that minimize the contact of the tails with the water. The large number of parameters that can be varied—including, for example, temperature, concentration of amphiphiles, whether the head group is ionic or nonionic, and concentration of added components, such as alcohol, salt or oil—leads to a rich variety of structures and properties. A full description is beyond the scope of this section; we will mention only a few of the acoustic properties.

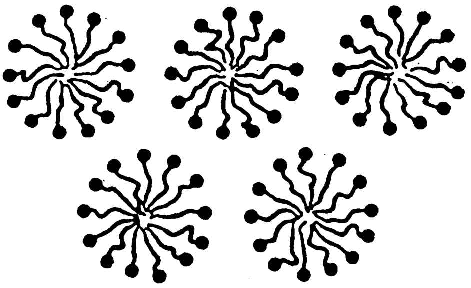

FIG. 15. Molecular structure of micelles.

3.7.1 Micelles. When the concentration of amphiphile molecules in water reaches a value called the critical micelle concentration (cmc), the molecules form themselves into spherical structures, called micelles, with the head groups on the outside, in contact with the water, and the tails on the inside. This is illustrated in Fig. 15. An equilibrium exists between the monomers left in solution and the micelles. When sound propagates through this system, one observes a large frequency-dependent maximum of the absorption as a function of concentration that begins at the cmc, rises to a maximum amplitude at 2–4 times the cmc, and then decreases toward zero at large concentrations. The relaxation frequency depends on the length of alkyl tail; for ultrasonic studies, one chooses an amphiphile with 12 or fewer carbon atoms in the end chain to have the relaxation frequency in the low megahertz region. This relaxation is attributed to the exchange of a surfactant molecule between the micelle structure and the surrounding water-rich environment.

When an alcohol with medium chain length is added to the solution, alcohol molecules are incorporated into the micelle structure and have their own exchange reaction with the environment, which leads to a second relaxation process with a somewhat higher relaxation frequency. These processes have been summarized by Lang *et al.* (1982).

With increasing concentration, eventually the micelles come into contact and interact with one another, leading to anisotropic structures. Common types are the lamellar phase, in which bilayers of surfactant molecules are separated by water layers, and the hexagonal phase, where long, cylindrical micelles are packed in a hexagonal array in a water medium. In this region, as the monomer-micelle exchange reaction disappears, a new relaxation process, with a lower relaxation frequency, is observed in some solutions. This has been attributed by Tiddy *et al.* (1982) to the exchange of water molecules between a "bound" state near the surfactant head groups and a "free" state.

3.7.2 Microemulsions. When oil is added to a water-surfactant-alcohol solution, the water and oil are generally separated by a structure of the surfactant with alcohol as a cosurfactant. For low oil concentrations, the oil may be held inside a spherical micelle that is floating in the water-rich environment. This is an oil-in-water microemulsion. At the other extreme of high oil concentration, one finds water inside an inverted micelle—a water-in-oil microemulsion.

The ultrasonic absorption of a large number of systems of both types has been reported by Lang *et al.* (1982). For surfactant and alcohol molecules with appropriate chain length, both structures are characterized by two relaxation processes in the low megahertz range. For the oil-in-water case, these have been attributed to the same exchange reactions found in micelles (see above). Similar exchanges take place in water-in-oil microemulsions, but the surfactant molecules can transfer to the interior water medium. Although the absorption can go through a maximum as a function of concentration in some microemulsions, no case has yet been found where this is attributable to concentration fluctuations associated with a critical process.

3.7.3 Magnetic Liquids. A magnetic liquid is composed of very fine magnetic particles, each coated with surfactant molecules, that are colloidally dispersed in a fluid. Since it is a fluid that can be controlled, to a certain extent, by a magnetic field, it has many practical uses, for example, as a sealant or lubricant. Magnetic fluids have a wide variety of acoustic properties, but since a large number of parameters are involved that can be varied, but not necessarily controlled, a detailed description that is generally applicable is not easily obtained. In the absence of an external magnetic field, increasing the concentration of particles causes a decrease in the sound velocity and an increase in the attenuation. The frequency dependence of α/f^2 indicates a relaxation process in the low megahertz region. In the presence of an external magnetic field, the absorption and velocity are anisotropic, but the shape of the anisotropy is not that of liquid crystals, given by Eq. (33). The situation is more complicated because the magnetic field causes the individual magnetic particles to agglomerate into large particles whose shape and size depend on the magnetic history.

3.8 Liquid Helium

Helium has two stable isotopes, ^{3}He and ^{4}He, each of which exhibits a superfluid state (see SUPERFLUIDITY: LIQUID HELIUM SYSTEMS). Liquid ^{3}He and ^{4}He behave quite differently and will be discussed separately.

3.8.1 Liquid ^{4}He. Between the normal boiling point of 4.21 K and the superfluid transition temperature of 2.17 K, ^{4}He is a simple, weakly bound van der Waals liquid that could be included in Sec. 3.1 except that its acoustical properties begin to be dominated by the approach to the superfluid transition as the temperature is lowered. Below 2.17 K (called the lambda point or T_λ), the superfluid state is a macroscopic quantum system, but many of its hydrodynamic properties can be described accurately with a two-fluid model. The fluid is assumed to consist of a mixture of two components, normal and superfluid, and the density of the fluid is simply the sum of the normal and superfluid densities: $\rho=\rho_n+\rho_s$. The superfluid component has zero viscosity and carries zero entropy, so that it can flow through narrow cavities (called superleaks) that immobilize the normal component. An increase in the ratio ρ_s/ρ_n corresponds to a decrease in temperature.

A number of propagating hydrodynamic modes exist in the superfluid state. Ordinary sound, in which the normal and superfluid components move together creating density and pressure variations, is called first sound. When the two components move out of phase in the bulk, so that the overall density remains unchanged, the resulting propagating temperature and entropy wave is called second sound. Third sound occurs in thin films of He when the normal component is immobilized by its viscosity and the superfluid component moves, creating a kind of surface wave with variations of the film thickness but not of total density. Fourth sound is a bulk

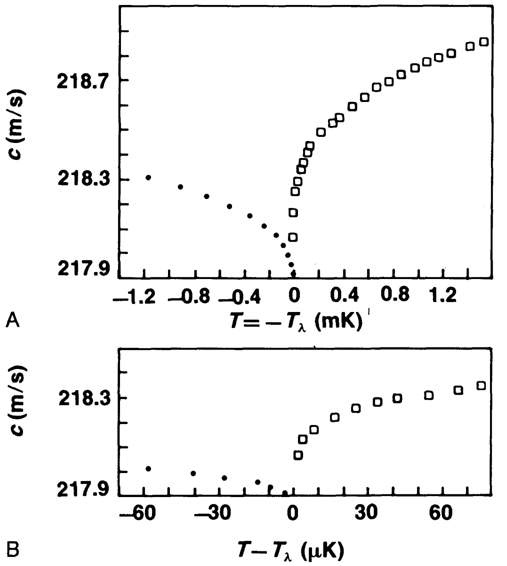

FIG. 16. Temperature dependence of the velocity of first sound at 22 kHz in liquid ^{4}He near the lambda transition on (a) the millikelvin and (b) the microkelvin scales. From Barmatz and Rudnick (1968).

pressure wave in which the normal component is locked by a superleak when, for example, the helium fills the narrow interstices of a packed powder. Finally, fifth sound is a thermal wave in which the normal component is immobilized by a superleak and the superfluid moves, but the pressure is not allowed to change. These modes are summarized by Rudnick (1983) and are discussed in the entry SUPERFLUIDITY: LIQUID HELIUM SYSTEMS. We will concentrate here on the properties of ordinary, or first, sound.

The speed of sound in liquid and solid helium is less than that in air at standard temperature and pressure, which is a manifestation of the loose packing and high compressibility of condensed helium that, in turn, is due to the weakness of the van der Waals force and the relative strength of the quantum mechanical zero-point energy. Near T_λ, the velocity has a sharp decrease associated with the critical nature of the phase transition. This is shown in Fig. 16.

The temperature dependence of the absorption of sound in ^{4}He is represented in Fig. 17. From about 2.5 K up to the boiling point, the absorption is due to the classical causes of viscosity and thermal conduction. A large peak occurs near the lambda point and then a maximum occurs at about 1 K, in the middle of the superfluid state. At low temperatures, the absorption goes to zero as T^4. The low attenuation at very low temperatures has been exploited in a scanning acoustic microscope (see MICROSCOPY, ACOUSTICAL).

The peak of absorption at 1 K is related to the elementary excitations that exist in superfluid ^{4}He. At very low temperatures, the only thermal excitation is the phonon, the quasiparticle associated with ordinary sound; above about 0.6 K, a new excitation, called the roton, can be found. The absorption peak represents a thermal relaxation process in which the sound wave disturbs the equilibrium distribution of phonons and rotons and the return to equilibrium is achieved with time-consuming collision processes.

The lambda transition in liquid ^{4}He is a critical process, as introduced in Sec. 1.4. The order parameter is a complex quantity that is related to the quantum mechanical wave function in the superfluid state. The sound velocity has a marked decrease near T_λ (Fig. 16), and the sound absorption has a dramatic increase (Fig. 17). The absorption for $T > T_\lambda$ is accurately described by the coupling of the sound to fluctuations of the order parameter, similar to critical binary mixture phase separations (Sec. 3.5). The peak in the sound absorption occurs slightly below T_λ, as can be seen in Fig. 18. This is attributed to the Landau–Khalatnikov mechanism in the superfluid state, which is the relaxation of the order parameter that has been perturbed by the temperature variations of the sound wave.

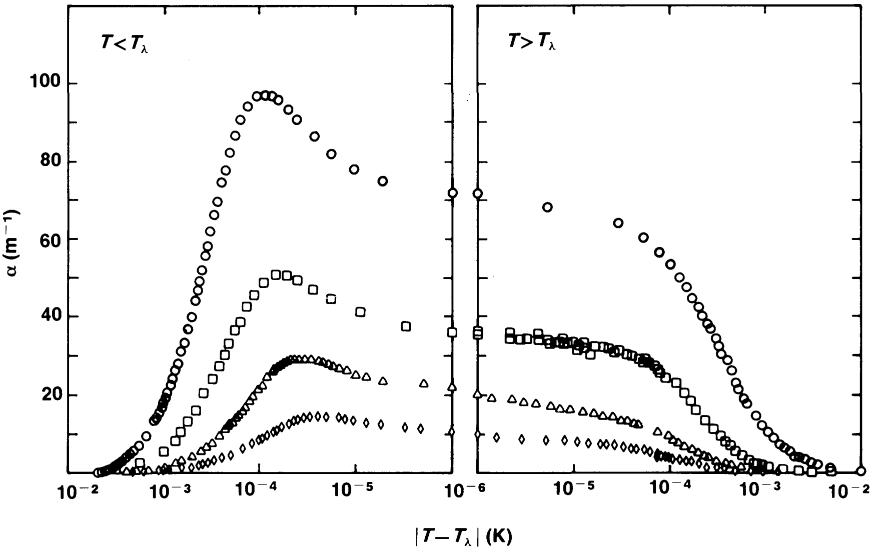

FIG. 18. Temperature and frequency dependence of the absorption of first sound in ^{4}He near the lambda transition. Starting from the lowest curve, the frequencies are 600 kHz, 1 MHz, 1.75 MHz, and 3.17 MHz. The data represent the critical absorption, after the background has been subtracted. From Williams and Rudnick (1970).

3.8.2 Liquid ^{3}He. Ultrasonic spectroscopy has been a valuable tool in un der standing the remarkable properties of liquid ^{3}He. At temperatures above 1 K, ^{3}He behaves like a simple liquid and its sound absorption is due to viscosity, which has a temperature dependence of T^{-2}, and is proportional to the square of the frequency. Helium-3 is, however, a Fermi liquid and at sufficiently low temperatures these properties begin to manifest themselves. The atoms fill discrete energy levels up to the Fermi energy and only those atoms with momentum near the corresponding Fermi surface participate in collisions. In this regime, the time between collisions τ varies rapidly with temperature according to T^{-2}. For high ultrasonic frequencies, a point is reached where $\omega\tau > 1$; the time between collisions is greater than the period of the sound wave. This is called zero sound. It is the Fermi liquid analog of sound propagation in rarified gases where the molecular mean free path is greater than the wavelength. The absorption of zero sound is proportional to T^2. The zero-sound regime occurs below about 20 mK and the first, or ordinary, sound, above 20 mK.

Below about 2 mK (depending on the pressure), liquid helium-3 enters one or another of three superfluid states: ^{3}He-A, ^{3}He-B, or, in the presence of a magnetic field, ^{3}He-A_1. The helium atoms form Cooper pairs, in exact analogy to the electron pairs associated with superconductivity. The pairs form a reduced energy state that creates an energy gap that broadens as the temperature is reduced. The superfluid states can be described by a two-fluid model that predicts second through fifth sound, but these have been difficult to observe in ^{3}He because of large damping.

As an example of the behavior of sound absorption in superfluid ^{3}He, we mention briefly results in ^{3}He-B; the reader is referred to Wilkes and Betts (1987) and references therein and to the article SUPERFLUIDITY: LIQUID HELIUM SYSTEMS for further discussion. The absorption of 60-MHz ultrasound in ^{3}He-B is shown in Fig. 19. The large peak just below the superfluid transition is due to acoustic energy being used to break up Cooper pairs. The other large peak and the smaller, sharper peak are called the squashing and real squashing modes and refer to the distortion by the sound wave of the symmetry of the order parameter that describes the state.

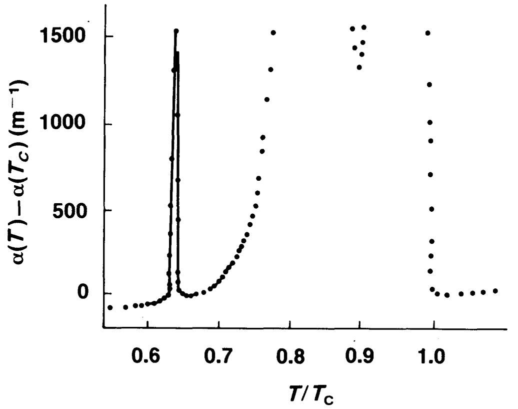

FIG. 19. Relative absorption of 60-MHz sound in the superfluid state of ^{3}He-B at 5.3 bar. The higher-temperature broad peak is due to the breaking of Cooper pairs. The other two peaks are due to the squashing and real squashing modes. From Lee (1983).

GLOSSARY

Associated Liquids: Materials such as water and the alcohols that tend to form molecular clusters or groups in the liquid state. They have a contribution to the sound absorption due to structural relaxation.

Classical Sound Absorption: The absorption of sound in a fluid that is due to shear viscosity and heat conduction.

Fermi Liquid: A liquid, such as ^{3}He, that obeys Fermi–Dirac statistics. See article on STATISTICAL MECHANICS, QUANTUM.

Irreversible Thermodynamics: Thermodynamics of systems that are not maintained in thermal equilibrium. The extent to which a system departs from equilibrium is treated as a new thermodynamic variable. See THERMODYNAMICS, NONEQUILIBRIUM.

Kneser Liquids: Liquids that undergo thermal relaxation processes of the same type that are found in gases.

Structural Relaxation: A relaxation process between different short-range structural configurations of a liquid that is induced by the pressure variations of a sound wave.

Thermal Relaxation: A relaxation process between different molecular energy states that is induced by the temperature variations of a sound wave.

INTRODUCTION

Acoustical instrumentation is used to generate and monitor compressive waves in gases, liquids, and solids. In gases, acoustical instruments are used in communication systems such as telephones, public announcement systems, and recreational audio systems. They are also commonly employed in noise control of industrial or community sources and in research on the properties of gases. In liquids, acoustical instruments have been widely used for sonar systems. They are also receiving progressively more attention in biotechnology, where they aid in sonograms and lithotripsy, and in geophysics, where they are useful for off-shore prospecting. In solids, acoustical instruments are being used for nondestructive testing of structures, for geophysical prospecting in the earth, and for surface acoustic wave devices useful in a variety of signal processing schemes. With this wide range of applications and frequency regimes acoustical instrumentation has found a sizable market.

In this article we will describe the unique aspects of acoustical instruments, concentrating on the sensors and actuators which convert acoustical energy to another form (generally electrical) or vice versa. We discuss the physical and technical principles of energy conversion in acoustical transducers and the measurable field-related properties such as directivity, intensity, and radiation efficiency. We describe the practical manifestations of these physical principles in various transducers. Specific examples mentioned include condenser microphones, piezoelectric and ceramic hydrophones, electrodynamic loudspeakers, and linear magnetic geophones. We also discuss new technologies for acoustical instruments, including fiber optic devices, solid-state sensors and actuators, transducers using new materials, and novel transduction

techniques. Finally, we describe the practical use of acoustical instruments in various common applications.

1. PHYSICAL AND TECHNICAL PRINCIPLES

The main feature of all acoustical sensors and actuators is the conversion of energy from acoustical form to another form, usually electrical, or vice versa. Below we describe the various mechanisms used in achieving this energy conversion. All of the mechanisms discussed may be used for applications spanning a wide range of frequencies. We also discuss sound intensity, directivity, and radiation efficiency.

An acoustic wave is associated with a pressure fluctuation about the ambient pressure. A pressure gradient produces a particle velocity in the direction of the gradient. Thus, pressure and particle velocity are the basic quantities to be measured. The product of these two is the intensity, a vector which gives the direction and magnitude of power flow per unit area of a propagating acoustic wave. The square of the pressure is related to the potential energy density and the square of the velocity is related to the kinetic energy density in the wave. In a reverberant field resulting from the random summation of many waves, the sum of the potential and kinetic energy densities is the total energy density in the sound field.

1.1 Conversion of Energy

Acoustic pressures can be sensed or generated effectively and accurately over a wide frequency range. Measurement (or generation) of the pressure at two spatial positions allows the determination (or specification) of the pressure gradient and hence particle velocity. All other quantities describing the sound field can be derived from the pressure and velocity.

Pressure transducers use a diaphragm or another surface that acts to convert pressure to force (sensor) or force to pressure (actuator). It is this moving element that results in the conversion of energy from acoustical form to electrical form or vice versa. The conversion process may involve electric fields with capacitive characteristics, magnetic fields with inductive characteristics, or changes in conductance with resistive characteristics.

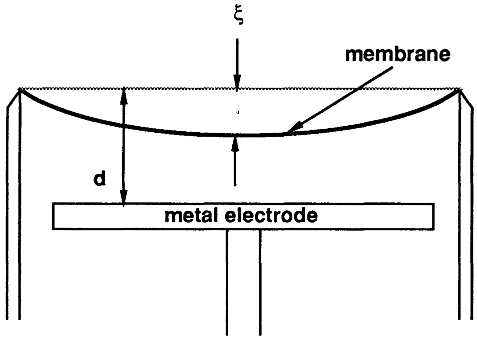

FIG. 1. Typical quadratic capacitive sensor using a membrane as the active transducing element.

1.1.1 Capacitive Transducers. There are two general classes of capacitive transducers: those which are quadratic and those which are linear. Both are described below.

1.1.1.1 Quadratic Types. In quadratic capacitive transducers energy conversion is accomplished by means of an electromechanical coupling which causes or results from a change in the energy stored in an electric field. In acoustical instruments this typically takes the following form. A very thin circular metal or plastic membrane is used to sense or generate an acoustic pressure. In the sensor the pressure acts as a uniformly distributed force to produce a parabolic displacement ξ of this membrane, as shown in Fig. 1. The average displacement in meters is then given by (Merhaut, 1981)

$$\xi=\frac{a^2}{8T}p, \tag{1}$$

where a is the diaphragm radius, T is the tension on the membrane (in units of force/length), and p is the acoustic pressure in Pa.

The instantaneous energy stored in the electric field is described by

$$W=\frac{Q_0^2}{2C}=\frac{Q_0^2(d+\xi)}{2\epsilon A}, \tag{2}$$

where Q_0 is the static charge which is assumed to be constant, C is the capacitance of the device, ϵ is the electric permittivity of the dielectric between the capacitor plates, A is the membrane area, and d is the distance between the two electrodes. The force on the membrane is given by

$$F=\frac{\partial W}{\partial \xi}=\frac{Q_0^2}{2\epsilon A}, \tag{3}$$

and the electric potential is given by

$$V=\frac{\partial W}{\partial Q_0}=\frac{Q_0(d+\xi)}{\epsilon A}. \tag{4}$$

Note that the force is quadratic in charge and thus depends quadratically on the electric field strength. In Eq. (4) we identify the time varying portion of the potential as v, and find through use of Eq. (1) that

$$v=\frac{a^2 V_0}{8Td}\, p, \tag{5}$$

where $V_0 = Q_0/C_0$, C_0 being the static capacitance. This linear relation holds for uniform electric fields and deflections ξ small compared to d so that Q_0 is essentially constant.

1.1.1.2 Piezoelectric. There is a class of dielectric anisotropic crystals that provide coupling between elastic and dielectric phenomena (Mason, 1964). This coupling is referred to as the piezoelectric effect. Natural and artificially grown piezoelectric crystals exhibit linear electromechanical coupling relationships. Certain rare-earth compounds when used to produce a ceramic yield polycrystalline ferroelectrics which have square-law electromechanical relationships. When a high potential is applied to the material at a temperature above the Curie point, a remnant polarization is retained. For small strains and potentials small compared to the remnant polarization, essentially linear piezoelectric coupling is obtained for these materials as well. See Kino (1987) for properties of several materials.

Since piezoelectric crystals are anisotropic elastic solids, the stress-strain relationship must be represented by matrix equations with a 6×6 array of elastic terms and a 3×6 array of electromechanical coupling terms. The electric field relations are a 3×3 array. Fortunately many of the off-diagonal terms of these arrays are zero and some useful configurations allow a one-dimensional representation.

For illustration, a thin plate used as a low-frequency pressure sensor is shown in Fig. 2. The pressure produces a force on the 3 surface. (The 3 direction is always defined as the principal direction in which physical properties are least like those in the other principal directions.) The top and bottom 3 surfaces are covered with a thin conducting material so that the electric field in the 3 direction can be sensed. The bottom surface is considered clamped. The equations of state for the piezoelectric plate simplify to the following:

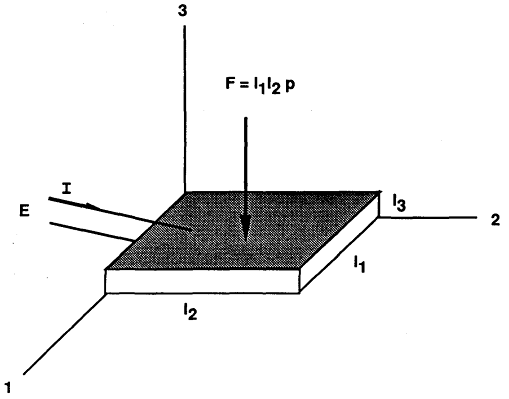

FIG. 2. Example of a piezoelectric pressure sensor. A force in the 3 direction causes the establishment of an electric field in that direction, which varies as the plate thickness changes in response to the pressure.

$$\begin{aligned} D_3&=\epsilon_{33}^{S}E_3+e_{33}S_3,\\ -\sigma_3&=e_{33}E_3-c_{33}^{E}S_3, \end{aligned} \tag{6}$$

where D is the electric flux density, σ is the stress, S is strain, ϵ_{33}^{S} is the clamped permittivity in the 3 direction, c_{33}^{E} is the short-circuit elastic modulus in the 3 direction, and e_{33} is the short-circuit charge density per unit strain or the clamped strain per unit potential gradient, all in the 3 direction. Note that Eq. (6) indicates that there is a linear coupling between mechanical and electrical fields, and that it is described by three matrices of constants: one for purely mechanical coupling, one for purely electrical coupling, and one for electromechanical coupling.

As an example, Fig. 3 shows a standard representation of the constants describing barium titanate ($BaTiO_3$) where dots indicate nonzero values for material constants and lines connect elements with equal values. Note that barium titanate has two useful piezoelectric couplings: the 3–3 or thickness mode, and the 1–5 and 2–4 or shear modes. In addition, through the presence of the e_{13} and e_{23}, Fig. 3 shows that the thickness piezoelectric mode is coupled to piezoelectric behavior (of a smaller magnitude) in the other principal directions.

When the mass of the plate $m_c = \rho l_1 l_2 l_3$ is included the two-port terminal equations become

$$I = Y_e V + \alpha U,$$

$$-F = \alpha V - Z_m U, \tag{7}$$

where I is the current, U is the velocity of one electrode relative to the other, F is the force in the 3 direction at the surface of the piezoelectric, Y_e is the electrical admittance $(j\omega \times \epsilon_{33}^{s} l_1 l_2 l_3)$, Z_m is the mechanical impedance $(j\omega m/3 + l_1 l_2 / j\omega_{33}^{e} l_3)$, and $\alpha = e_{33} l_1 l_2 / l_3$. The open-circuit potential then becomes

$$V = \frac{l_3}{e_{33}(\epsilon_{33}^{s} l_1^2 l_2^2 / \alpha^2 l_3^2 c_{33}^{E} + 1)} p \tag{8}$$

for low frequencies. Thus the output potential is linearly related to pressure.

1.1.2 Inductive. There are also two general classes of inductive acoustic transducers: those which are quadratic and those which are linear. Both are described below.

1.1.2.1 Quadratic Types. In quadratic inductive transducers the electromechanical coupling is produced by a change in the energy stored in a magnetic field. These devices are the duals of the capacitive instruments based on changes in the energy stored in an electric field.

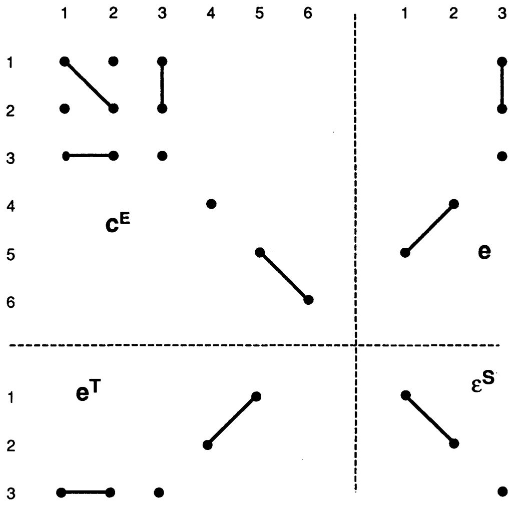

FIG. 3. Graphical representation of the physical parameters of barium titanate, a common piezoelectric material.

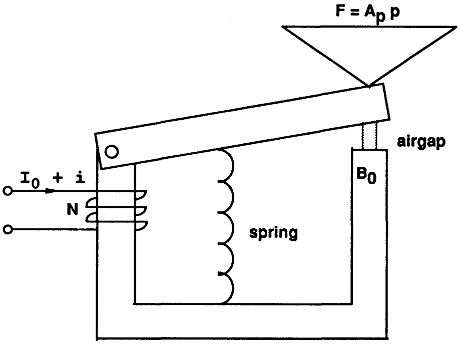

FIG. 4. Typical quadratic inductive sensor using a changing air gap thickness to generate an output signal.

Figure 4 shows a typical example of a quadratic inductive acoustic sensor. An acoustic pressure acts on a piston to change the length of the air gap in a magnetic circuit made up of material whose permeability μ is very much larger than that of air, μ_0. The air gap dimensional change is given by

$$\xi = p A_p C_m, \tag{9}$$

where A_p is the piston area and C_m is the mechanical compliance of the restoring spring.

The instantaneous energy stored in the magnetic field is

$$W = \frac{\lambda_0^2}{2L} = \frac{\lambda_0^2 (d + \xi)}{2N^2 \mu A}, \tag{10}$$

where λ_0 is the flux linkage of the device which is assumed to be constant, L is the inductance, d is the static air gap length, N is the number of turns of the solenoid, and A is the cross-sectional area of the gap. The force on the piston is given by

$$F = \frac{\partial W}{\partial \xi} = \frac{\lambda_0^2}{2N^2 \mu A} \tag{11}$$

and the current is given by

$$I = \frac{\partial W}{\partial \lambda_0} = \frac{\lambda_0 (d + \xi)}{N^2 \mu A}. \tag{12}$$

We note that the force is quadratic in λ_0 and thus depends quadratically on the magnetic field strength. In Eq. (12) we identify the time varying portion of the current as i, and find using Eq. (9) that

$$i=\frac{\lambda_0 A_p C_m}{N^2\mu A}p. \tag{13}$$

Thus a linear relationship results.

Another quadratic phenomenon is illustrated in Fig. 5. An acoustic pressure produces a force on the end of a bar of magnetostrictive material in which the permeability μ changes with density. With a polarizing current I_0 a magnetic flux is produced in the rod. The force on the end of the rod is found from Eq. (10) by recognizing that μ is now a function of ξ, and then transforming from displacement to density using conservation of mass. The result is

$$F=\frac{\lambda_0^2\rho}{2N^2\mu^2A}\frac{\partial\mu}{\partial\rho}. \tag{14}$$

The time varying portion of the current may be similarly found using Eq. (9):

$$i=-\rho\frac{\partial\mu}{\partial\rho}\frac{\lambda_0}{\mu^2}\frac{A_pC_m}{N^2A}p. \tag{15}$$

Again a linear pressure sensor is produced.

1.1.2.2 Linear Types. In linear types of inductive acoustic transducers the electromechanical coupling is produced by the interactions of magnetic fields. When a conductor of length l is placed in a magnetic field B the following coupling relations hold: There is a force on the conductor of $\mathbf{F}=(\mathbf{I}\times\mathbf{B})l$; if the conductor moves, a potential $\mathbf{V}=(\mathbf{U}\times\mathbf{B})l$ results.

When a constant flux density B_0 is used and the current, motion, and B_0 are placed orthogonal to maximize the cross products, the result is as follows:

clamped force, $F_c=B_0lI$, (16a)

open-circuit potential, $V_{oc}=B_0lU$. (16b)

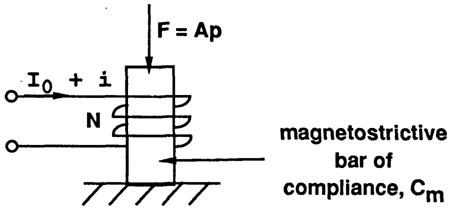

FIG. 5. Example of a magnetostrictive transducer. A force on the end of the magnetostrictive bar causes a change in the bar magnet's permeability and produces a time varying output current.

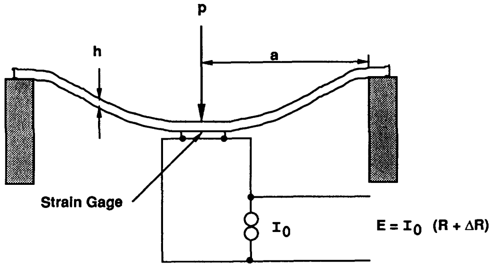

FIG. 6. Example of a resistive acoustic sensor. In this device the pressure strains a membrane which incorporates a strain gage. Hence the pressure causes a change in resistance which is typically monitored as a current change.

If a force is applied to this conductor through a piston exposed to an acoustic pressure, the mechanical parts being retained by a spring and the conductor terminated in an electrical resistance, the following two-port equations result:

$$-V=-IR=Z_eI-B_0lU,$$

$$F=pA_p=B_0lI+Z_mU. \tag{17}$$

Here Z_e is the electrical impedance of the conductor in the magnetic field and Z_m is the mechanical impedance of the moving mechanical structure. Note that these equations imply that there are linear relations between all four port variables: F, U, I, and V. The potential at the electrical terminals is

$$V=\frac{B_0lRA_p}{Z_e\,Z_m+(B_0l)^2+Z_mR}p. \tag{18}$$

Thus a linear pressure sensor results.

1.1.3 Resistive. Resistive acoustic sensors transform pressure to strain in a diaphragm or thin beam. The strain then acts on some material that changes resistance with strain causing a change in either a current or a potential. There are two mechanisms of resistance change which result from imposition of a strain on a material: an increase in resistance due to elongation of the material, and a piezoresistive effect in which the strain affects the crystal lattice of a material and alters its resistivity. The relative magnitude of the piezoresistive effect (compared to the dimensional effect), and its sign, are highly dependent upon the material.

In Fig. 6 acoustic pressure acts on a clamped-edge circular plate to deform it and produce a strain on the surface. That strain on the surface at the center is

$$S=\frac{a^2h/2}{16D_{\text{mod}}}\,p, \tag{19}$$

where D_{mod} is the bending modulus [$D_{\text{mod}}=Y_{\text{mod}}h^3/12(1-\nu^2)$ where Y_{mod} is Young's modulus, h the plate thickness, and ν Poisson's ratio].

The strain gage produces a change of resistance $\Delta R/R=KS$, where K is defined as the gage factor. Hence

$$\Delta R/R=\frac{Ka^2h/2}{16D}\,p. \tag{20}$$

Through a constant-current source a change in potential is linearly related to the pressure. For metals, the dimensional resistance change mechanism dominates and the gage factor is about 1.6. For silicon, the piezoresistive mechanism is dominant and the gage factor varies from 100 to 200.

1.2 Intensity Measurement

Over the last decade there has been increasing emphasis on measurement of intensity rather than sound pressure. There are two primary reasons for this shift in measurement approach: sound intensity measurement permits location of acoustic sources in a volume because intensity is a vector quantity, and intensity measurements can be made in the near field, eliminating the need for specialized testing chambers. As a result there are now intensity measuring devices commercially available. For further information on intensity measurements in acoustics see Schultz *et al.* (1975).

Most of the intensity measuring instruments currently on the market use a two-microphone technique to determine the intensity. The acoustic pressure is determined directly from microphones (or hydrophones). The particle velocity along the line on which the two microphones are located is found by differencing the two microphone signals. The linear inviscid force equation generally used for small-amplitude acoustic processes relates the particle acceleration to this pressure difference:

$$\frac{\partial U}{\partial t}=-\frac{1}{\rho}\frac{\partial p}{\partial t}. \tag{21}$$

The use of two-microphone intensity measurements is limited at the low-frequency end by the need to have the phase change in the signal exceed the sensor-pair phase mismatch. The typical phase mismatch in conventional intensity measuring microphones is ±0.005 rad. In order to have an error of less than 1 dB the signal phase must exceed this mismatch by at least a factor of 5. This defines a minimum separation between the two transducers which scales inversely with frequency. At 20 Hz the minimum separation is 6.8×10^{-2} m.

At the high-frequency end intensity measurements are limited by the need for the wavelength to exceed the separation between the microphones. The maximum separation distance at 10 kHz for a 1-dB error is about 6×10^{-3} m. If conventional microphones (1.25×10^{-2}-m diameter) are placed closer than about 5×10^{-3} m, then diffraction of the sound field by the microphones becomes a problem. Hence the upper limit for intensity measurements using conventional microphones is about 10 kHz. One can go to higher frequencies using smaller microphones or microphones with small-aperture probe tubes.

In addition to the conventional two-microphone intensity measuring instruments there are efforts under way to build surface-intensity and energy-density measuring instruments. Surface-intensity acoustical instruments determine the acoustic intensity in a liquid or gaseous medium which is attributable to a vibrating structure in the medium. They typically use a single microphone (or hydrophone) and a single accelerometer attached to a vibrating body, although attempts have been made to use noncontacting displacement measuring devices instead of accelerometers. Energy-density measuring devices are similar to conventional acoustic intensity measuring instruments but use four microphones to find the acoustic pressure and the particle velocity in three orthogonal directions simultaneously.

1.3 Directivity

Most real acoustical instruments exhibit spatially nonuniform response characteristics. For sound generators the nonuniformity is comprised of two parts: range dependence and angular dependence. For sound detectors

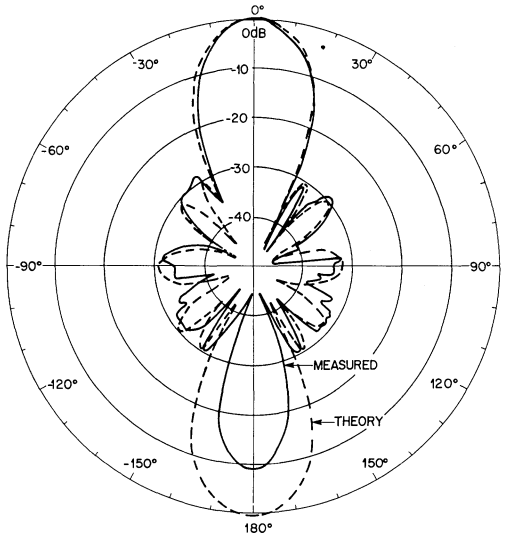

FIG. 7. Directivity of a typical linear microphone array: DF = 16 and DI = 12 dB.

it is the angular dependence alone which is significant. Since the range dependence of generators is determined by the medium, rather than the instrument, we concentrate here on angular variations.

The most commonly used measures of angular variation of acoustical transducers are the beam width, directivity factor, and directivity index. The beam width is typically experimentally determined and is the angular range embracing the peak over which the response is within a specified amount (usually a factor of 0.5) of the peak value. Here the term "response" refers to a quantity, such as sound intensity or mean squared pressure, which is proportional to energy or power. For example, for the transducer array whose angular response is shown in Fig. 7, the beam width is 16°.The directivity factor (DF) is the ratio of the peak response at radius r to the response averaged over a sphere of radius r. The directivity index is a logarithmic measure of the directivity factor: $\mathrm{DI}=10 \log_{10} (\mathrm{DF})$. For the response pattern shown in Fig. 7, DF = 16 and DI = 12 dB.

There are two general causes of directive response: the geometry of individual transducers and the result of summing multiple transducers in arrays. First consider the behavior of a single acoustical transducer. If the transducer is large compared to the wavelength of the sound it is not well approximated by a point receiver or radiator in space and it will generally exhibit directive response. The precise form of the directivity depends upon the exact geometry of the transducer. For example, many directional tranducers expose the energy-converting material on both the front and back faces. The result is an instrument which either responds to pressure differences or radiates out-of-phase sound pressures which add in the medium. Such transducers exhibit a far-field directivity factor which is generally described by

$$\mathrm{DF}(\theta)=\frac{1+\beta\cos\theta}{1+\beta}, \tag{22}$$

where β is defined by

$$\beta=\Delta l/CR\,. \tag{23}$$

Here Δl is the distance between the front and rear sound ports, C is the compliance of the system which is generally determined by the air in a cavity behind the transducing material, and R is the excess acoustic resistance of the rear sound port compared to the front port.

For conventional pressure elements, there is no rear port and so $\beta=0$ and DF = 1, i.e., they are nondirectional. For first-order gradient elements, there is negligible resistance in the rear port, so β is very large and $\mathrm{DF}(\theta)=\cos(\theta)$. Cardioid elements combine pressure and first-order gradient behavior by designing the rear sound port, to have $\beta=1$, in which case $\mathrm{DF}(\theta)=[1+\cos(\theta)]/2$. The three directivity patterns produced by these elements are shown in Fig. 8. Note that these patterns have broad main lobes with no side lobes, and are not frequency dependent.

Another example of this class of directive transducer is a small transducer surrounded by a parabolic reflector. This produces unidirectional sound radiation or reception if the transducer is located at the focus. For further information on directive acoustical transducers see Rossi (1988) and Beranek (1954,1986).

Now consider the effect of summing the output signals from transducers in arrays. For a sensor array with length large compared to a wavelength, there will be a wide variation in the phases and possibly the amplitudes of sound observed by each element due to path differences to the source. For such a sensor array one can write the response O (either a voltage or a current) as

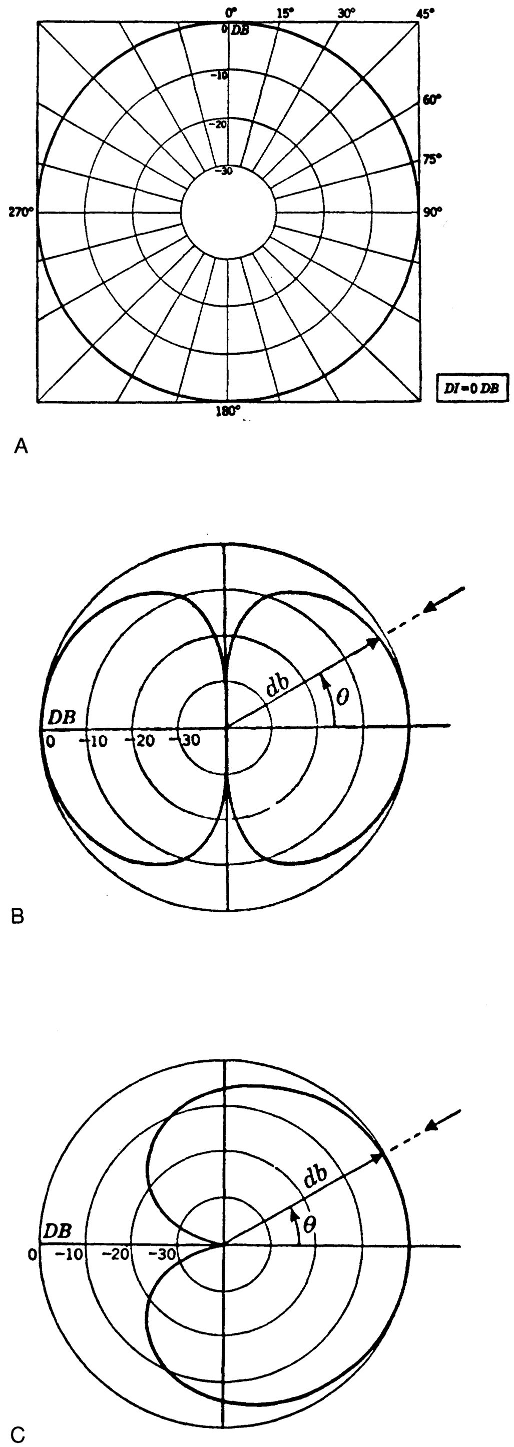

FIG. 8. Directivity patterns of typical microphones: (a) omnidirectional element; (b) first-order gradient element; and (c) cardioid element [from Beranek (1986)].

$$O = \sum \frac{a_i p}{r_i} \exp(jkr_i), \tag{24}$$

where a_i is the complex amplification gain associated with element i, p is the pressure amplitude of the source at a unit distance, r_i is the distance from the source to element i, and k is the wave number of the sound. Note that since k is proportional to frequency, the response is frequency dependent. If the sound source is in the far field of the transducer array, then the phase changes dominate over the amplitude variations and the response can be approximated by

$$O = \frac{p}{r} \sum a_i \exp(jkr_i). \tag{25}$$

For example, consider a line array of n omnidirectional sensors as shown in Fig. 9. Assuming the source to be in the far field, the response goes as

$$O = \frac{p}{r} \sum a_i \exp(jkx_i \sin\theta), \tag{26}$$

where x_i is the distance to element i from the array center, and θ is the angle between the normal to the array center and the source. If the amplifier gains and element spacing are uniform, Fig. 10 shows the resulting directivity pattern at a number of frequencies. Note that there is a main lobe whose beam width decreases with increasing frequency, and a number of side lobes. If the amplifier gains are not uniform, the directivity pattern is modified. For example, by introducing phase delays, one can steer the main beam away from the broadside ($\theta = 0$ rad) angle. Further, using various amplitude shadings one may narrow or widen the beam width, and raise or lower the side lobes. The commonly used array shadings are discussed in virtually all texts on antennas and filters.

For a radiating array a similar argument holds: even driving the elements in phase results in out-of-phase contributions at a point in the medium off the normal to the array. For example, consider a broadside source array which consists of a number of identical sources spaced uniformly in a line. The far-field array response is as shown in Fig. 10. By varying the amplifier gains for each element, the amplifier phase for each element, or the spacing between elements one may dramatically affect the directive response. This is a

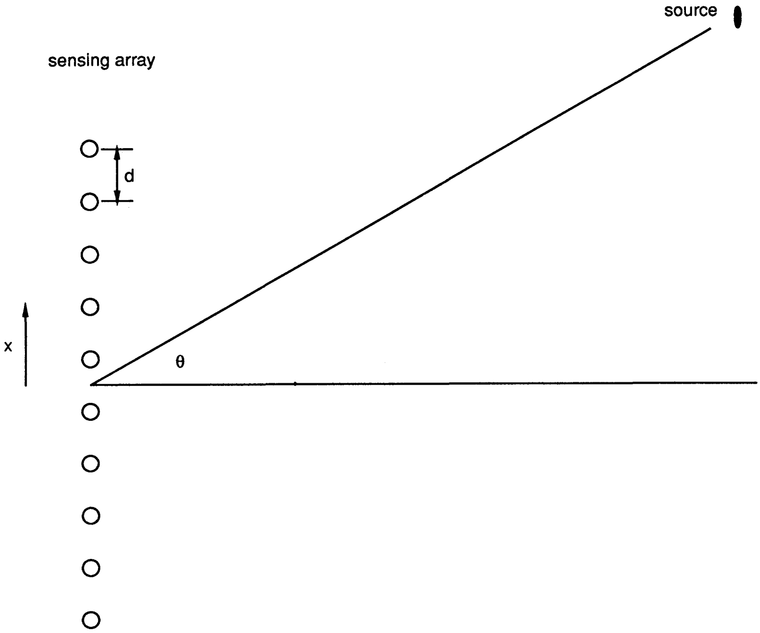

FIG. 9. Geometry of a typical linear array of transducers. In this array, spacing between elements is fixed at *d*.

routine practice in underwater sound sources and leads to beam forming, in which one chooses to emit sound in a specified direction.

Using these same principles one may build two- and three-dimensional arrays of various sorts. Typically, the directive response for arrays is frequency dependent, and includes side lobes as well as a main lobe. For more information on arrays, see Beranek (1954, 1986).

It should be noted that it is possible to build acoustical transducer arrays in which the elements are themselves directional. In this case, the product theorem guarantees that the directivity factor of the array is the product of the directivity of the elements and that of the array geometry.

1.4 Radiation Efficiency

It is important to characterize the ability of acoustical sources to couple vibratory motion of a transducing element with the surrounding medium in order to radiate sound. One means of describing the efficiency of this coupling is the radiation efficiency σ_{rad}, defined as the ratio of the acoustic power radiated by a source to that radiated at high frequencies by a baffled uniform circular piston source of the same size and mean squared velocity.

In general, the radiation efficiency of a vibrating object is less than 1 for low frequencies, and rises monotonically as frequency is increased to a value of 1 at frequencies for which the object is large compared to a wavelength. At low frequencies the energy imparted to the medium is stored in masslike or springlike behavior rather than being converted into acoustical waves. The above results are essentially independent of the shape of the vibrating object and the material of which the surrounding medium is comprised. This suggests that acoustical generators must be made large compared to the wavelengths of interest in the surrounding medium, or else their efficiency of radiation will be low.

2. FUNCTION AND OPERATION

Below we describe the practical operation of a number of acoustical transducers of various types.

2.1 Condenser Microphones

The condenser microphone shown in Fig. 11 uses a stretched membrane to convert acoustic pressure to displacement and as one plate of a capacitor. As was shown in Sec.

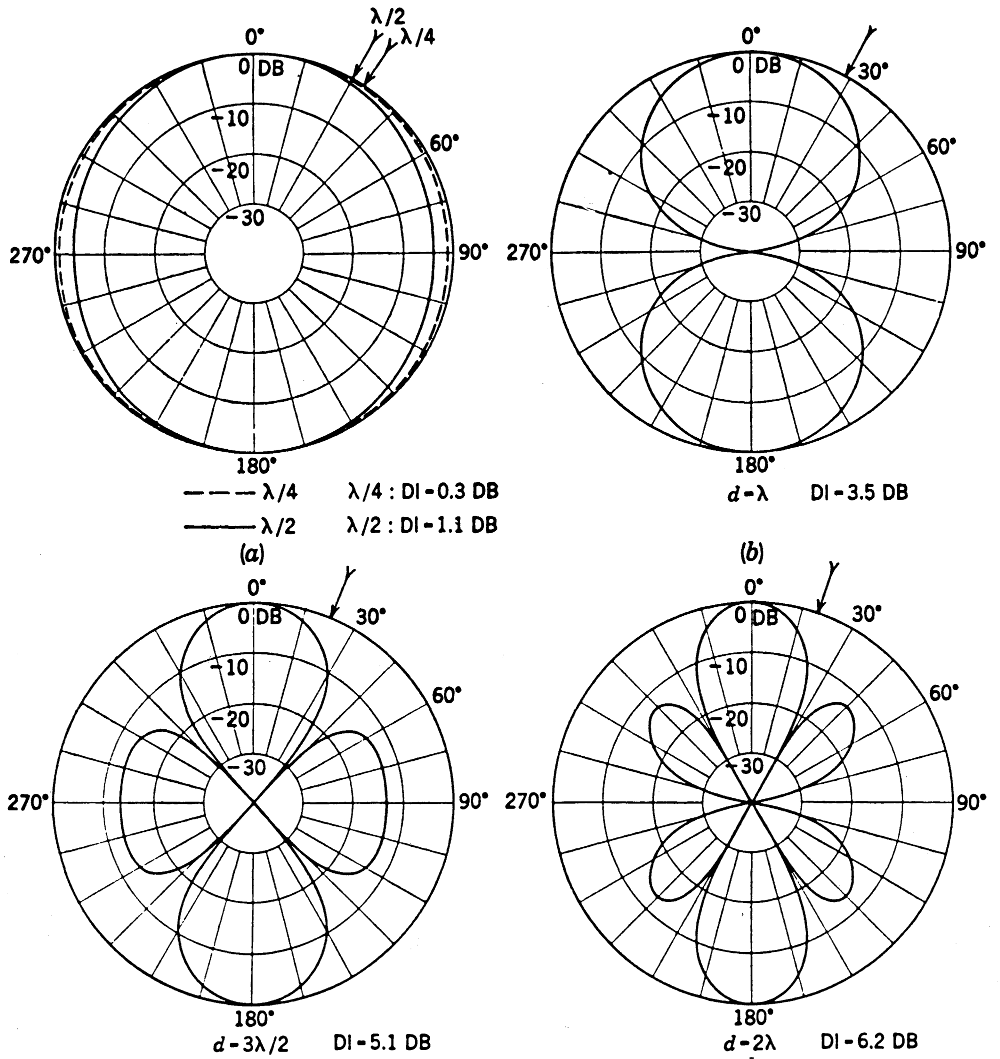

FIG. 10. Far-field directivity of the linear array shown in Fig. 9 as a function of frequency, from low frequency (a) to high frequency (d) [from Beranek (1986)].

1.1.1.1, the application of a static charge allows the pressure-induced change in capacitance to produce a potential proportional to pressure.

The static charge may be supplied by using a plastic membrane with embedded charge and a metallized outer surface. This arrangement is usually referred to as an electret microphone. Here tension and polarizing charge are reduced over those for the metal membrane but sensitivities can be large. Another alternative to the conventional condenser microphone shown in Fig. 11 is one in which the membrane tension is quite small. Under this condition the stiffness of the membrane is dominated by the stiffness of the surrounding air, which primarily depends on the air cavity depth and volume.

Because condenser microphones have a capacitive internal impedance, static or very low-frequency pressures are impractical to measure. This is because potential-sensing instruments have a finite input resistance. In general, the lower frequency limit is given by

$$f_1 = 1/2\pi R_{\mathrm{in}} C_0, \tag{27}$$

where R_{in} is the instrument input resistance. This low-frequency limit is averted by using

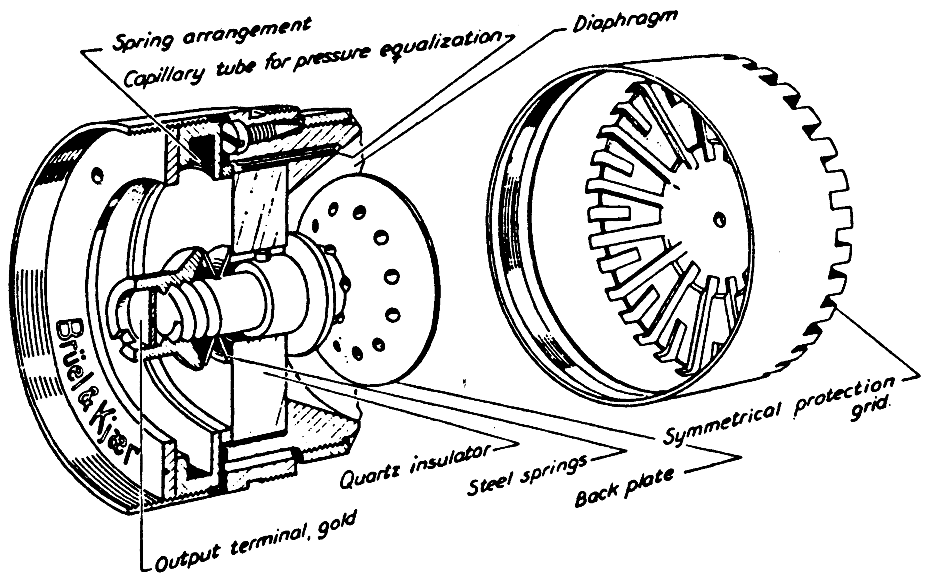

FIG. 11. Typical condenser microphone. Active element is a stretched diaphragm which is placed in proximity to a perforated backplate.

an ac polarization potential. When C_0 is made part of a parallel L-C circuit that determines the frequency of an oscillator, the change in C with acoustic pressure causes an oscillation frequency change which can be monitored using a frequency detector. The change with membrane displacement is

$$\Delta f = \frac{f_0}{2d}\xi, \tag{28}$$

where $f_0 = 1/(2\pi\sqrt{LC_0})$. Condenser microphones have been built to monitor sound at frequencies of fractions of 1 Hz using this method. However, it should be noted that in order to obtain a flat response to such low frequencies it is generally necessary to eliminate the rear pressure equalization port from the transducer because it is acoustically transparent at very low frequencies and makes the condenser microphone respond as a gradient microphone in this frequency regime. Note that even in the ac polarization case there is a static collapsing force on the membrane because the mean square polarizing potential is not zero.

The upper frequency limit of a condenser microphone is the lowest membrane resonant frequency and is determined by the tension and mass of the membrane. For a circular membrane the lowest resonance is given by

$$f_1 = \frac{1.20}{\pi a}\sqrt{T/\rho_s}, \tag{29}$$

where ρ_s is the surface density of the membrane (mass per unit area). The response at f_1 is controlled by acoustic resistance behind the membrane. Precision condenser microphones with flat response up to about 150 kHz are readily available.

When a microphone is used to measure a traveling wave (free field), diffraction affects the high-frequency response. When the diameter of the membrane is approximately equal to the acoustic wavelength, sound arriving at normal incidence experiences a pressure doubling at the membrane causing a 6-dB error. At grazing incidence, pressure averaging across the face can reduce sensitivity. By controlling the acoustic resistance the normal incidence response can be corrected; however, directivity still remains. For use in a diffuse sound field with waves arriving from random directions, a different compensation is used to account for directivity. Microphones can be compensated to yield a flat frequency response to free field, random incidence, and uniform pressure.

A condenser microphone made with a stainless-steel membrane and other metal parts is the most stable with temperature and other environmental changes. It holds its calibration for long periods of time and may be used as a secondary standard.

2.2 Piezoelectric and Ceramic Transducers for Liquids

2.2.1 Hydrophones. Devices for the measurement of acoustic pressure in liquids usually use solid sensors such as piezoelectric crystals or polarized ceramics. Often, as shown in Fig. 12, stacks of transducing material are used in order to enhance the overall transducer sensitivity. When the pressure is applied to one face, such as in Fig. 2, the potential is proportional to pressure as in Eq. (8). Because of the capacitive internal impedance, response down to dc is not practical without the use of an oscillator circuit as in condenser microphones. Since the ceramic is stiffness controlled, the frequency response is flat up to the first longitudinal resonance which is determined by the speed of sound in the material and its thickness. Piezoelectric and ceramic hydrophones for use in monitoring sound in the range of 20 Hz to 300 kHz are commonly available.

FIG. 12. Typical piezoelectric hydrophone. Active transduction elements are the stacks of piezoelectric crystals [from Bobber (1988)].

In piezoelectric and ceramic hydrophones the maximum sensitivity would be obtained if one face were exposed to the pressure and the opposite face were clamped. However, because of the high mass and stiffness of the transducing materials, this cannot be done effectively. A compliant backing is usually used to give free conditions. Such a backing is shown in the commercial hydrophone in Fig. 12.

Ceramic elements can be exposed to acoustic pressure on all sides to give omnidirectional response if the device is small compared to the acoustic wavelength. The response then is proportional to the sum of the direct and transverse piezoelectric coupling terms $e_{33}+e_{13}$. The term e_{13} is negative but smaller than e_{33} so a net response results with a lower sensitivity than the single-sided case.

Ceramic materials also can be formed into cylinders and spheres to provide nearly omnidirectional pressure sensors (Wilson, 1985). Here the geometry offers a natural shielding of the back side of the sensing surface (interior electrode) from the acoustic pressure.

In addition to rigid ceramics and piezoelectrics, piezoelectric plastic film such as polyvinylidene fluoride (PVDF) can be used in pressure sensors. These polymers offer the advantage of flexibility but are usually inappropriate for sound sources since their piezoelectric constants are roughly an order of magnitude lower than those of conventional rigid piezoelectric ceramics.

2.2.2 Sound Sources. The crystals and polarized ceramics discussed above are reciprocal and can be used as sources of sound pressure. Because these solids are stiff compared to liquids, coupling to the liquid is usually poor. Below the first resonance, the devices are stiffness controlled which gives a sharply rising frequency response. For example, Fig. 13 shows the transmitting and receiving sensitivity of a ceramic underwater transducer. Thus, use of a piezoelectric and ceramic transducer is restricted to operation at resonant modes resulting in narrow-band operation.

Polarized ceramic can be driven with high potentials to produce large acoustic intensity at resonant modes. However, there are three factors which limit the usefulness of polarized ceramics for high-intensity projectors. First, the square-law nature of the source mechanism produces harmonics. This can be seen from Eq. (2) by recognizing that for high-amplitude driving the charge is no longer well approximated by the static polarization charge alone. Replacing Q_0 by Q_0+q in Eq. (4) yields a second-order term in the electric potential of $q\xi/\epsilon A$ which produces second-harmonic distortion and a change to the dc bias. Second, heating changes the material parameters of ceramics substantially. Third, poor material tensile strength can result in fracture of ceramics. For example, PZT-4, a common ceramic used in underwater transducer applications, can withstand a maximum stress of roughly 24 MPa. This corresponds to a maximum strain of about 10^{-3}.

For further information on hydrophones and underwater sound sources see Bobber (1988) and Wilson (1985).

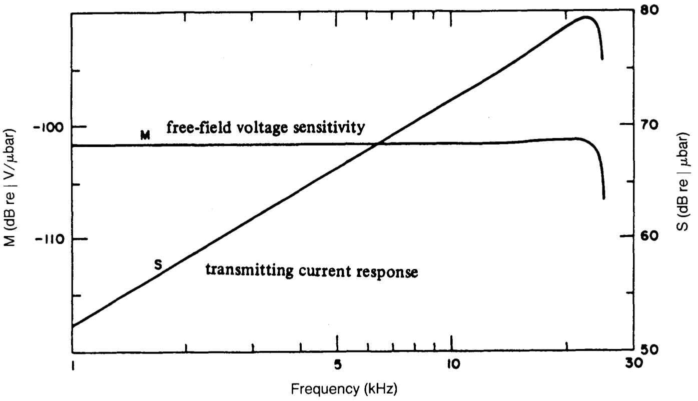

FIG. 13. Typical transmitting and receiving sensitivities of a piezoelectric underwater transducer as a function of frequency [from Bobber (1988)].

2.3 Loudspeakers

Sound pressure in gases can be generated by a vibrating piston. The piston size should be comparable to the acoustic wavelength for good coupling and the required motion is large because of the low acoustic impedance of gases.

In theory, the piston can be a thin membrane under tension and driven electrostatically. Examination of Eqs. (3) and (4) shows that the force then is quadratically related to the potential by

$$F=\frac{\epsilon A}{2(d+\xi)^2}V^2\sim\frac{\epsilon A}{2d^2}V^2, \qquad (30)$$

and a large polarizing charge is required for linearity. However, this produces a large dc electrostatic attraction force which tends to destabilize the system by causing the membrane to collapse onto the electrode. Hence large motions are difficult to obtain and electrostatic loudspeakers are rare.

Most loudspeakers use a light-weight piston which is driven to large motions electromagnetically. Such a loudspeaker is pictured in Fig. 14. Paperlike material in the form of a cone provides a light-weight stiff piston. The cone is usually supported by corrugated springs and driven at the apex. Current in a coil in a fixed magnetic field provides the driving force as in Eq. (16a). At frequencies below the resonances of the springs and cone-driver mass the motion is large causing significant distortion. Operation therefore is usually in the mass-controlled region and a relatively constant frequency response is obtained. The upper frequency limit usually is set by the first radial resonance in the cone material. Typical loudspeakers operate in the audio frequency range, from roughly 20 Hz to 20 kHz.

Operation at and below the suspension system resonance is possible if damping is added to limit the cone motion. If an aluminum coil form is used to hold the wire in the magnetic field, motion will produce eddy currents in the coil form. The mechanical resistance is then given by $R_m = B_0/R_c$ where R_c is the electrical resistance around the coil form. Additional electrical resistance in the electrical circuit can add mechanical damping.

In general the loudspeaker cone is mounted in an open frame. Thus the piston produces a pressure at the back which is π rad out of phase from that at the front. The effect is a negative source placed about a piston diameter behind a positive source. This dipole effect produces a frequency response which falls off at low frequencies:

$$p\sim(2\pi f)^2 I \qquad (31)$$

for frequencies where the piston is small compared to an acoustic wavelength. To eliminate this effect it is necessary to put the loudspeaker in a box or baffle so that the back side does not radiate. The box may be designed so that the acoustic impedance presented at the back of the cone can improve the low-frequency response of the loudspeaker system.

Small pistons driven electromagnetically often are placed at the throats of horns to improve the loudspeaker directivity. Special horn shapes provide frequency-independent directivity characterisitcs. The horns also serve to provide better matching between the piston and the air, resulting in improved efficiency. However, large piston excursions and high intensities in the throat lead to nonlinearities. The use of horns below 500 Hz is usually not practical.

2.4 Geophones

In geophysical exploration using seismic waves, it is desirable to measure motion of the ground resulting from a distant excitation. Because of frequency-dependent attenuation in the medium only waves below 1 kHz are useful. The surface motion can be determined by acceleration, velocity, or displacement sensors, but acceleration sensors exhibit poor low-frequency response and displacement sensors require a fixed displacement reference. Due to the frequency range and rigors of field operations, velocity sensors called geophones are used.

The geophone, an example of which is shown in Fig. 15, uses a compliantly supported seismic mass and the electromagnetic effect of Eq. (16b) to measure the relative velocity of the earth's surface with respect to the mass. As in the loudspeaker a coil of wire is placed in a constant magnetic field. This coil is attached to the structure that moves with the earth's surface. A permanent magnet and magnetic circuit conveniently provide the seismic mass. When the mass is stationary the output potential is directly proportional to the ground velocity.

Since the mass must be supported by springs essentially attached to the ground, a spring-mass resonator results. At and below the resonant frequency the mass motion is not zero. Thus the resonant frequency must be well below the frequency of interest. The resonant peak in the response can be controlled with eddy current and mechanical damping.

The upper frequency response limit is determined by the inductance of the wire in the sensing coil and the resistance in the coil and external measuring circuit:

$$f_h = R_t / 2\pi L, \tag{32}$$

where L is the inductance and R_t is the total circuit resistance. Typical geophones operate with relatively flat frequency response from a few Hz to 1 kHz.

Geophones can be made very rugged, and because of a low internal impedance, long cables can be used without on-board amplifiers.

2.5 Calibration

There are generally three calibration methods used in acoustic instrumentation: comparison calibration, absolute direct calibration, and absolute reciprocal calibration. In comparison methods the transducer to be calibrated is compared to a similar transducer of known characteristics. This method is fast and eliminates the need for specialized equipment, but is the least precise of the techniques because errors in the calibration of the known source propagate.

In absolute direct calibration a specialized piece of equipment is used to provide a known calibration signal, which must be nearly independent of the load seen by the calibrator. A common acoustical example of this type of technique is the use of pistonphones for calibration of microphones. Pistonphones use reciprocating pistons to change the volume of a calibrated cavity in order to generate a well-known sound level. The advantage of absolute direct calibration methods are that they generally are fast and very precise. However, since they require the purchase of dedicated instrumentation, they tend to be expensive. Further, in order to obtain the desired precision, they generally offer absolute calibration at a very limited number of frequencies. For example, most pistonphones operate at a single frequency only. Complete calibration of a transducer then requires the use of the comparison method as well as absolute direct calibration.

The third calibration procedure which is commonly used for acoustical instrumentation, and which was historically developed for microphone calibration, is absolute reciprocal calibration. It is this method which separates the calibration of acoustical instrumentation from calibration methods common to other fields. Reciprocal calibration requires three transducers: one to be calibrated, one which is reciprocal (meaning it can operate either as a sensor or as an actuator), and one additional transducer which is complementary to the transducer to be calibrated (i.e., an actuator if a sensor is being calibrated and a sensor if an actuator is being calibrated). It is not necessary that any of the transducers have known calibration characteristics.

Although there are now many reciprocal calibration methods, all require a minimum of three measurements. For example, the following is a method for reciprocal calibration of a microphone or hydrophone. First, reciprocal transducer B is placed a distance l from source C. A current i_C is run through C and the open-circuit potential of B, v_B, is monitored. Next, transducer B is replaced by the transducer whose calibration we desire, transducer A, and the measurement is repeated yielding v_A. Finally, sound source C is replaced by B, a current i_B is run through it, and v'_A, the new open-circuit voltage from A is found. Defining φ, the sensitivity of A, as the ratio of the open-circuit voltage to the sound pressure, the measurement procedure yields

$$\varphi^2 = \frac{v_A v'_A}{v_B i_B} \frac{2l\lambda}{\rho_0 c_0}, \tag{33}$$

where λ is the wavelength of the sound, and ρ_0 is the mass density of the medium.

The advantages of reciprocal calibration compared to direct absolute and comparison calibration are that it is very accurate, can be applied at many frequencies, and requires only electrical and length calibration equipment. The major disadvantage is that it is more tedious than the other calibration methods. For more information on reciprocity calibration see Beranek (1954, 1986).

3. NEW TECHNOLOGIES

Over the past 15 years there have been rapid advances in acoustical sensors and actuators. These advances have matched advances in physics in general and can be classed into four areas: fiber optic transducers, solid-state sensors and actuators, new materials, and novel techniques. Below we describe each of these areas in some detail.

3.1 Fiber Optic Transducers

Fiber optic transducers offer many advantages over conventional nonoptical transducers: higher resolution, higher signal-to-noise ratio, immunity to electromagnetic interference, and compatibility with fiber optic communication systems. In addition they are easier to use than most other optical transducers. Hence they are rapidly finding their way into sensors spanning the frequency range from dc to over a MHz.

In acoustical sensors, there has been great interest in the use of fiber optic transducers underwater, where they are good candidates for undersea surveillance and seismic monitoring. They are also in demand for active vibration control of structures and for process control in chemical plants.

All fiber optic sensors have four main portions: a light source, a sensor, a detector, and a demodulator. The light source may be incoherent or coherent. The detector includes circuitry designed to process the optical signals.

Fiber optic sensors are divided into two classes: those in which the light carried in a fiber leaves the fiber, reflects off of a vibrating object, and then returns to the detector via a fiber (extrinsic), and those in which the light never leaves the fiber (intrinsic). Figure 16(a) shows a fiber optic lever, a simple example of an extrinsic fiber optic sensor. The main component of this instrument is a fiber optic probe consisting of multiple fibers, half of which transmit light and half of which carry the light reflected off of the target back to the detector. The detector generates an output voltage proportional to the intensity of the reflected light. No modulation is required. As shown in Fig. 16(b), the output voltage is null when the probe touches the target since the light reflects specularly into the sending fibers rather than the receiving fibers. As the distance between the target and the probe end increases, the output voltage rises rapidly until the entire surface of the probe is illuminated. Increases in separation beyond this distance result in a voltage drop due to square-law reduction in reflected light intensity on the probe surface.

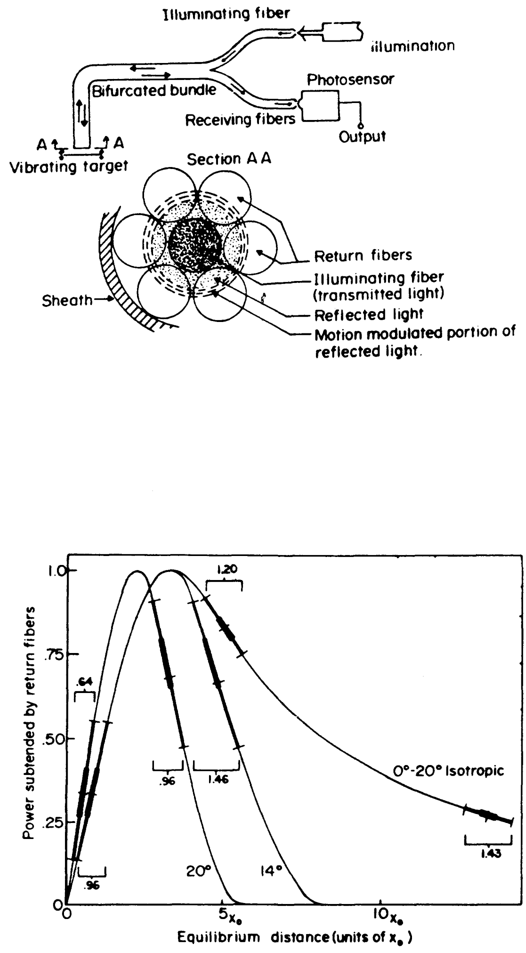

FIG. 16. Fiber optic lever: (a) system operation; (b) view of fiber bundle used in the probe; and (c) reflected power received from a planar target as a function of distance. The three curves are for three different fiber bundle configurations: concentric rings of transmitting and receiving fibers, semicircles of sending and receiving fibers, and random transmitting and receiving fiber orientation.

Intrinsic fiber optic sensors are designed so that the length of a fiber varies with changes in a parameter to be measured. Typically the length variation is determined by comparison to a reference length of fiber. An example of such a sensor is shown in Fig. 17, which illustrates a Mach-Zehnder interferometer. In this sensor a coherent light source is split so that part of the beam travels in a reference fiber and part in a sensing fiber. The reference fiber is wrapped around a piezoelectric crystal which is used as a phase modulator. By applying a potential across the piezoelectric, the reference fiber length is controlled, thus permitting the modulator to establish a bias point and to correct for any initial mismatch in the length of the two fibers. The sensing fiber is exposed to acoustic pressure which produces a strain in the fiber. This causes a change in the refractive index and thus a change in the effective length of the fiber. By recombining the reference and sensor signals and monitoring the phase shift from the original, the sensor fiber length change is very accurately determined.

The fiber optic devices discussed above are also representative of the common modulation schemes. Most fiber optic devices are based on amplitude modulation, as in the optic lever, or phase modulation, as in the

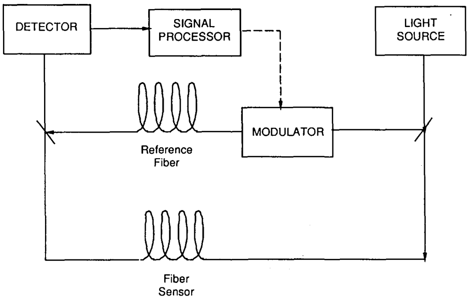

FIG. 17. Schematic of a Mach-Zehnder interferometer.

Mach-Zehnder interferometer. Phase-modulation fiber optic sensors are more sensitive but the signals are more difficult to modulate.

For more information on fiber optic sensors see Winsor (1980), Grant (1988), and Krohn (1988).

3.2 Solid-State Sensors and Actuators

For the past decade there has been substantial work in the area of solid-state sensors, and in the last few years there has been increasing interest in solid-state actuators. Solid-state transducers are generally devices made using the standard materials found in microelectronic devices such as silicon. The advantages of solid-state sensors and actuators are many: there is good fabrication process control, miniaturization is easily achieved, transducers may be integrated with the electronics on a single chip, and costs per item are low. The notable successes in solid-state sensors include devices for the measurement of acoustic pressure.

The construction of solid-state sensors differs substantially from the standard fabrication processes involved in microelectronics. Two items in particular have presented problems: size scales and feature shapes. The sizes of sensor and actuator transducing elements are generally much larger than standard microelectronics features and there have been problems obtaining consistently high yields of large-feature items. Further, most solid-state transducers require nonstandard feature shapes such as cavities. These nonplanar shapes can be difficult to obtain, although selective chemical etches, which follow preferred crystal orientations, have permitted rapid progress overcoming this stumbling block. Another difficulty with solid-state sensors and actuators has been the desire to integrate the processing electronics with the device. Although such an approach offers advantages from the perspective of signal-to-noise ratio, the yields for electronics alone are still substantially higher than those for the transducer alone. Hence, insisting upon integration usually results in loss of a large amount of viable electronics. In addition, many of the fabrication processes for sensors and actuators seem to be fairly incompatible with electronics processing. For further information about the fabrication of solid-state sensors see Petersen *et al.* (1988).

Acoustical solid-state transducers generally have been limited to pressure sensors (for air and water), although attempts to build sound generators have been reported. Solid-state pressure sensors have been designed using a piezoresistive effect, a piezoelectric effect, and the effect of stress on a *p–n* junction. A varying capacitance effect much as described in Eq. (5) is also used. Of these, the varying capacitance and piezoresistive have received the most attention.

In typical capacitive solid-state pressure sensors such as shown in Fig. 18, a moving membrane is coated with metal and a bias voltage is applied between the membrane and a fixed backplate. Devices such as this are miniaturized versions of conventional condenser microphones, except that the stiffness is usually determined by the size of the air cavity rather than the membrane tension. However, the solid-state capacitive transducers may be more sensitive and usually are useful up to much higher frequencies due to the increase in the first resonant frequency which accompanies the miniaturization. Their main disadvantage is a low capacitance of generally 1–3 pF, necessitating close location of processing electronics and causing poorer low-frequency response than their macroscopic counterparts. For further information on capacitive solid-state pressure sensors see Ko (1986).

Piezoresistive solid-state pressure sensors are more numerous than the capacitive type. In these devices, an example of which is shown in Fig. 19, resistors are typically diffused into a membrane and used in a half-bridge or full-bridge form. Membrane motions cause strain and thus result in differential resistances. These devices are easier to fabricate than the capacitive pressure sensors, and thus are less expensive, but are generally more limited in range due to hysteresis and nonlinearities. In addition, the piezoresistive solid-state sensors are susceptible to interference due to stressing of the package since they sense differential stresses.

3.3 New Materials

In recent years there have been great advances in materials which are finding their way into acoustical instruments with great rapidity. These advances are primarily in two areas: polymers and rare-earth magnetostrictive materials.

3.3.1 Polymers. Before the advent of polymer-based transducers, acoustical sensors and actuators used heavy transducer materials. With the discovery that some of these materials could be replaced by light-weight polymers without a drastic change in the transduction principles, new transducers were invented. Until recently, these new materials were not used to their full extent because they were viewed merely as replacements for heavier materials.

The first of these new transducers using polymers were electret acoustic sensors which make use of a permanently polarized polymer film (usually Teflon). Electret transducers operate like conventional condenser (capacitive quadratic) transducers, but the bias is supplied by the polarization rather than an external source. This results in a device which has very low power requirements, low distortion, and high sensitivity. Electret microphones are now the standard microphones found in telephones, hearing aids, and tape recorders. There are well over one hundred million electret microphones sold every year worldwide.

More recently piezoelectric transducers have been investigated in which ceramics and crystals are replaced by piezoelectric polymer films, particularly polyvinylidene fluoride (PVDF). PVDF acoustic transducers include microphones, earphones, hydrophones, and biomedical devices. In addition to conventional piezoelectric acoustical instruments, there have been a few transducer designs which take advantage of the flexibility of the film. For example, Bennett *et al.* (1977) designed a variable-focus hydrophone in which a source is located in a volume by varying the curvature of a PVDF membrane. PVDF sensors generally have higher sensitivity than their ceramic and crystal counterparts and are generally more accurately linear, but PVDF is expensive to fabricate and does not exhibit good temperature stability. New piezoelectric polymers and copolymers offer some of the same advantages of PVDF without the fabrication problems. For a review of PVDF transducers see Sessler (1981).

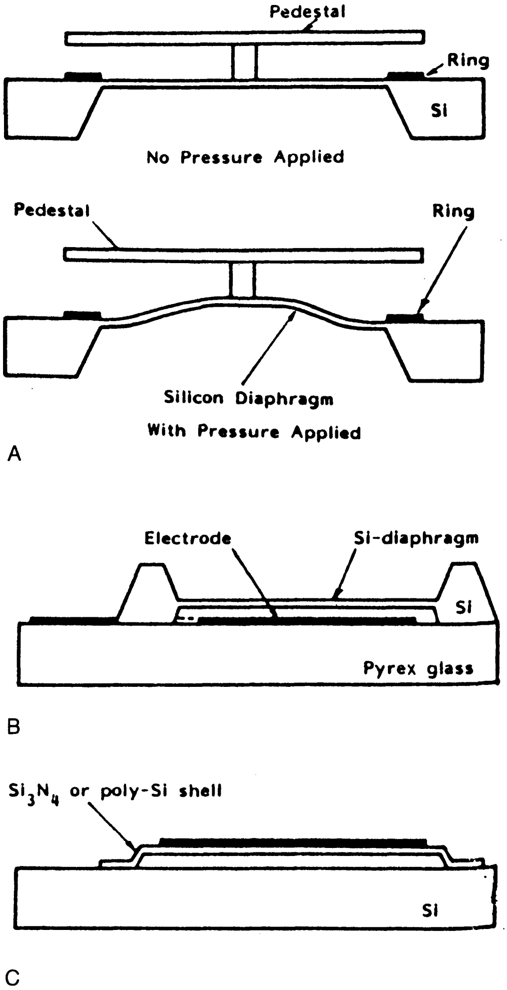

FIG. 18. Three examples of capacitive solid-state pressure sensors: (a) using a pedestal connected to a silicon diaphragm; (b) using a silicon diaphragm over a metallized piece of Pyrex glass; and (c) using a solid-state membrane over a silicon substrate [from Ko (1986)].

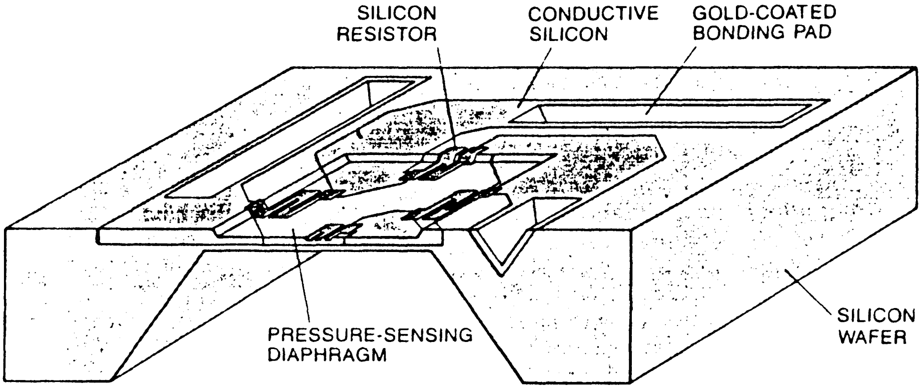

FIG. 19. Piezoresistive solid-state pressure sensor. Pressure strains a solid-state membrane into which strain gages have been diffused [from Angell *et al.* (1983)].

Recent work in polymer composites has also been leading to new acoustical instruments. In particular, work by Newnham (1986) has led to an ability to combine nonactive polymeric materials with transducing materials in a composite. The resulting composite has mechanical properties similar to the polymer, and transduction properties determined by the additive. An interesting example of this technology has been the invention of a material composite using barium titanate (a piezoelectric ceramic) as the additive. As shown in Sec. 1.1.1.2, one of the troubling properties of barium titanate is a relatively strong coupling between strains in the three principal directions; i.e., a forced strain in one direction will result in a strain in the orthogonal directions. By placing the material in a polymer matrix it has been possible to effectively decouple the principal strains while simultaneously raising the material effective piezoelectric constants due to increased flexibility. This material is currently being studied for underwater acoustic applications.

New polymers are being discovered and designed at a breakneck speed. Although many have not yet found a niche in acoustical instrumentation, several offer intriguing possibilities. For example, the magnetic materials used for disk storage and conducting polymers seem to be well suited to transduction.

3.3.2 Magnetostrictive Materials. In the early 1950s the bulk of the work done in acoustical transducers for underwater operation considered magnetostrictive materials (nickel compounds, for example). With the discovery of piezoelectric ceramics the magnetostrictive materials were largely abandoned, as they did not compare favorably in cost or sensitivity. Recent work in rare-earth materials has prompted new interest in magnetostrictive transducers.

The current interest in magnetostriction has focused on a material known as Terfenol-D ($Tb_{0.3}Dy_{0.7}Fe_{1.9}$). This material was developed by Clark (1980) and has just become commercially available. It can safely generate peak strain amplitudes of about 2×10^{-3}, which is roughly a factor of 3 times greater than that of conventional piezoelectric ceramics, and more than an order of magnitude better than nickel. The first attempts to use Terfenol-D in acoustical instruments are just being reported and modest successes are being observed.

3.4 Novel Techniques

In addition to advances in materials, recent years have seen advances in techniques used in acoustical instruments. Among these are laser-generated sound, magnetohydrodynamic transducers, acoustic heat engines and refrigerators, and acoustic microscopy.

Laser-generated sound is the process of using a laser to generate sound in a medium. Most of the work has involved fluid media, although there has been work on laser-generated sound in solids. Several transduction mechanisms have been identified for laser-generated sound in fluids, varying widely in efficiency and directivity. The two mechanisms that have received the greatest attention are the thermal mechanism and surface ablation.

In the thermal mechanism a laser shined into a fluid medium causes the medium to heat and expand. By modulating the laser, the expansion of the medium is modulated, resulting in sound wave propagation. The advantage of this approach to sound generation in a fluid is that no instruments need be located in the fluid medium where they are subject to corrosion. However, the process of sound generation is very inefficient. Attempts to increase the source sensitivity using a moving laser beam have met with moderate success.

In the surface ablation mechanism of laser sound generation the laser is focused onto the surface of a fluid where it induces a localized boiling. This causes a momentum transfer into the medium which radiates away as sound. Although much more efficient than the thermal mechanism of laser sound generation, this blast mechanism is less directive and has proved difficult to control and analyze. Surface ablation using a laser has also been used to create short duration acoustical pulses in solid materials.

Magnetohydrodynamic (MHD) acoustical instruments are transducers which rely on the coupling between magnetic, electric, and velocity fields in a conducting medium. A typical realization of an MHD acoustic transducer is shown in Fig. 20, and uses salt water in a duct. Permanent magnets establish a magnetic field in one direction, and an applied electric field in an orthogonal direction results in a mean velocity of

$$U = V_0 / d\mu H \tag{34}$$

for the medium in the third orthogonal direction which is generally taken to be along the axis of the duct. Here V_0 is the mean electric potential, H is the magnetic field established by the permanent magnets, and d is the diameter of the duct. In addition to the mean fluid flow (which is nonexistent in the absence of a dc bias voltage), there is an oscillating fluid motion which causes acoustic radiation into the medium surrounding the source. Alternatively the MHD transducer may be used as a receiver, in which case the fluid oscillation caused by incoming sound results in the establishment of an electric field. These MHD transducers offer the advantage of broadband operation, but they are less efficient than their piezoelectric counterparts.

Acoustic refrigerators and heat engines based on both MHD and thermally induced sound have been studied. In these devices thermal variations are used to generate sound waves which propagate in a duct. The thermoacoustic sound generating mechanism is analogous to the thermal mechanism for sound generation by a laser discussed above. The sound in the duct is coupled to electrical power through an MHD mechanism. The result is a compact instrument which has high-energy conversion efficiency. For example, Migliori and Swift (1988) have reported on a liquid-sodium acoustic engine in which an imposed temperature difference is used to generate sound; most of the sound energy is recovered in an MHD transduction process.

Acoustic microscopy (see MICROSCOPY, ACOUSTICAL) has been the subject of intense research for about 15 years. In acoustic microscopy a sound wave is reflected off of a submerged target and compared to the incident sound. The sound wave is generated using a piezoelectric crystal or a polarized ceramic, and the returning wave is typically sensed using the same device. The sound beam is focused using a lens such as shown in Fig. 21. This lens consists of a sapphire crystal with a spherical cavity cut into it. The lens moves in a raster pattern to scan the surface of the target. Acoustic microscopes operate at about 3 MHz in water and 8 GHz in mercury. They span over four orders of magnitude of wavelengths, much broader than optical microscopes. They offer about a 200-Å resolution, which is better than that for optical or x-ray microscopes, but inferior to ion or tunneling microscopes. Applications in which acoustic microscopy has been demonstrated to be the method of choice include examining fibers in composite materials, examining features in biological cells nondestructively, and detection of individual grains in polycrystalline samples of anisotropic metals. For further information on acoustic microscopy, see Quate (1985).

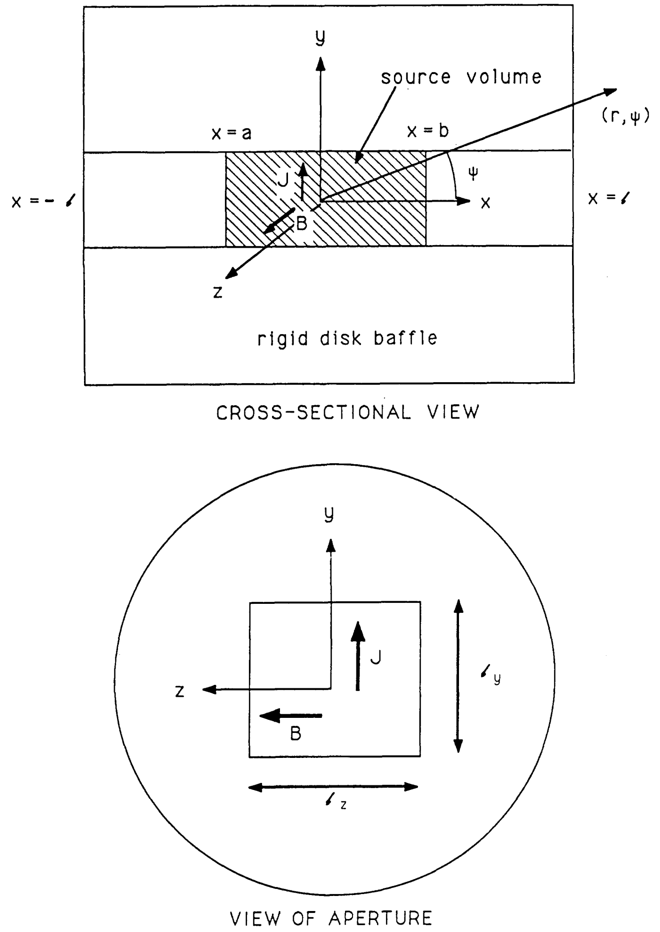

FIG. 20. Example of a magnetohydrodynamic transducer which couples a magnetic and electric field to velocity of a conducting fluid [from Quate (1985)].

4. APPLICATIONS

Acoustic instruments have numerous applications in communication, testing, signal processing, and research. Below we describe some of the most common of the applications.

4.1 Gases

The most common use of acoustical instruments is in telephony. Every telephone contains at least two acoustical transducers, a microphone and an earphone. Taken together these items account for most of the weight and cost of conventional handsets. For decades the standard telephone microphone was the carbon button microphone, a nonlinear resistive device. Now electret capacitive microphones are replacing the carbon microphone worldwide. Besides transducers, telephony research involves a number of other acoustical instruments including artificial ears which are microphones that are mounted at the bottom of standard-sized cavities, acoustical dummy heads which are used to simulate sound received binaurally, and microphone arrays which are used for teleconferencing.

Another very large segment of the acoustical instrument industry is dedicated to public announcement (PA) and home music entertainment (see ENGINEERING ACOUSTICS). PA systems typically concentrate on loudspeakers and speaker arrays suitable for speech communication. Transducer efficiency is more important than the quality of sound reproduction. Audio entertainment equipment includes a very wide range of acoustical instrument types and qualities. Standard components are loudspeakers, tuners (for radio reception), audio amplifiers, tape players (reel-to-reel and cassette), phonograph turn-

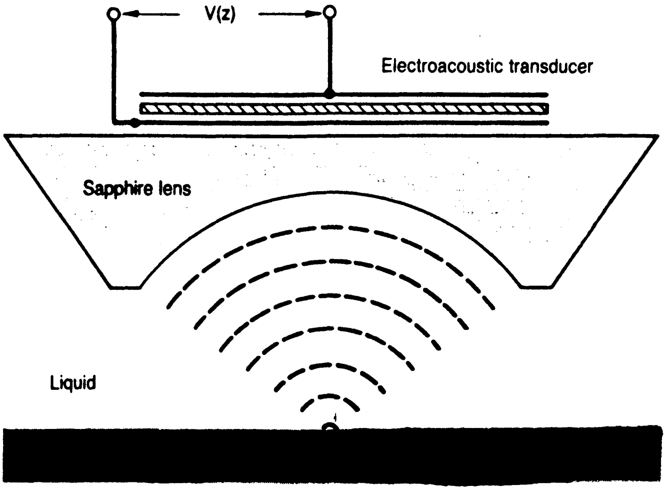

FIG. 21. Transducer portion of an acoustic microscope. A piezoelectric element generates a compressional wave which is focused by a lens and transmitted through a fluid to a target [from Quate (1985)].

tables, compact disk players, microphones, and earphones. The most recent advances have been the advent of compact disk technology and the development of very efficient polymer earphones which have permitted rapid growth of the portable audio equipment industry.

A third segment of the market has been the area of noise control. Due to government regulations worldwide, noise control work has concentrated on quieting the industrial noise sources which are sufficiently loud to cause hearing damage, and community noise sources most likely to interfere with speech communication and sleep. Typical acoustical instruments employed in studies to document noise sources are sound level meters and sound exposure meters. Sound level meters are acoustical instruments which combine a microphone, amplifier, logarithmic converter, filter, and a meter which displays a sound pressure level in dB, re 20 μPa. Most sound level meters provide an A-weighting filter network which is designed to simulate human hearing. In addition, some meters have octave band and one-third octave band filter sets available. In sophisticated sound level meters one may also vary the response time of the signal processing from very fast for impulsive sounds to slow for steady sounds.

Exposure meters are similar to sound level meters but are designed to determine the average A-weighted level to which a worker is exposed in order to check legal compliance. They thus use very slow averaging and do not have alternative filter sets.

4.2 Liquids

By far the largest application of acoustical instrumentation in liquids is in underwater sound systems (see ACOUSTICS, UNDERWATER). Historically the impetus for much of this work has been the heavy use of sonar systems for navigation, communication, and target location in the oceans. Working in oceans presents severe problems because the environment is highly corrosive to equipment, and opaque to visible light, infrared, radio, and radar signals. Acoustical signals are the only feasible means of transmitting information for distances greater than a few meters.

The early applications of underwater acoustical instruments concentrated on depth sounding and navigation. In the 1940s the emphasis shifted to target detection and sonar (sound navigation ranging) systems. There are two classes of sonar systems: passive sonar in which the received acoustic signal is that generated by a remote source, and active sonar in which a sound source is reflected off of a target and the echo detected. In both cases and in virtually all underwater communication systems used in oceans, a key problem is the detection of weak acoustical signals in the presence of noise. There are three standard means of overcoming this signal to noise problem. First, one may increase the power of an active sonar system. However, reverberation of the source signal off of the ocean bottom and other scatterers limits the effectiveness of power increases. Second, one may use a directive sound receiver so that sound arriving from undesired directions may be rejected. This is typically accomplished in sonar systems using both stationary hydrophone arrays and arrays which are towed by ships. Third, one may use a notch filter in the receiving circuit to reject a narrow band of frequencies which encompasses the greatest reverberation noise. This will also tend to reject the echo from a stationary source, but since moving sound sources result in Doppler shifted signals, moving targets still can be detected. For further information on sonar see Urick (1975).

In addition to underwater communication in the oceans, acoustical instruments are becoming progressively more important in biotechnology. Sonograms are routinely used in circumstances which do not permit x rays, such as in fetal monitoring. In sonogram equipment a directive, intense sound source is placed in contact with a body and the reflected sound signal is monitored, processed, and displayed graphically. Lithotripsy, the use of intense sound to break up kidney stones, has recently become more available and popular as a nonsurgical treatment. In lithotripsy a sound source is used to produce an intense, focused sound beam which selectively applies forces to hard objects such as kidney stones due to the large acoustical impedance mismatch with the soft tissue. Other biotechnical applications of acoustical instruments include ultrasound therapy for muscles, and acoustic microscopy in which sound waves are reflected from specimens rather than light.

Acoustical instruments for use in liquids are also widely employed in geophysical prospecting in oceans. In this application a source is used to generate a low-frequency sound wave in the water. This wave propagates through the water and partway into the ocean bottom. By monitoring the echo signals, a description of the ocean bottom at that location is obtained.

Acoustical instruments are also used for communication purposes in oil wells. Here, information is propagated in the form of compressional waves in the drilling mud which are monitored by hydrophones at the well surface. The information is sent at very low frequencies (under 3 Hz).

4.3 Solids

The applications of acoustical instruments in solid media parallel those in liquid and gaseous media. Among the major applications are nondestructive testing, length gaging, down-hole communication, geophysical prospecting, and surface acoustic wave devices.

Nondestructive testing of solids may be accomplished by generating an acoustic wave in the medium and looking for reflected acoustic signals. Such reflections indicate an impedance change located at a distance given by $t = \Delta t/2c_0$, where Δt is the time between the source signal and the echo. In this manner it is possible to check large structures for cracks or material voids such as occur in delaminations. Another popular application of this technology is the determination of lengths of objects which are only accessible at one end. In this case a transducer may send an acoustic wave into the object and monitor the time for the return of the signal reflected from the end. If the sound speed is well known for the material comprising the object, then its length may be accurately determined. Such a technique has been used, e.g., to determine lengths of muddy drilling pipes which are laid in stacks.

An alternative to down-hole oil well communication through acoustic wave propagation in drilling mud is the use of acoustic stress waves in drilling pipes or pumping rods. The generated waves carry information at much higher frequencies (audible range) and similarly do not require the locating of electrical instrumentation down the well. For further information on stress wave communication see Hixson (1966) and Drumheller (1989).

Geophysical prospecting in the earth's surface has been a significant application of acoustical instruments in solids. Typically a low-frequency wave is sent into the ground and the reflected signals monitored using geophones. There are generally two means of generating the acoustic wave: directed explosives and very powerful and massive shaker trucks.

Surface acoustic wave (SAW) devices have been used for a number of years for high-frequency filters and oscillators. In SAW devices a thin metal film is deposited onto a piezoelectric substrate typically of quartz or lithium niobate. The film consists of two electrically isolated contacts, each with fingers, deposited so that the fingers are interdigitally spaced. These fingers are used to excite an acoustic wave whose intensity decays exponentially with depth into the piezoelectric. Typical penetration depths and finger spacings are about an acoustic wavelength. By shaping the fingers and varying the spacing between them it is possible to control the time or frequency response of the device thus making them prime candidates for filters of various sorts. SAW devices are generally available in the 10 MHz to 2 GHz range, and are compatible with standard microelectronics processing techniques. For further information on SAW devices see Kino (1987).

GLOSSARY

Beam Width: Angular range of the main lobe of sensitivity of a transducer.

Bending Modulus: Ratio of the moment applied to a structure to its angular strain.

Cardioid Transducers: Sensors and actuators which expose the transducing element to sound on both the front and back face so that the net result is an even combination of a conventional pressure transducer and a gradient transducer.

Directivity Factor: Ratio of the peak response of a transducer, measured at a distance *r*, to its average response measured at the same distance.

Directivity Index: Decibel measure of the directivity factor: $\mathrm{DI}=10\ \log_{10}\mathrm{DF}$.

Electrical Admittance: Ratio of current to voltage (inverse of electrical impedance).

Electrical Impedance: Ratio of voltage to current (inverse of electrical admittance).

Gage Factor: Figure of merit for resistive strain gages. The gage factor is the ratio of resistance change to nominal resistance.

Geophone: A transducer designed to measure the motion of the ground in response to a remote excitation.

Gradient Transducers: Sensors and actuators in which the transducing element responds to the gradient of a state of the system, usually due to exposing the front and back sides of the transducing element to the environment.

Hydrophone: Underwater acoustic pressure sensor.

Magnetostriction: An effect in some materials in which the magnetic permeability is a function of the mass density.

Mechanical Admittance: Ratio of velocity to force (inverse of mechanical impedance).

Mechanical Impedance: Ratio of force to velocity (inverse of mechanical admittance).

Piezoelectricity: The coupling of the mechanical elastic field and electric fields in a material. An imposed strain of the material produces a changing electric field and an imposed electric displacement produces a mechanical stress in the material.

Piezoresistivity: The dependence of the electrical resistivity of some materials to the mechanical strain imposed on them. The strain affects the crystal lattice of the material and the material dimensions, thus changing the material resistance in two ways.

Radiation Efficiency: Ratio of the acoustic power radiated by a source to that radiated at high frequencies by a baffled uniform circular piston source of the same size and mean squared velocity.

Reciprocal Calibration: Calibration of a transducer which is accomplished using one or more other transducers, at least one of which is reciprocal (i.e., which can operate either as a sensor or as an actuator).

Reverberant Sound Field: A sound field which is uniformly (or nearly uniformly) distributed in a space, usually due to multiple reflections of source sound waves on boundaries.

Sound Level Meter: Device for measurement of sound pressure levels incorporating a microphone, amplification, filtering, and a display.

Surface Acoustic Wave (SAW) Device: High-frequency transducer in which the acoustic wave intensity decays exponentially with depth into the transducing material.

INTRODUCTION

Various forms of acoustic imaging are playing an increasing role in research and everyday life. It is becoming common practice for a pregnant woman to have a "sonogram" of her baby to be sure that all is well. Statistical quality control requires rigorous testing of manufactured items; much of the testing is done using acoustic nondestructive evaluation (NDE). In science and research, acoustic microscopes are being used that can often give a sharper image than optical microscopes. In clinical applications, research is providing simultaneous quantitative images of the sound velocity, attenuation, and fluid velocities. In the field of fluid dynamics, acoustic techniques are being used to map the temperature and velocity fields in laboratory to ocean scale flows.

The invention of x-ray tomography by Hounsfield in 1972 stimulated the current interest in all kinds of tomography. Since then the instrumentation and computer hardware and software have been improved so that accuracies of one part in 1000 are achievable from 10^6 data points. In the field of medicine, tomography has let doctors study the interior of a patient's body with precision and safety. While x rays are used to produce images of the x-ray attenuation coefficient, other forms or sources of energy including radio waves, magnetic resonance, positrons, radioisotopes, and sound are used to image different parameters.

Acoustic imaging can be loosely divided into tomographic and nontomographic systems. Nontomographic imaging generally consists of a single view of an object and presents the raw data with little or no processing. The resulting qualitative images highlight regions of strong scattering associated with large gradients in the refractive index or, equivalently, regions of high reflectivity, such as distinct boundaries. However, the "correct" interpretation of these qualitative images is largely dependent on the skill of a trained analyst. Nontomographic imaging is widely used in medicine and NDE.

In contrast, tomographic imaging is a distinctly two-step process. In its most pristine form, the object is first probed from many different angles. The measured data from the various views are then processed and combined to yield a quantitative reconstruction of some physical parameter such as the acoustic index of refraction. Tomographic reconstruction is therefore a much more experimentally and computationally intensive procedure, but the quantitative images that are generated

FIG. 1. Reconstruction of four cylinders of radius five obtained by filtered backpropagation for a wavelength of unity. The quality of the reconstruction improves as additional views are incorporated (from Devaney, 1983; ©1983, IEEE).

can reveal subtleties that are not recovered by nontomographic methods.

In practice, the classification of a particular acoustic imaging system is not always clear. Many practical systems combine both tomographic and nontomographic features. For example, inherently nonquantitative medical images taken from different angles may be superimposed to create a superior image. In medical or geophysical applications of tomography, the number of views available may be far fewer than the number that are required for ideal inversion. The type of system used for a particular application depends on a variety of factors. In nondestructive evaluation, for example, the mere detection of a flaw may be sufficient, and quantitative information may not be needed.

The tomographic reconstruction process is illustrated in Fig. 1. In the simulation, a system of four cylinders is probed by an acoustic plane wave. An image based on a single view is inadequate for recovering the system. However, as the images generated from additional views taken at other angles are superimposed, the reconstruction is improved and the individual cylinders become apparent.

Acoustic tomography is related to several other topics covered in this volume. Acoustic microscopy (see MICROSCOPY, ACOUSTICAL) can be used in detecting surface cracks in NDE. Some forms of microscopy are in fact tomographic, but are beyond the scope of this article. The coherent field measurements required for diffraction tomography can be interpreted as acoustic holograms. Indeed, generalized acoustic holography (*q.v.*) can form the basis of a variety of both tomographic and nontomographic inverse scattering algorithms (Porter, 1989). Finally, because of the large amount of recorded data needed for tomographic inversion, efficient acoustic signal processing (see SIGNAL PROCESSING) techniques are required.

The contents of this article are divided primarily by imaging technique rather than by application. By taking this approach, we stress the similarity of the imaging problem for such seemingly disparate fields as medicine, geophysics, nondestructive evaluation, and oceanography. The first section briefly reviews nontomographic techniques as background for the tomographic methods discussed in the balance of the paper. The next section describes conventional straight-ray tomography. In this method, the probing energy is assumed to travel along straight ray paths through the object. Conventional tomography also illustrates the importance of multiple views for quantitative inversion. The third section discusses diffraction tomography. In diffraction tomography, the probing wave is assumed to obey a wave equation. Recent encouraging experimental results in dif-

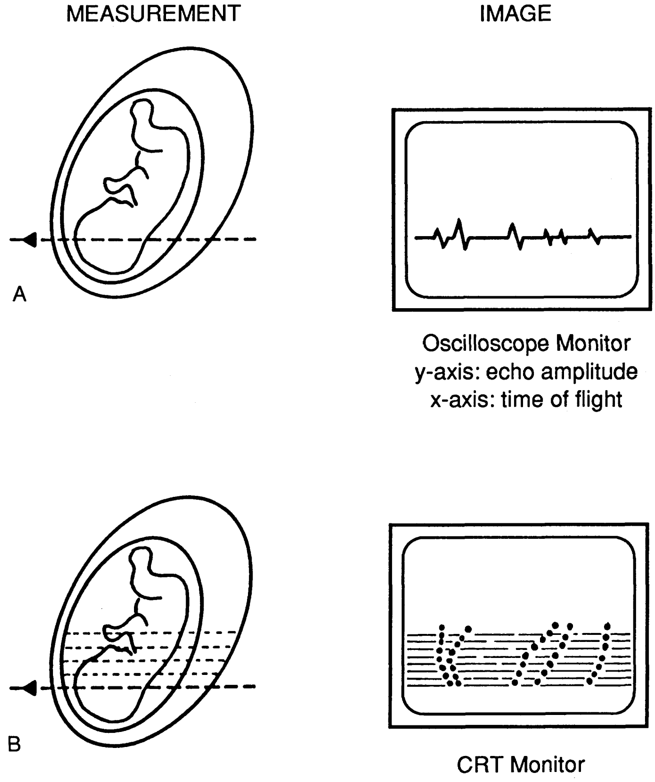

FIG. 2. Nontomographic imaging. (a) A-scan. Output displays echo amplitude vs distance into medium. (b) B-scan. Output is a cross-sectional image. The image brightness is related to the amplitude of the return pulse.

fraction tomography are discussed. Examples of current research from medicine, geophysics, and small-scale oceanography are included.

Straight-ray and diffraction tomography are similar because in many applications reconstructions are often "agnostic"; i.e., there is sufficient data that nothing need be assumed about the field being reconstructed. Section 4 deals with ocean acoustic tomography, in which the rays are refracted by the ocean sound channel. Because of a paucity of data, *a priori* information is necessary to constrain the reconstruction. Concluding remarks are in Sec. 5.

1. NONTOMOGRAPHIC IMAGING

Most methods of acoustical imaging currently used in clinical and NDE applications are nontomographic and are based on reflection or pulse-echo techniques. The different methods have historically been assigned letter designations: A-scan, B-scan, C-scan, etc. [Figs. 2(a) and 2(b)]. Many of the commercial systems incorporate some aspects of each method (Schueler *et al.*, 1984).

The A-scan is based on "time of flight": A pulse is transmitted and bounces off a scattering or reflecting boundary and the echo is detected, often by the transmitting element which also acts as a receiver [Fig. 2(a)]. The time between transmission and reception of scattered energy gives the range to the reflecting surface (assuming a constant speed of sound). The amplitude of the echo provides information on the strength of the scattering. The time corresponding to a large- amplitude peak is used to locate a major scattering boundary. It could be the interface between different organs in the body, a wall of a pipe, or the ocean bottom. Weaker amplitudes would be representative of, for instance, the relative severity of a flaw in a weld or casting, or scatter from schools of fish or zooplankton, or sediment layers beneath the ocean floor.

Time modulated (T/M) mode interrogation involves a succession of A-scan measurements taken at a fixed transducer location in even time increments. The output gives the

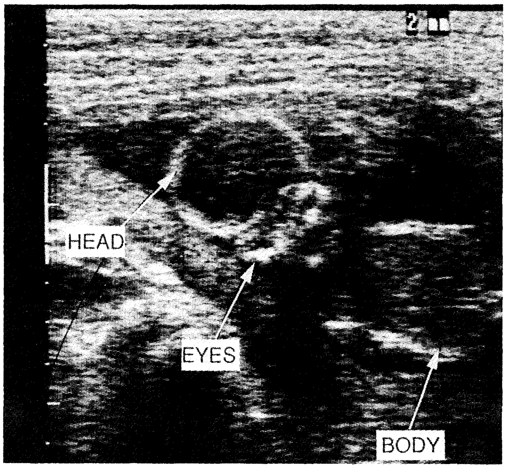

FIG. 3. B-scan image of the first author's son at the end of the first trimester.

range to a reflecting surface as a function of time and can be used to monitor cardiac motion.

By carefully moving the transducer along a line and taking a series of A-scan measurements, a cross-sectional "image" as a function of range and the scan dimension can be obtained; in medical systems, this is called a B-scan [Fig. 2(b)]. The transmitted acoustic wave is focused so that the imaged section is more nearly planar. The brightness of the display is related to the amplitude of the reflection. Scanning can be controlled either mechanically or electronically. Electronic scanning can be done very rapidly to give nearly real-time images. The output can be displayed on a television screen with a new image generated each 1/30 of a second. Figure 3 shows a typical sonogram of a fetus.

The corresponding oceanographic instrument is called Seabeam. A swath of the sea floor is mapped by an array of transducers on the bottom of the ship. As the ship moves along its track, topographic maps of the ocean bottom are produced with high accuracy. Seabeam is being used to chart the 200-mile Exclusive Economic Zone (EEZ) of the United States and other countries.

The objective in nondestructive evaluation is to locate faults in a structural component. While conceptually similar to medical A- and B-scan techniques, NDE has several important differences. Since the structural component is a solid, it can support shear and surface waves in addition to longitudinal waves. It is difficult to couple acoustic waves from air into a solid because most of the energy is reflected. Furthermore, the faults present in an object may vary widely in size, shape, and location; this diversity can complicate the interpretation of the output.

A similar procedure is also found in geophysics (see SEISMOLOGY). The objective in seismic inversion is to determine the structure of the earth beneath its surface. This information is crucial in oil exploration or in the disposal of nuclear waste. Low frequencies of less than 100 Hz are used to obtain information at depths of several kilometers. As with NDE, shear and surface waves are generated. Seismic imaging is simplified by the *a priori* assumption that structures vary primarily in depth by geologic layer.

The C-scan can operate in either the reflection or transmission mode. As a transmitter is moved over a plane, a receiver is also moved and the received intensity as a function of position is recorded. This is equivalent to a simple x-ray picture since both provide a "shadowgraph" of the object.

Doppler ultrasound uses the change in apparent frequency between the transmitted and received signals to measure relative motion. The technique is often used in medical applications to monitor blood flow. A typical transmission frequency is 3 MHz and the shift in frequency due to blood flow is usually in the audio range. Consequently, after demodulation the output signal is often sent to an audio speaker allowing the clinician to "hear" the blood flow. Continuous- wave Doppler systems require separate transducers for transmission and reception and give no information about the location of a flow. Pulsed Doppler systems do give range data, but require more elaborate timing and demodulation circuitry.

2. STRAIGHT-RAY TOMOGRAPHY

The nontomographic systems of the previous section operate primarily in the pulse-echo mode. Many tomographic systems operate in the transmission mode; the object is between the transmitter and receiver. In propagating through the object, the probing wave is perturbed in accordance with the properties of the medium. The simplest prop-

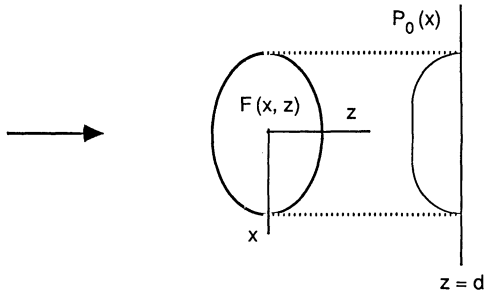

FIG. 4. Straight-ray tomography. Probing energy travels in straight-line paths through the unknown object F(*x*, *z*). The measured quantity $P_0(x)$ is the geometric projection or "shadowgraph." If the projection corresponds to travel time measurements along rays parallel to the *z* axis, then $F(x, z) = C_0/C(x, z) = n(x)$, the index of refraction.

agation model is to assume that the transmitted energy travels along straight ray paths through the object. This model permits the derivation of relatively simple inversion algorithms that parallel those common to x-ray tomography.

For simplicity, we begin with a two-dimensional imaging problem and later generalize to the full three-dimensional case. The typical experimental configuration is shown in Fig. 4. The object function $F(x, z)$ describes some physical parameter of an object such as the attenuation rate or the index of refraction that we wish to determine. For this view, the object is probed by energy traveling along a straight ray in the z direction. It is assumed that the measured quantity (such as intensity or travel time) is related to the geometric projection $P_0(x)$ of the object. The geometric projection at this angle is related to the object function by

$$P_0(x) = \int_{-\infty}^{\infty} F(x, z)dz. \tag{1}$$

The objective is to recover the unknown function $F(x, z)$ from projections measured at many different angles. If the data are measurements of intensity, then $F(x, z)$ is the attenuation field; if the data are measurements of travel time, $F(x, z)$ is the reciprocal of the sound speed. From a practical point of view, the projection can only be sampled at a finite number of points corresponding to a finite number of rays.

2.1 Projection-Slice Theorem

It is instructive to examine the relationship between the projection and the object function in the Fourier domain. Because of its relative simplicity, the analysis for the geometry shown in Fig. 4 is now presented. Defining the Fourier transform of the projection as $\tilde{P}_0(k_x)$, we find from Eq. (1) that

$$\begin{aligned} \tilde{P}_0(k_x) &\equiv \int_{-\infty}^{\infty} P_0(x)e^{-ik_x x}\,dx \\ &= \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} F(x, z)e^{-ik_x x}\,dx\,dz. \end{aligned} \tag{2a}$$

Defining the two-dimensional transform of the object as

$$\begin{aligned} \tilde{F}(k_x, k_z) \equiv \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} & F(x, z) \\ & \times e^{-ik_x x}\, e^{-ik_z z}\,dx\,dz, \end{aligned} \tag{2b}$$

it follows that

$$\tilde{P}_0(k_x) = \tilde{F}(k_x, k_z{=}0). \tag{2c}$$

Equation (2c) indicates that by taking the one-dimensional transform of the measured projection, we recover the two-dimensional transform of the object evaluated in Fourier space along the line $k_z = 0$. This result is easily generalized to an insonification angle ϕ as shown in Fig. 5. This fundamental relationship is referred to as the Projection-Slice theorem: The one-dimensional transform of the projection taken at angle ϕ maps onto a radial line at angle ϕ in the two-dimensional Fourier space of the object.

It is apparent from Fig. 5 that if we could probe the object at all possible directions over 180°, we would "fill" Fourier space and could then, in principle, recover the object function $F(x, z)$ by an inverse two-dimensional transform. The figure also illustrates a concept relevant to all types of tomography: A single view provides only limited information about an object and many views are necessary for an accurate quantitative reconstruction.

In practice, the reconstruction is usually performed in the spatial domain. Each projection is first filtered. Alternate filtering schemes are available, but the idea is to compensate for the relatively sparse sampling of $\tilde{F}(k_x, k_z)$ at high spatial frequencies when a finite number of projections are measured (Horn, 1978). These filtered projections are

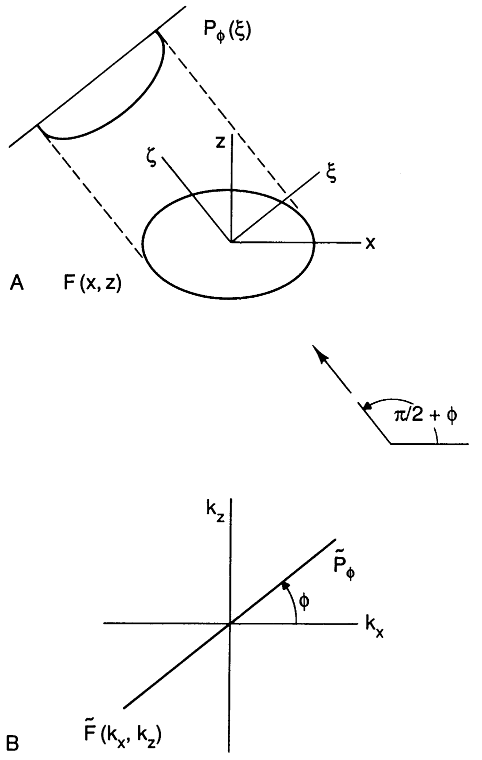

FIG. 5. The Projection-Slice theorem. The one-dimensional projection $P_\phi(\xi)$ maps onto a line in two-dimensional Fourier space of object *F*.

then backprojected along straight-ray paths. The resulting images from each view are then superimposed to yield the reconstruction. This inversion method is called *filtered backprojection* (Kak and Slaney, 1988). It avoids problems with interpolating in the Fourier domain, in favor of (usually linear) interpolation in the spatial domain. Most importantly, it is computationally efficient because calculations can start once the first projection is measured.

The generalization of these concepts to full three-dimensional inversion is straightforward. Because the energy is assumed to travel along straight ray paths, there is no out-of-plane scatter. Consequently, any cross section of the object can be reconstructed independent of all others by using the filtered backprojection algorithm. Reconstruction of the entire object is accomplished by reconstructing several parallel cross sections and stacking the results to give a three-dimensional effect. Thus the three-dimensional imaging problem is reduced to a series of independent two-dimensional problems. Each two-dimensional slice is reconstructed using one-dimensional projections.

2.2 Example of Straight-Ray Tomography

Schreiman *et al.* (1984) conducted a study of ultrasound-transmission computed tomography of the breast to evaluate its capability for detecting anomalies. The technique measures both the speed of sound and the attenuation within the breast by measuring the time of flight and reduction in amplitude of sound pulses. There was enough variability between patients in the imaged parameters that relative rather than absolute values were required; reference values were taken from "normal" adjacent tissue.

The scanning apparatus consisted of four focused transmitters and four receivers operating at 5 MHz; the corresponding acoustic wavelength was approximately 0.3 mm. Each transducer was 10 mm in diameter and separated from its neighbor vertically by 14 mm (Fig. 6). Using a translate/rotate scan, each transducer pair obtained a set of data used for reconstructing images in its plane of the breast. At each of 60 viewing angles, the instruments were translated horizontally to construct a projection made up of 200 parallel rays. A second set of scans was made with the transducers lowered 7 mm. This resulted in data for eight planes, 7 mm apart and approximately 3 mm thick. The entire procedure lasted about 5 min. Data were stored on magnetic media and processed off-line.

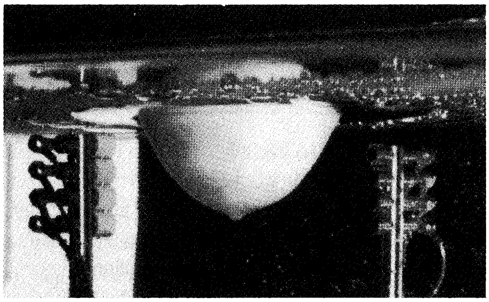

FIG. 6. The four transducer (transmitter-receiver) pairs used to scan a phantom breast. The patient lies face down on a table above a water tank and the breast is immersed in water during the scanning (from Schreiman *et al.*, 1984).

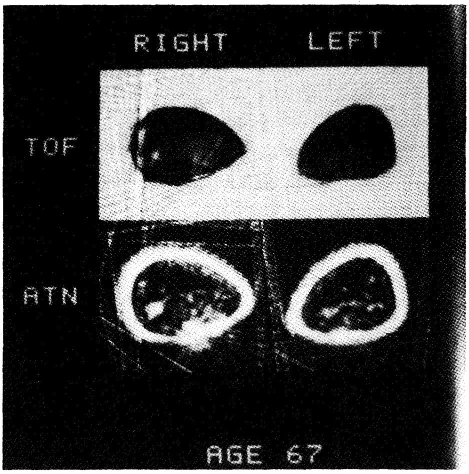

FIG. 7. The time of flight (TOF) images on top and the attenuation (ATN) images on the bottom show the small cancer. The sound speed change for the tumor over the background is 45 m/s (from Schreiman *et al.*, 1984).

The arrival time of the sound pulse at the receiver was measured using threshold detection of the signal after it had been passed through a full-wave rectifier and a bandpass filter. The amplitude of the received signal was estimated by integrating the first two microseconds of the signal after detection. Although this latter method averages the attenuation coefficient over frequency, its virtue is simplicity.

An example of the ultrasonic tomographic images is shown in Fig. 7. The reconstruction was done using the filtered backprojection method. It was found that malignant lesions could be identified by various ranges of sound speed and attenuation. The tumor shown has a low sound speed and a high attenuation. More work needs to be done to correlate tomographic results with tissue malignancy. It would also be interesting to see what effects ray bending and diffraction would have on these images. For additional examples of ultrasonic tomography as applied in medicine, the reader is referred to Robinson and Greenleaf (1985).

Tomographic techniques can also be applied to seismic data. Typically several boreholes are drilled between which either acoustic or electromagnetic signals are transmitted. Reconstruction methods often rely on *a priori* information and reduce to the solution of a system of equations. A similar procedure for the oceanographic case is discussed in detail in Sec. 4. For additional examples from seismology, see Daily (1986).

3. DIFFRACTION TOMOGRAPHY

The conventional tomography algorithms discussed in the previous section were largely developed for x-ray tomography (see X-RAY IMAGING: RADIOLOGY AND TOMOGRAPHY). The central assumption of the method, i.e., that the probing energy travels along straight ray paths, is certainly true for x rays. The successful application of such techniques to acoustics, however, has been limited. In acoustics, diffraction effects often cannot be neglected. Diffraction occurs whenever the acoustic wavelength is comparable to spatial scales associated with changes in the index of refraction of the medium. In diffraction tomography, the measured information is treated like a scattered field governed by the wave equation. We first derive an expression for the scattered field and then show how it can be used to reconstruct an object.

3.1 Scattering Problem

The two-dimensional scattering problem is shown in Fig. 8(a). A scatterer characterized by the index of refraction $n(\mathbf{x})$ is probed by a known incident acoustic plane wave. For a source-free region, we assume that the total acoustic pressure wave ψ satisfies the linearized, time-harmonic $[\exp(-i\omega t)]$ Helmholtz equation:

$$[\nabla^2+k^2n^2(\mathbf{x})]\psi(\mathbf{x})=0, \tag{3}$$

where $k = \omega/C_0$ is the wave number and C_0 is the speed of propagation in the background medium. In general, the index of refraction can be real or complex, the latter applying when the scatterer is lossy. Outside the object, the index of refraction is equal to that of the homogeneous background and $n(\mathbf{x}) = 1$.

The total field $\psi(\mathbf{x})$ outside the object can be written as the sum of the known incident field $\psi_i(\mathbf{x})$ and a scattered field $\psi_s(\mathbf{x})$. The incident field is that which would propagate in the absence of the scatterer. The scattered field contains the perturbations in the total

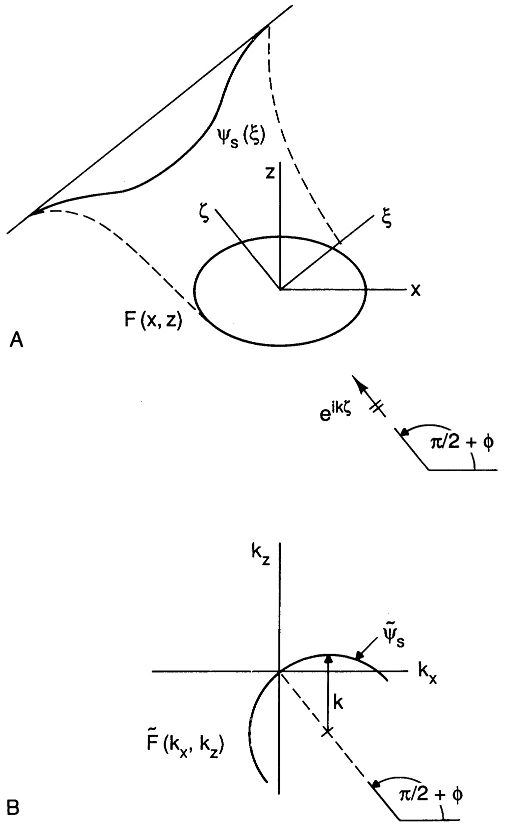

FIG. 8. Diffraction tomography. (a) An incident plane wave probes the unknown scatterer *F*(*x*, *z*). The measured field is governed by the wave equation. (b) The Fourier diffraction theorem. The one-dimensional transform of the scattered field $\psi_s(x)$ maps onto a semicircle in the two-dimensional Fourier space of the object *F*. The radius of the semicircle is the wave number *k* of the incident wave.

field due to the object and is given by (Ishimaru, 1978)

$$\psi_s(\mathbf{x}) = \int_V F(\mathbf{x}')\psi(\mathbf{x}')G_f(\mathbf{x}, \mathbf{x}')d\mathbf{x}'. \tag{4}$$

Here $F(\mathbf{x}) = k^2[n^2(\mathbf{x}) - 1]$ is the scattering function, V is the volume of the object, and G_f is the free-space Green's function. The objective is to recover the scattering function from measurements of the scattered field. This task is complicated by the presence of the unknown total field $\psi(\mathbf{x})$ in the integrand, so simplifying approximations are often made. Equation (4) can be linearized by approximating ψ in the integrand with the known incident field ψ_i. This is the so-called (first) Born approximation and is valid when the scattered field is significantly weaker than the incident field and multiple scattering can be ignored. The first Born approximation includes only single scattering. Higher order approximations correspond to the incident field being scattered twice, and so on.

As an alternative to the Born approximation, the total field $\psi(\mathbf{x})$ may be expressed as the *product* of the incident field $\psi_i(\mathbf{x})$ and a perturbation term:

$$\psi(\mathbf{x}) = \psi_i(\mathbf{x})e^{\phi_c(\mathbf{x})}, \tag{5}$$

where $\phi_c(\mathbf{x})$ is the complex phase. A series expression for $\phi_c(\mathbf{x})$ can be generated where the first term in the expansion is referred to as the (first) Rytov approximation:

$$\phi_c(\mathbf{x}) \approx \psi_s(\mathbf{x})/\psi_i(\mathbf{x}), \tag{6}$$

where $\psi_s(\mathbf{x})$ is given by Eq. (4). The Rytov solution describes how the wave fronts of the incident wave are distorted as they go through the object. If the complex phase is small, the exponential in Eq. (5) can also be expanded in a series and the Born and Rytov solutions for the total field are equivalent to second order.

It is generally believed that the Born approximation is most valid for large-angle scattering while the Rytov solution is most valid in forward, line-of-sight propagation (the usual tomographic configuration). Which formalism should be adopted for numerical implementation? There is an important practical problem associated with inversion algorithms based on the Rytov approximation. In the Born approximation, the scattered field is obtained from the measured total field by a simple subtraction of the known incident wave. In the Rytov approximation, the complex phase is obtained by taking a logarithm, which is not straightforward since the logarithm of a complex argument is multivalued and phase unwrapping is notoriously difficult. In most cases, the assumption is that the scattering is sufficiently weak that either the Born or the Rytov approximation adequately models the forward scattering process. Inversion algorithms are therefore usually based on the Born approximation with the understanding that the Rytov solution might be better if the phase can be correctly unwrapped.

3.2 Fourier Diffraction Theorem

In direct analogy with straight-ray tomography, diffraction tomography inversions are usually based on the *Fourier diffraction theorem,* illustrated in Fig. 8. An object characterized by scattering function $F(x, z)$ is insonified by a plane wave propagating in direction ϕ. The total field is measured along a linear receiving array orthogonal to the incident field direction, and the scattered component $\psi_S(\xi)$ is obtained by subtracting the known incident wave [Fig. 8(a)]. The theorem states that the one-dimensional Fourier transform of the scattered field maps onto a semicircle in the two-dimensional Fourier space of the object [Fig. 8(b)]. We observe that the radius of the semicircle is the wave number k of the probing wave. This result can be proved by substituting an appropriate integral representation of the Green's function into Eq. (4) and taking the transform of the scattered field (Devaney, 1982).

By rotating either the measurement system or the object, the scattered field can be recorded at other angles. Rotating the insonification vector corresponds in Fourier space to rotating the semicircle, much in the same way as a line in Fourier space is rotated in the nondiffracting case. If we were to take views at all directions over 360°, we would cover all spatial frequencies out to a cutoff wave number $\sqrt{2}k$. Higher spatial frequencies cannot be recovered from the forward scattered field, so it is only possible to recover a low-pass filtered version of the object. Physically the low-pass filtering constraint corresponds to the fact that we cannot see details of the object much smaller than the wavelength of the incident wave. Consequently, we can recover only a smoothed version of the original object.

As the frequency of the probing wave is increased, the wavelength becomes smaller and we can therefore recover more of the fine detail in the object. This can be observed from Fig. 8(b). Raising the frequency increases the wave number and hence the radius of the semicircle. In the high frequency limit, Fig. 8(b) reduces to Fig. 5(b) and diffraction can be neglected.

3.3 Inversion Algorithms

Having formulated the scattering problem, we now consider techniques for inverting the scattered field to determine the scattering function. Inversion is more complicated when diffraction effects are considered; the measured quantity ψ_s is related to the unknown scattering function by a volume integral containing a Green's function [Eq. (4)] rather than a simple line integral [Eq. (1)].

Given the Fourier diffraction theorem, there are two basic techniques for inverting the measured scattered fields and reconstructing the two-dimensional object. The first essentially reduces to interpolation in the frequency domain, while the second involves interpolation in the spatial domain.

The first and most obvious reconstruction technique makes use of the discrete Fourier transform. The scattered field, which is measured along a linear recording surface, is uniformly sampled. The continuous transform of the field is then efficiently approximated using the fast Fourier transform (FFT). The discrete transform maps onto sampled arcs in the two-dimensional discrete Fourier space of the object. We can then, in principle, perform an inverse transform into real space to yield the reconstruction. The inverse transform is best achieved by a two-dimensional FFT which requires that the data be distributed on a uniform grid. The reconstruction problem therefore becomes one of interpolating from sampled arcs onto a uniform grid. Bilinear interpolation appears to work satisfactorily in some cases (Pan and Kak, 1983).

The second reconstruction approach operates entirely in the spatial domain. The filtered backprojection method used in conventional straight-ray tomography is modified to include an additional depth-dependent filter (Devaney, 1982). The backpropagation filter attempts to model the acoustic wave propagation within a finite depth interval. An example of this reconstruction technique was given in Fig. 1.

The Fourier diffraction theorem suggests another possible approach to the inversion problem. As shown in Fig. 8(b), the radius of the mapped semicircle is the wave number k of the probing wave. Recalling that the wave number is proportional to the temporal frequency, this implies that if the object were probed by a plane wave with a wide temporal bandwidth, additional information would be recovered in spatial Fourier space. It can be shown that there is a duality between probing a weak scatterer from many directions using a single-frequency wave and probing at a single direction using a wideband pulse (Porter, 1989). It should be noted, however, that the validity of the Born approximation becomes particularly questionable at high frequencies.

The Fourier diffraction theorem is easily extended to three dimensions. The two-dimensional transform of the scattered field measured along a plane maps onto a spherical shell in the three-dimensional Fourier space of the object (Wolf, 1969). In three dimensions, the incident field will be scattered out of the plane containing the insonification vector. Consequently, unlike straight-ray tomography, three-dimensional reconstruction cannot be accomplished by a succession of independent two-dimensional problems. Optimal inversion requires that the object be insonified at all possible angles over a complete sphere. In practice, this substantially increases both the number of views needed and the computational effort required to invert the data.

3.4 Examples of Diffraction Tomography

Diffraction tomography has yet to find widespread clinical applications. The fact that the two-dimensional algorithms of the preceding section are not easily extended to full three-dimensional inversion has limited their usefulness. Another major difficulty is the weak-scattering assumption; the measured field must obey either the Born or Rytov approximation. In the medical application, bones are not weak scatterers.

The clinical application of diffraction tomography with the greatest potential is imaging the breast. As we saw in the previous section, cancerous lesions can often be characterized as regions with relatively small perturbations in the acoustic index of refraction (Schreiman *et al.*, 1984); it is therefore hoped that the forward scattering can be accurately modeled by weak scattering.

In cases where the scattering is strong, Eq. (4) cannot be linearized and diffraction tomography does not yield a quantitative reconstruction of an object's acoustic parameters. Rather, it gives the sources induced in the object which depend on the pressure field within. The qualitative images that are produced, however, may reveal features of the object that could not be resolved by nontomographic techniques.

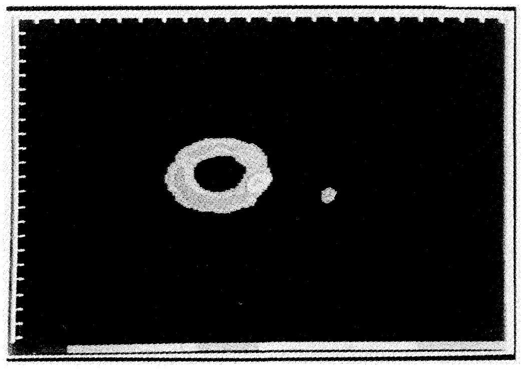

FIG. 9. A reconstruction of a rubber pipe and a nylon string. Each axis tick is 1 mm (from Duchêne *et al.*, 1988).

Duchêne *et al.* (1988) have reported on qualitative experimental reconstruction of cylindrical targets. They used an acoustic frequency and corresponding wavelength of 2 MHz and $\lambda_0 = 0.75$ mm, respectively. The targets were a rubber pipe and a nylon string. The inside and outside diameters of the pipe were 2 and 5 mm ($2.7\lambda_0$ and $6.8\lambda_0$), and the sound speed was 1560 m/s. The nylon string with a diameter of 0.6 mm ($0.8\lambda_0$) was highly refractive with a sound speed of 2600 m/s. A line receiver with 80 individual elements $0.7\lambda_0$ apart was used as the receiving array, with coupling between elements measured and taken into account in the processing. The magnitude of the complex reconstruction of a single pipe and string is shown in Fig. 9. This image was built up from 32 views. It appears to be qualitatively correct except for the bright spot in the pipe wall; this can be attributed to the nonoptimal element spacing. These authors employed the same technique to image the heart of a rabbit (size$\approx$24 λ_0), but the result is qualitative at best. Much remains to be done before high quality reconstructions can be realized.

Another potential application of diffraction tomography is imaging ocean microstructure, the perturbations in the sound speed field on scales less than a meter. Since the relative variance of these perturbations is on the order of 10^{-8}, the forward scattering problem is well modeled by either the Born or the Rytov approximation. Theoretical investigations have used diffraction tomography to recover realizations of such diffuse continua. Microstructure can also be modeled as an anisotropic random medium governed by a set of statistics. Tomographic techniques can then be used to estimate these statistics (Rouseff, 1989).

At larger oceanic scales, the effects of refraction dominate those of diffraction. This situation is discussed in the following section.

4. RAYS IN A WAVEGUIDE: OCEAN TOMOGRAPHY

Observing the ocean is an exceedingly challenging task because of the wide range of oceanic time and space scales. Spatial scales range from millimeters to megameters, while temporal variability ranges from seconds to years. Oceanographic measurements until recently have typically been point measurements in space and/or time. Aliasing because of undersampling has been the nemesis of oceanographers since the founding of the discipline over a hundred years ago. Satellite sensors will help a great deal in that they offer very rapid measurements over essentially the entire surface of the Earth, but they do not provide information on the interior of the ocean. However, the ocean is transparent to sound, and oceanic processes change the sound speed field by several percent. These facts led to the idea of ocean acoustic tomography, a method for using sound to probe the three-dimensional structure of the oceans.

This concept was formalized by Munk and Wunsch (1979). Their idea, reminiscent of medical x-ray tomography, was to transmit sound between instruments in a moored array over ranges of hundreds of kilometers. A mesoscale eddy or some other ocean feature would affect the travel times along some transmission paths but not others (Fig. 10). Because of practical limits on the number of instruments involved and thus the number of data, one must deal with many individual transmission paths rather than a projection made up of many paths. Geophysical inverse theory is used to sort out the magnitudes and locations of the perturbations. This measurement technique has many attractive features. Compared with conventional sampling methods, relatively few instruments are needed to sample a large volume because the number of data grows quadratically with the number of instruments, rather than linearly as with point measurements. Furthermore, because of the ocean sound speed channel (discussed in the next section), sound travels along many different paths sampling different depths, so information on the depth structure can be obtained from a single source-receiver pair. Because the measurement inherently averages the ocean along the path the sound takes, small-scale ocean processes are averaged out, thus improving the resolution of the larger scale features. Also, because sound travels faster with a current than against one, differential travel time is a measure of the water velocity along the path.

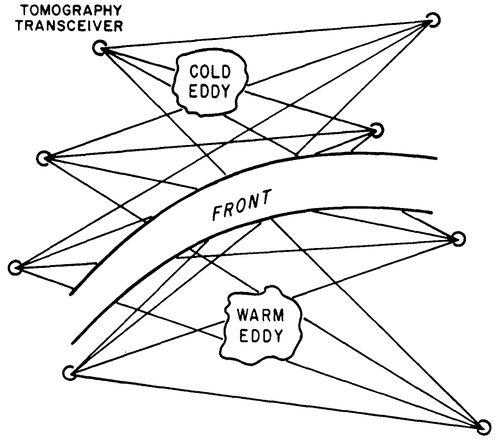

FIG. 10. Acoustic transceivers send and receive pulses along many paths. Inhomogeneities such as eddies and fronts alter the sound speed and thus change the travel times (from Spindel, 1986; ©American Society of Mechanical Engineers).

4.1 Forward Problem

Before one can use measured travel times to obtain maps of sound speed (roughly proportional to temperature) or currents, one must be able to predict the travel times for a given sound speed field. The feature that most distinguishes ocean tomography from other kinds of tomography is the ocean sound channel. The speed of sound (inversely proportional to the index of refraction) typically decreases from the surface as the water temperature decreases, but then increases due to the competing effects of pressure (see ACOUS-

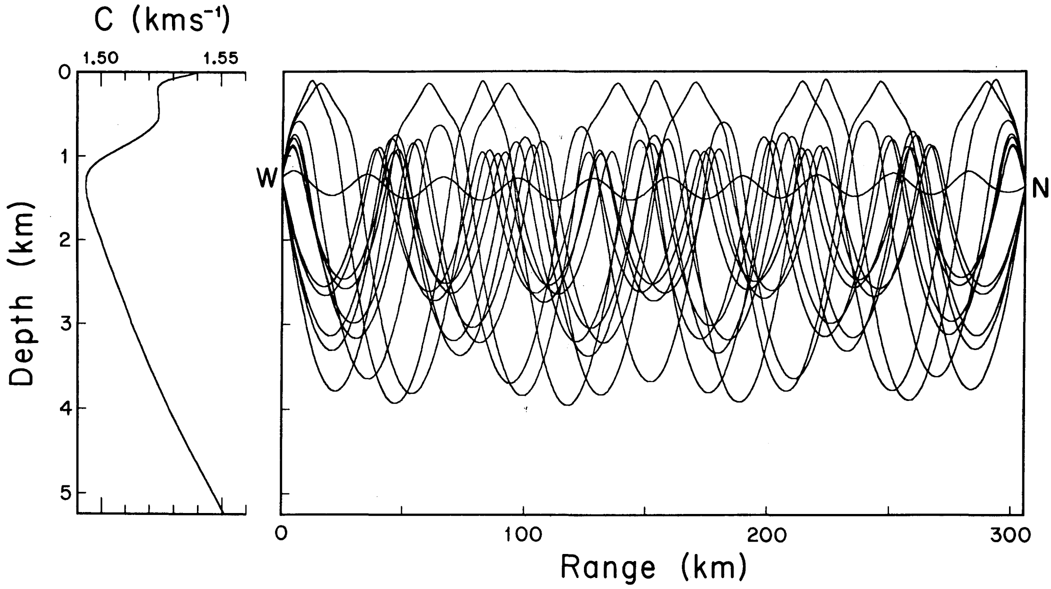

FIG. 11. (Left) Reference sound speed profile $C_0(z)$. This range-averaged profile was obtained by smoothing fairly deep historical data with profiles obtained every 20 km to 1800 m depth. (Right) Corresponding eigenrays. Note the ray groups with shallow and deep upper turning points as well as the axial ray (from Howe *et al.*, 1987).

TICS, UNDERWATER). The effect is to produce a waveguide; sound in the waveguide or channel is constantly being refracted back toward the axis of the channel and travels along many quasisinusoidal rays (Fig. 11). Typical ray "wavelengths" are 50 km. The sound leaves an omnidirectional sound source in all directions; only sound leaving at specific launch angles along eigenrays (Fermat paths) will intersect a receiver. The energy from a single transmitted pulse will be split up among the various rays and will arrive at the receiver at different times, not only because the different rays have different lengths but because they go through regions of the ocean with different sound speed. A typical arrival pattern is shown in Fig. 12.

The success of the method depends on several essential features of ocean acoustic propagation. Separate ray arrivals must be resolved, the arrival pulse must be identified with a known ray path, and the ray paths must be stable over the duration of the experiment. A 1979 experiment verified that arrival patterns remained stable over long periods of time; mesoscale and other oceanic processes merely distorted but did not confuse the pattern (Spiesberger *et al.*, 1980). The small changes in the travel times of the ray arrival peaks are the data for tomography. Typical changes in travel time due to sound speed perturbations and currents are 100 and 10 ms, respectively.

In the geometric optics approximation the travel time along a ray path Γ_i in the presence of a current $\mathbf{u}(\mathbf{x}, t)$ is

$$T_i(t) = \int_{\Gamma_i} \frac{ds}{C(\mathbf{x}, t) + \mathbf{u}(\mathbf{x}, t)\cdot\boldsymbol{\tau}}, \tag{7}$$

where $\boldsymbol{\tau}$ is a unit vector tangent to the ray and s is arc length. The sign of $\mathbf{u}\cdot\boldsymbol{\tau}$ depends on the direction of propagation, and the travel times in opposite directions differ because of the effects of currents. The ray paths Γ_i are obtained using a numerical eigenray code. Equation (7) is analogous to Eq. (1) but is for one ray rather than a multitude of parallel paths.

The travel-time path integral [Eq. (7)] is nonlinear in propagation velocity. Defining a reference sound speed field $C_0(\mathbf{x})$, one has

$$C(\mathbf{x}, t) = C_0(\mathbf{x}) + \delta C(\mathbf{x}, t), \tag{8}$$

where the perturbation sound speed $\delta C(\mathbf{x}, t) \ll C_0(\mathbf{x})$. Substituting in Eq. (7), forming perturbation travel times, and linearizing gives

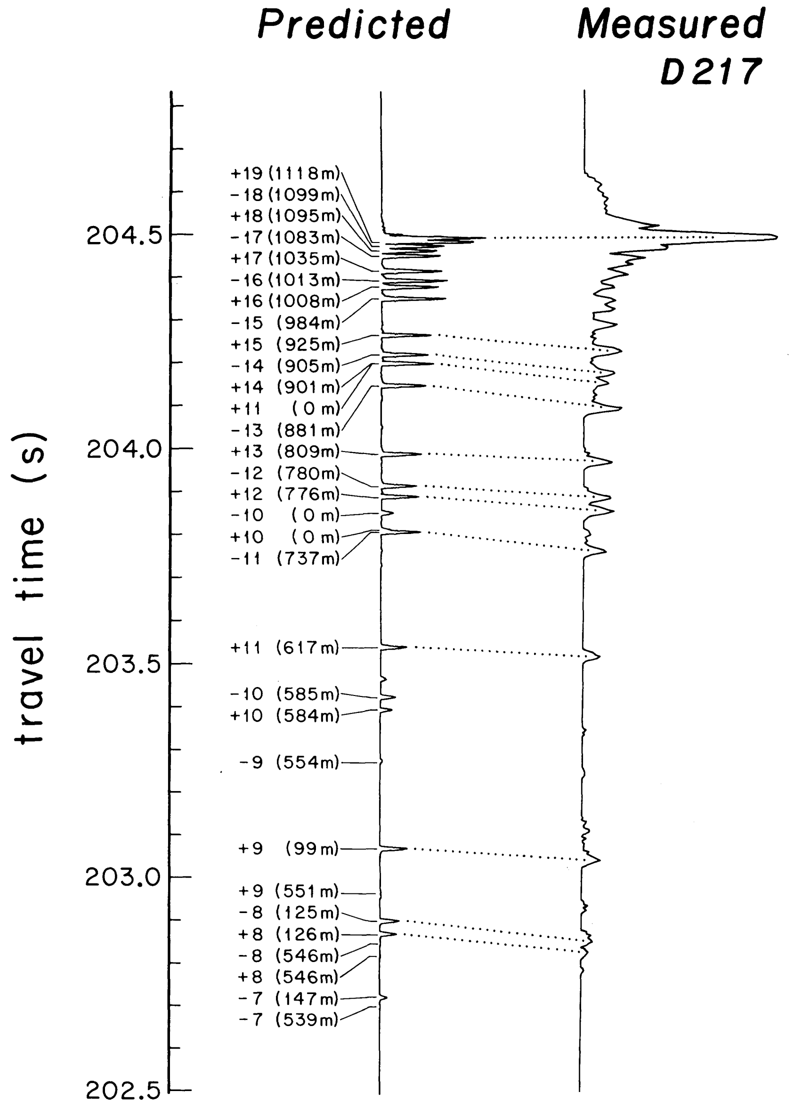

FIG. 12. Comparison of the predicted and measured arrival patterns. The patterns represent sound pressure amplitude at a hydrophone (arbitrary units) vs time. The measured arrival pattern is an average for day 217. The predicted arrival pattern was calculated from $C_0(z)$ using the WKBJ method of Brown (1982). Geometric eigenray arrivals are labeled $\pm n(\hat{z}^+)$ where positive (negative) rays depart upward (downward) from the source, have a total number of upper and lower turning points n, and have upper turning depths $\hat{z}^+$ (from Howe *et al.*, 1987).

$$\delta T_i^+ = T_i^+ - T_{0i} = -\int_{\Gamma_{0i}} \frac{[\delta C(\mathbf{x}, t) + \mathbf{u}(\mathbf{x}, t)\cdot\boldsymbol{\tau}]}{C_0^2(\mathbf{x})}\, ds, \tag{9}$$

$$\delta T_i^- = T_i^- - T_{0i} = -\int_{\Gamma_{0i}} \frac{[\delta C(\mathbf{x}, t) - \mathbf{u}(\mathbf{x}, t)\cdot\boldsymbol{\tau}]}{C_0^2(\mathbf{x})}\, ds. \tag{10}$$

The superscript plus (minus) refers to propagation in the $+(-)$ $\mathbf{x}$ direction; $\boldsymbol{\tau}$ is negative in the second case since propagation is in the $-\mathbf{x}$ direction. The ith reference ray path Γ_{0i} is determined in the reference ocean $C_0(\mathbf{x})$. The corresponding reference travel time is

$$T_{0i} = \int_{\Gamma_{0i}} \frac{ds}{C_0(\mathbf{x})}. \tag{11}$$

Forming sums and differences gives

$$s_i = \tfrac{1}{2}(\delta T_i^+ + \delta T_i^-) = -\int_{\Gamma_{oi}} \frac{\delta C(\mathbf{x}, t)}{C_0^2(\mathbf{x})}\, ds, \qquad (12)$$

$$d_i = \tfrac{1}{2}(\delta T_i^+ - \delta T_i^-) = -\int_{\Gamma_{0i}} \frac{\mathbf{u}(\mathbf{x}, t)\cdot\boldsymbol{\tau}}{C_0^2(\mathbf{x})}\, ds. \qquad (13)$$

The problem has separated: s_i is linearly related to the sound speed perturbation, while d_i is linearly related to the water velocity $\mathbf{u}\cdot\boldsymbol{\tau}$ along the ray path.

4.2 Inverse Problem

Equations (12) and (13) constitute the acoustic forward problem: Continuous δC and $\mathbf{u}$ fields are used to predict a finite data set s_i and d_i. The corresponding inverse problem uses the measured data to estimate the continuous fields. The problem is an underdetermined one because values of the δC and $\mathbf{u}$ fields must be specified at all $\mathbf{x}$ using only a finite number of data. To proceed, the fields δC and $\mathbf{u}$ are parametrized with a finite number of discrete parameters by a model that is oceanographically meaningful. This procedure has three advantages: The parametrization can be very efficient, the inverse solution can become more accurate because the model injects our oceanographic knowledge concerning permissible structure of the fields (reducing the degrees of freedom), and the procedure can be used to evaluate data-model consistency.

Current models are represented by a linear combination of basis functions describing the horizontal (x, y) and vertical (z) structures,

$$\delta C(x, y, z) = \sum_{i,j,k} a_{ijk}\, X_i(x) Y_j(y) Z_k(z). \qquad (14)$$

The coefficients a_{ijk} are the model parameters we are trying to determine. The horizontal dependence is often taken to be a truncated Fourier series or, even more simply, pixels. The functions describing the vertical dependence $Z_k(z)$ are chosen to efficiently parametrize expected variations in the ocean. Typically they are functions based on oceanographic theory or data which describe the dominant modes of variability (see OCEANOGRAPHY).

To obtain estimates of the model parameters and thus the sound speed anomaly from the measured travel times, the "stochastic inverse" of geophysics (see GEOPHYSICS) is used (Aki and Richards, 1980). The method assumes that an *a priori* estimate of the mean and covariance of the unknown field exists, and constructs an estimator that minimizes the square of the difference between the estimate of the unknown field and the true field. In the overdetermined case, this reduces to the weighted least squares fit where the sum of the squares of the data residuals (weighted by the inverse of the data error) is minimized and the *a priori* information is not necessary. In the mixed or underdetermined case, the problem is constrained by adding the *a priori* information about the model parameters. In the absence of any data, the best estimate of the field is simply the *a priori* estimate of the mean, and the associated error is just the *a priori* estimate of the covariance. The stochastic inverse provides a rational way of combining measurements and *a priori* information. Such a method is almost always necessary in geophysical, data poor, situations.

The generalized forward problem can be written

$$\mathbf{d} = \mathbf{G}\mathbf{m} + \mathbf{n}. \qquad (15)$$

The vector $\mathbf{d}$ contains the data, for instance the s_i in Eq. (12), and $\mathbf{m}$ contains the "true" model parameters [the a_{ijk} in Eq. (14)]. $\mathbf{G}$ is the matrix of partial derivatives $G_{ij} = \partial d_i/\partial m_j$ relating the model parameters to the data, obtained by substituting the model Eq. (14) into Eq. (12) and differentiating, while measurement noise and uncertainty in the forward problem physics and model are incorporated in the noise vector $\mathbf{n}$. The stochastic inverse operator is given by (Aki and Richards, 1980)

$$\mathbf{L} = \mathbf{W}\mathbf{G}^T(\mathbf{G}\mathbf{W}\mathbf{G}^T + \mathbf{E})^{-1}. \qquad (16)$$

The matrices $\mathbf{W}$ and $\mathbf{E}$ are the model and data error covariances, respectively. The estimated model parameters $\hat{\mathbf{m}}$ are given by

$$\hat{\mathbf{m}} = \mathbf{L}\mathbf{d}. \qquad (17)$$

The model parameters are a linear combination of the data.

In a mixed or underdetermined problem it is important to have a measure of how well each model parameter is resolved by the data. The resolution matrix $\mathbf{R}$ is defined by

$$\hat{\mathbf{m}} = \mathbf{R}\mathbf{m}. \qquad (18)$$

The $\mathbf{G}$ matrix along with the covariance matrices enter into the calculation of the resolution matrix (Menke, 1989). The resolution matrix shows how well the combined measuring system and the reconstruction method are able to determine each model parameter. Ideally **R** is the identity matrix so that the estimated model parameters $\hat{\mathbf{m}}$ equal the true model parameters **m**. Unfortunately, this is rarely the case.

If a Fourier spectral model is being used, the resolution matrix will tell how well each Fourier coefficient is resolved, i.e., how well Fourier space is filled, in a way analogous to the Projection Slice theorem. If a simple pixel model is used, one can directly obtain the impulse response, i.e., how well a unit perturbation in one pixel is reconstructed, and how the reconstruction depends on the values in all the other pixels.

When data are time dependent, one can use a Kalman filter to assimilate new data. The field at the new time is first estimated from the old field using either a rigorous physical model, such as a three-dimensional, primitive equation numerical model, or *ad hoc* methods such as letting the field decay to the *a priori* values with some characteristic time scale. The error covariance is estimated in a similar fashion. The inverse is then performed with these estimates of the mean and covariance of the field, producing a new estimate of the mean and error covariance.

Over long ranges it is no longer valid to assume the ray paths in the reference ocean are "close" to the ray paths in the actual ocean. This introduces a nonlinearity, the degree of nonlinearity being proportional to range and the average eddy energy along the path (Spiesberger, 1985; Munk and Wunsch, 1987). For a horizontal array of instruments with many crossing paths in the horizontal, the first inversion should be able to place the eddies in approximately the right location, at least within a fraction of a ray wavelength (implying some resolution at all wave numbers). Simple iteration should converge to the correct solution. For a single-slice experiment, there is some information in the travel times about range dependence, but it is not clear whether there will be enough information for an iteration to converge.

In the source localization problem (e.g., finding submarines), one takes the entire measured wave form over a large spatial array and solves for source position; this is called matched field processing and incorporates aspects of matched filtering, backpropagation, and holography (Baggeroer *et al.*, 1988). This is done by assuming various source positions and predicting the wave form at the array until the difference between the predicted and measured wave forms is small. This technique is in its infancy and will most likely have to include sound speed variability. In the typical ocean tomography case, the instrument positions are usually known to within a few tens of meters and this position residual can be included as a model parameter in the (linear) inverse. In the localization problem, the position is not known to even a convergence zone, making the problem very nonlinear with many local solutions. The links between the tomography and localization problems are being actively pursued.

4.3 Examples of Ocean Tomography

An ocean acoustic tomography system requires instruments capable of sending and receiving acoustic pulses whose duration is short enough to resolve separate ray arrivals, that are precisely timed to allow absolute measurement of travel time, and are strong enough to be received above the ambient noise. A short duration pulse implies a broad bandwidth signal; present sources have a bandwidth approaching 100 Hz which gives a pulse width of 10 ms. Precision time keeping (1 ms/yr) is accomplished by using rubidium frequency standards in the underwater instruments. Even the loudest acoustic sources available (193 dB re 1 μPa at 1 m) do not produce enough energy in a 10 ms pulse to be heard at any significant distance. The remedy has been to transmit a long, coded signal, spreading the signal energy out in time, and then in the signal processing to recombine the energy to make it appear as if it all had been sent in one loud pulse. The signals sent are pseudorandom, phase-modulated sequences; the processing is called replica cross correlation, which is closely related to matched filtering. (The Hadamard transform is used to do this efficiently.) A signal processing gain of 35 dB is typical.

One of the tomography transceivers presently being used is shown in Fig. 13. The instruments are deployed on single-point, subsurface oceanographic moorings. Although the moorings are designed to be quite stiff,

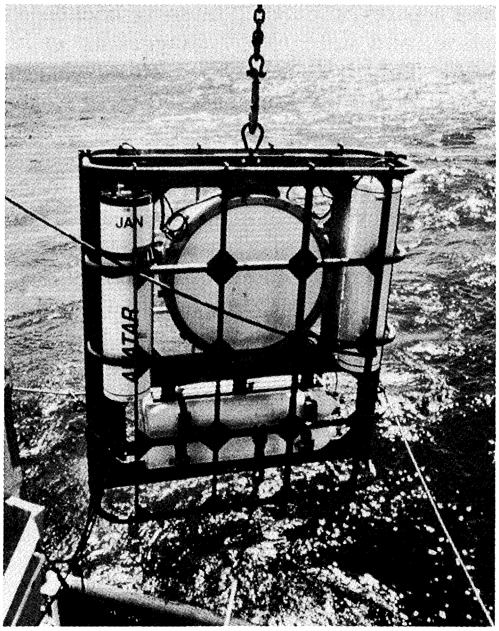

FIG. 13. Tomography transceiver used in the 1986/1987 Gyre-Scale Reciprocal Transmission Experiment. This is a second generation transceiver, using an HLF-5 acoustic source from Hydroacoustics Inc. and a newly designed set of electronics. The high-pressure nitrogen bottles in the bottom of the cage are used to pressure compensate the source at its operating depth of approximately 1000 m. The cage is 2.4 m high, 2.1 m wide, and about 1 m thick; it weighs roughly 1590 kg in air and 590 kg in water (from Munk and Worcester, 1988; © 1988, The Oceanography Society).

their motion in response to ocean currents is measured with a long-baseline acoustic navigation system to account for changes in range between the instruments.

The first ocean tomography experiment, billed a "demonstration," was conducted southwest of Bermuda in 1981. Four sources and five receivers were deployed on the perimeter of a 300-km square. Sources with a center frequency of 224 Hz and a bandwidth of 10 Hz were used, producing pulses with 100 ms widths. This was less than optimal, but these sources were the only ones available at the time. Nevertheless, there were sufficient data to construct maps of the sound speed field (Fig. 14) (Cornuelle *et al.*, 1985).

Travel time differences between co-located sources and receivers can be used as a measure of currents (Fig. 15). The signal-to-noise ratio of the travel time difference depends on how nearly reciprocal the paths in each direction are; if the paths are exactly reciprocal, then the effects of internal waves on the one-way travel times (3–10 ms rms) will cancel. In the 1983 reciprocal transmission experiment over 300 km, the reciprocal noise variance was smaller than the one-way noise variance by a factor of 10.

More recently, three tomography transceivers were deployed in the northeast Pacific in a 1 Mm triangle for four months. The primary purpose of the experiment was to measure large-scale gyre vorticity or swirl: By measuring the current velocity along each leg of the triangle using reciprocal transmissions, one can calculate the circulation around the triangle, $\int \mathbf{u} \cdot d\mathbf{l}$. This is in turn proportional to the average vorticity by Stokes's theorem. The vorticity is a desirable quantity because it is the basis for much of theoretical oceanography, yet it has never been measured directly on large scales. This experiment exploits the integrating (projection) nature of the method to filter out the mesoscale features, leaving the gyre-scale features of interest.

There are several ocean tomography projects in progress. One involves six moorings deployed in September 1988 in the Greenland Sea for one year. This area far to the north is interesting because it is thought that very cold, dense water forms during the winter in small-scale overturning events, then sinks, and finally spreads throughout the world ocean. This has never been directly observed; it is hoped that the tomography data will show indications of these events. A complicating feature of acoustic propagation in polar waters is that the sound speed monotonically increases with depth producing a surface-bounded waveguide; all rays are surface reflected. Acoustic energy propagating within several hundred meters of the surface is not well modeled by ray theory. The dual of rays, normal modes, is necessary to describe the propagation.

The moorings in the Greenland Sea are also being used for engineering tests of moving ship tomography (Cornuelle *et al.*, 1989). A simulated geometry is shown in Fig. 16. The idea in this application is to obtain a "snapshot" of the ocean by circumnavigating the moored array, dipping a hydrophone array every 4 h or 70 km to listen to the sources, and thereby building up a net of many rays. This is an obvious analogy to x-ray tomogra-

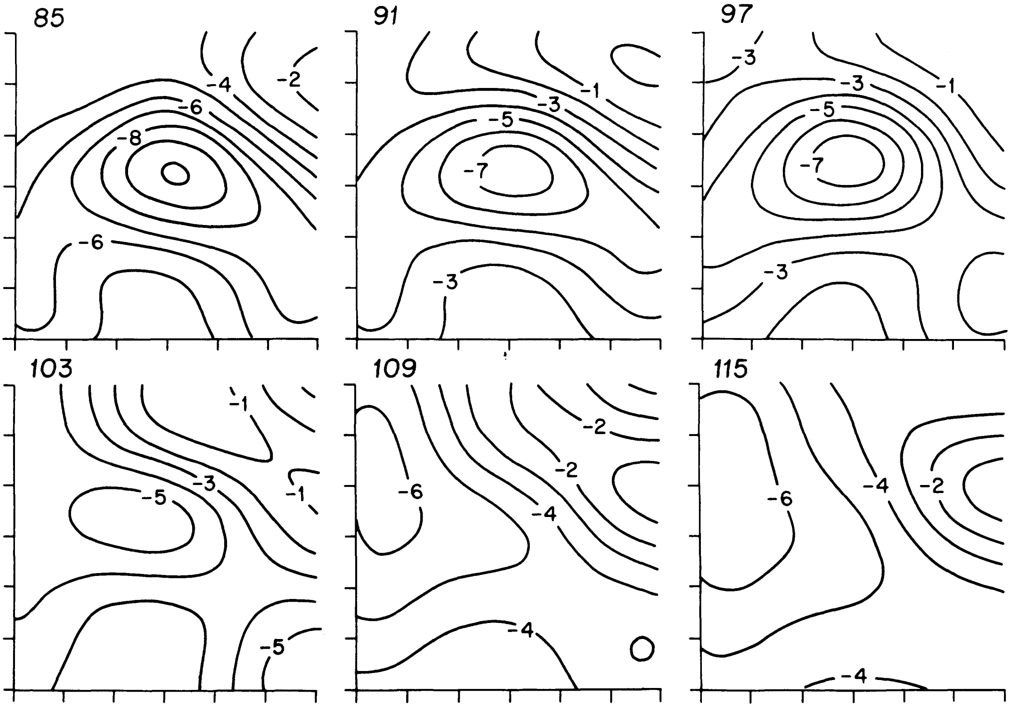

FIG. 14. The acoustic travel time data obtained in the 1981 Ocean Acoustic Tomography Experiment were used to draw maps of the sound speed field at 700 m depth in the 300 km by 300 km area of the experiment (each panel). Maps at 6-day intervals from year day 85 through year day 115 show a cold eddy with low sound speed remaining stationary for several days and then moving rapidly out of the experiment area beginning on year day 103. The sound speed contours relative to 1506 m/s are drawn at intervals of 1 m/s, which roughly corresponds to a temperature change of 0.2 °C. Maps at other depths can also be constructed from the acoustic data (from Munk and Worcester, 1988; ©1988, The Oceanography Society).

phy. For this technique to succeed, it is necessary to locate the receiving hydrophones to better than 10 m accuracy. Two acoustic tracking systems are being used in conjunction with the NAVSTAR Global Positioning System, a very long-baseline system using satellites.

Munk and Forbes (1989) have proposed placing a source off Heard Island south of Australia and listening to it as far away as Bermuda and California. This idea is motivated by the reanalysis of a 1960 experiment in which a 140-kg explosive charge was detonated off Perth, Australia, and heard in Bermuda some four hours later. Such long-range transmissions will average out much of the ocean variability, and it is possible that changes in travel time will be proportional to global-scale changes in ocean temperature. Munk and Forbes calculate that a 4 mdeg C/yr change corresponds to a 100 ms/yr change in travel time for a Heard Island–California path. A major unanswered question is whether the forward problem can be adequately solved so that a quantitative inversion can be made. Ultimately, a tomographic network is envisioned where sources and receivers will be distributed around the world, continually monitoring the global ocean.

5. CONCLUDING REMARKS

The ultimate physical limit to spatial resolution in any tomography experiment is the acoustic wavelength. The image quality and accuracy achieved in a particular experiment will depend on a multitude of factors including the number of transducers, the number of views, the size of the viewing aperture, and the signal-to-noise ratio. All of these are controlled to a large extent by practical considerations such as geometry, signal processing, and cost (Schueler *et al.*, 1984).

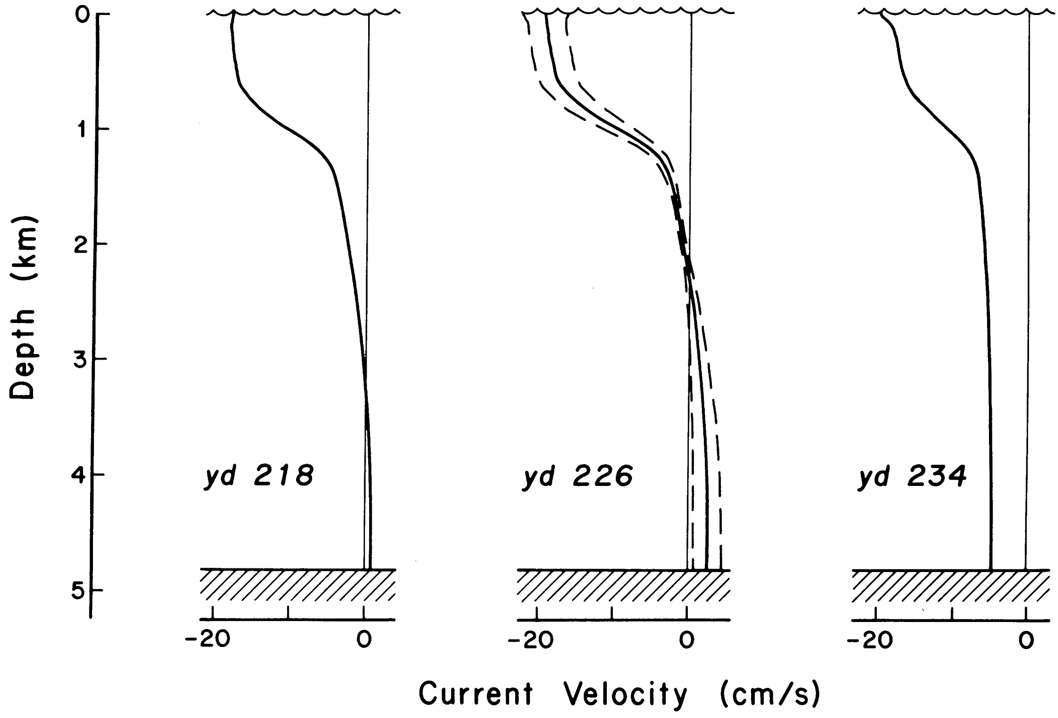

FIG. 15. The differences in travel times between sound pulses traveling in opposite directions in the 1983 Reciprocal Acoustic Transmission Experiment were used to compute the average current velocity in the 300-km-long vertical slice between the transceiver moorings as a function of depth. Three profiles obtained at 8-day intervals show the slow changes that occur in the current profiles in the ocean. All have stronger currents near the surface than at great depths, as is typical of ocean currents. The calculated errors in the profiles are approximately 1 cm/s, as shown by the dashed lines around the central profile. Note the change from a baroclinic mode structure on year day 218 to a strong barotropic (top-to-bottom) component on year day 234 (from Munk and Worcester, 1988; ©1988, The Oceanography Society).

However, the accuracy of any quantitative reconstruction will be directly related to the quality of the forward-problem solution. Any inaccuracies in the forward problem will appear in the inversion or reconstruction. This is the major problem facing diffraction tomography with strong scattering. The Born and Rytov approximations are often not valid, implying that higher order scattering needs to be taken into account as well as three-dimensional effects. This will make the problem nonlinear and thus even more difficult. With desktop minisupercomputers becoming more common, brute force numerical approaches may be appropriate.

Straight-ray tomography is relatively easy to perform, but again the accuracy of the forward problem must be checked. For instance, a ray trace through the reconstructed sound-speed field should be done to see if the differences in travel times along the curved rays are significantly different from those along the straight rays, or whether diffraction effects are important.

Ocean tomography is just evolving from the testing and demonstration stage and is at the point where useful oceanographic measurements are starting to be made. Current research is focused on improving horizontal resolution by making use of the special nature of the ocean waveguide and the ocean structure (Cornuelle and Howe, 1987), recasting the forward/inverse problems in terms of acoustic normal modes, creating synthetic apertures with moving instruments, and using long range transmissions aimed at basin and global monitoring.

Many difficult problems remain to be solved before acoustic tomography becomes a common tool of scientists and engineers. It is clear, though, that acoustic methods can yield information that is either unobtainable any

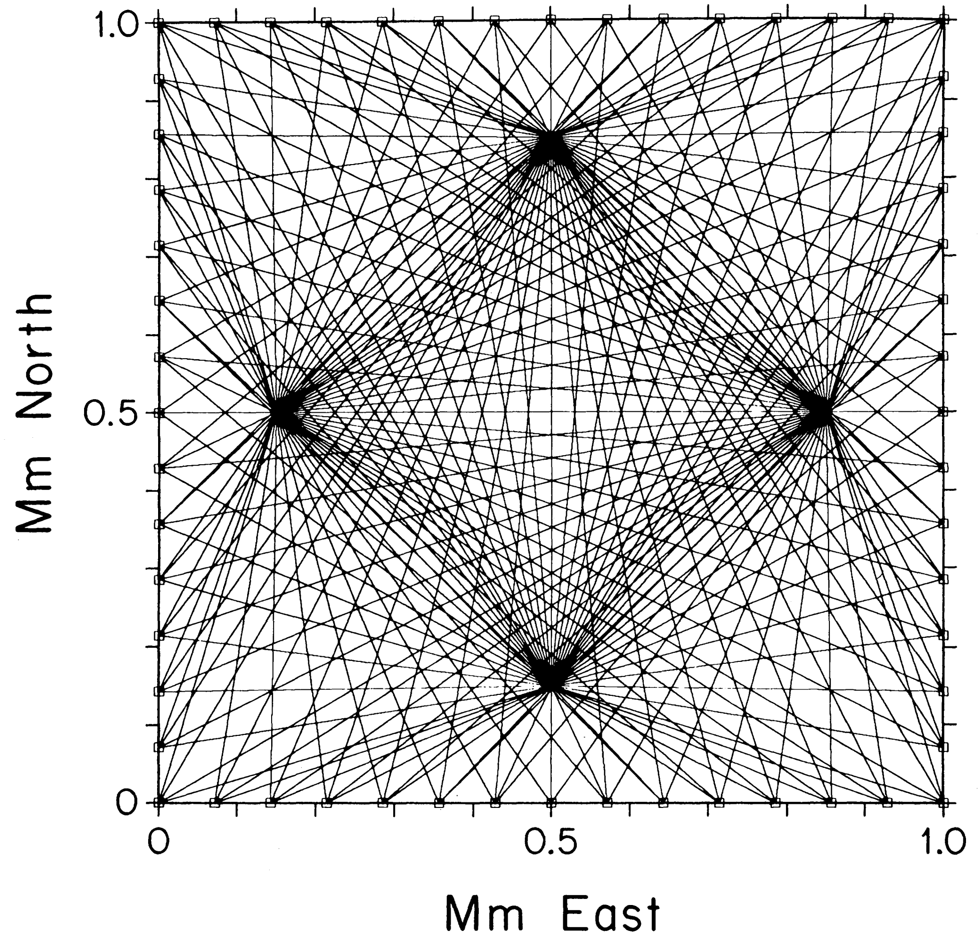

FIG. 16. Plan view of the ray geometry in a simulated moving-ship tomography experiment. Four sources are located on a 350-km-radius circle about the center of a 1000-km by 1000-km square. Receivers are located at approximately 70-km intervals around the square. In this simulation the ocean is assumed to be two dimensional, with no vertical structure; straight-line ray paths can therefore be used in the calculation. The inversion procedure (using realistic travel-time and positioning errors) leads to mapping which accounts for 95% of the mesoscale variance. Subsequent 3-D simulations with vertical multipaths lead to similar mapping errors. In this preliminary simulation all receptions are assumed to be simultaneous. The actual experiment will be conducted by lowering a receiver from a ship at roughly 70-km intervals as it transits around the square. This involves "nowcasting" in a 4-D (space + time) environment (from Munk and Worcester, 1988; ©1988, The Oceanography Society).

other way or complementary to results from other methods.

GLOSSARY

Born Approximation: Linearizing approximation in scattering theory. Approximates unknown total field in a scatterer by the known incident field.

Diffraction: Deviation of energy from straight ray paths due to effects other than reflection or refraction. Occurs when size of irregularities in a medium become comparable to the wavelength of the probing wave.

Forward Problem: Predicting data given the parameters which affect the data.

Fourier Diffraction Theorem: Fundamental theorem of diffraction tomography. Fourier-domain relationship between measured data and unknown scatterer.

Inverse Problem: Determining the parameters which affect measured data.

Projection-Slice Theorem: Fundamental theorem of conventional straight-ray tomography. Fourier-domain relationship between measured data and unknown object.

Ray: A curve whose tangent at any point lies in the direction of propagation of a wave.

Refraction: The bending of a wave as it passes through regions with varying wave velocities or indexes of refraction.

Tomography: Imaging procedure that uses multiple views to produce quantitative cross-sectional reconstructions of an object.

Waveguide: A physical situation which constrains or guides the propagation of waves by reflection off solid boundaries and/or by refraction within the medium.

INTRODUCTION

The basic concern of architectural acoustics is to provide a satisfactory acoustical environment in any space of a building. Essentially, this requires an integration of the physical and technical aspects of acoustics and building technology with the psychological and subjective requirements of the users of the building. On the technical side, the physical behavior of sound both in a space and in the building structure itself must be understood. On the subjective side, it is necessary to understand how the users of a building react to an acoustical environment in any of a number of situations including privacy, intelligibility, annoyance, task interference, sleep disturbance, enjoyment of the performing arts, etc. Architectural acoustics must therefore relate human responses to the physical stimuli of sound, and provide such information to the architects, designers, and engineers responsible for a building.

The two basic areas of architectural acoustics discussed in this article are room acoustics and sound isolation. Room acoustics in-

digital Encyclopedia of Applied Physics

volves the characteristics of sound in the air, together with the effects on the sound by the shape, size, and materials of the boundary surfaces of the space. Sound isolation deals with the manner in which sound is transmitted between spaces in a building. In each of these areas, both the physical characteristics of, and the human response to, sound are discussed. This article concentrates on the characteristics of sound in buildings and its effect on building technology, and, as such, does not include such topics as the basics of sound which are covered in detail in other articles of this publication.

Architectural acoustics as a specific discipline had its beginnings at the turn of this century with Wallace C. Sabine at Harvard University, whose work primarily involved the development and understanding of reverberation. He was the first to develop relationships between the objective measurements of sound in spaces and criteria of human judgments. The field of architectural acoustics, however, did not show any significant advances from the late 1920s until the 1950s. During the 1930s extensive research was completed in acoustics, but on the physical aspects of sound, primarily supported by the communications industry. In the 1940s the emphasis in acoustics was on war-related activities such as sonar, radar, speech perception in high noise levels, etc. The post-war building boom of the 1950s finally gave architectural acoustics the opportunity to expand but, due to the lack of actual building experience, it was difficult for those in the field to apply effectively all of the acoustical research that had been completed over the prior 50 years. This was caused by the practical limitations on advances in architectural acoustics which are directly related to the building industry itself. Since a typical building project can take from five to ten years from design to occupancy, advances in the field tended to be slower than in other applications of acoustics. However, by the 1970s acoustical consultants had achieved extensive experience with a large number of buildings and building types. At present, significant research in architectural acoustics continues both by practitioners in the field as well as by university researchers, based not only on experience with actual buildings, but also on the advances in model testing and computer simulation in which theoretical and analytical studies can be applied without the expense and long time delay associated with the construction process.

Public awareness of the effects of noise has also played an important role in the development of architectural acoustics as evidenced by the numerous design standards currently mandated by such agencies and authorities as the Department of Housing and Urban Development, the Uniform Building Code, various Departments of Public Health, Department of Transportation, local building codes and ordinances, etc. In current practice, architectural acoustics is an important part of the building design process, and its influence extends to a wide variety of building types including multifamily dwellings, hotels, office buildings, work environments, educational facilities, hospitals, etc., rather than just to performing-arts projects, which traditionally have required architectural acoustics design assistance.

1. ROOM ACOUSTICS

Room acoustics is primarily involved with sound in three dimensions within an enclosed space. It is therefore concerned not only with sound traveling in the air, but also with the effects on sound by the enclosure, which include the influences of the size, shape, reflection, and absorption characteristics of the boundary surfaces. Based on the type of information desired in studying the acoustics of enclosures, two basic approaches for analyzing sound can be used. For situations in which transient events are important, as in rooms for speech and music, time domain analysis is the most informative. Where a steady-state sound field is important, as in noise isolation situations, frequency domain analysis is the most useful. The human ear may be considered as a frequency-sensitive pressure transducer with a sufficiently wide bandwidth so as to be very responsive to transients. The ear is also quite directionally sensitive, particularly in determining azimuth along the horizon.

1.1 Sound in Enclosed Spaces

A large space has dimensions that are typically many times the wavelength of any sound wave being considered. Therefore, a sound source will excite many normal modes of vibration in the sound field. The sound field in a large room can be described either in terms of the mean square sound pressure or by the intensity, or net power flow per unit area, of the sound waves that travel around the room. Since pressure is a scalar quantity it can be measured using a single pressure-sensitive microphone. Intensity, on the other hand, is a vector quantity and requires directional information, with measurements usually utilizing a computer plus either two pressure microphones or one pressure microphone and a velocity-sensitive microphone. (Ordinary directional microphones used in the entertainment field give the total, but not the net, sound power flow in a given direction.) Both the mean square sound pressure and the intensity are influenced by the sound source and by the properties of the enclosure. Near a sound source the sound field has a relatively high level, and in such regions there is an identifiable flow of energy away from the source. This is the direct field. Far from the source, the direct sound becomes weak in comparison to the reverberant sound, which consists of the energy reflected from the various surfaces of the room. This is the reverberant field.

For example, the first sound that a listener receives in a room is the sound that travels directly from the source to the listener. It will arrive at a time

$$t_0+r_d/c, \tag{1}$$

where t_0 is the time (in ms), r_d is the distance (in m), and c is the speed of sound (in m s^{-1}). The intensity of the sound will be equal to

$$I_0-x_d, \tag{2}$$

where I_0 is the intensity at the source position (in W m^{-2}) and x_d is the attenuation.

The attenuation x_d consists of both the attenuation due to spherical spreading of the sound and that due to the molecular absorption effect of the air. After the direct sound has arrived at the listener there will be a series of sounds that have traveled by other paths which include one or more reflections from the surfaces of the room. Each reflected sound will arrive at a time

$$\sum_{i=1}^{n} (t_0+r_i/c), \tag{3}$$

where r_i is the total distance traveled by the sound reflections.

The intensity of each reflected sound will be

$$\sum_{i=1}^{n} (I_0-x_i), \tag{4}$$

where x_i is the respective attenuation.

The attenuation of these reflected sound waves will not only include the two factors contained in Eq. (2), but will also include the effects of absorption encountered at the boundary surfaces.

1.1.1 Room Modes. When a sound is generated in an enclosure, a sound wave spreads out in all directions from the source until it encounters a boundary surface, where it is reflected off the walls, floor, and ceiling and travels around the room in every direction. If each path that the sound wave travels is traced around the room, there will be certain paths that will be repeated and room resonances or standing waves will occur. Each room has its normal modes of acoustic vibration or resonances, and its normal or resonant frequencies, with the total number of modes asymptotically approaching, at sufficiently high frequencies, a number which is directly proportional to the volume of the enclosure. There are three types of normal modes n in an enclosure of dimensions l_x, l_y, and l_z: axial, in which the sound waves are reflected only by two opposite surfaces (one dimensional; two of the indices n_x, n_y, and n_z are equal to 0); tangential, in which the sound waves are reflected from two pairs of surfaces (two dimensional; one of the indices n_x, n_y, and n_z is equal to 0); and oblique, in which the sound waves are reflected from all boundary surfaces (three dimensional; all of the indices n_x, n_y, and n_z have nonzero values). For simple rectangular spaces it is possible to calculate the frequencies of these room resonances. The characteristic frequencies or normal modes of a rectangular enclosure are given by

$$f_n=(c/2)[(n_x/l_x)^2+(n_y/l_y)^2+(n_z/l_z)^2]^{1/2}, \tag{5}$$

where f_n is the resonant frequency (in Hz); c is the speed of sound in air (in m s^{-1}); n_x, n_y, and n_z identify the mode of vibration and can be any integers, 0,1,2,...; and l_x, l_y, and l_z are the dimensions of the room (in m). At the lower frequencies the room resonances are widely spaced so that with broadband acoustic excitation, it is relatively easy to hear the tonal or spectrum peaks at the resonant frequencies. As the frequency increases the resonances become spaced very close together. In typical spaces with some sound absorption present at the boundary surfaces, the width of the resonant frequency peaks of contiguous normal modes becomes greater than the spacing between peaks, and eventually are so close together that the overlapping peaks coalesce into a continuum and achieve a relatively uniform transmission characteristic. It is interesting to note that for every mode of vibration in a rectangular enclosure the sound pressure is maximum at the corners.

Equation (5) applies only to rectangular spaces. This same type of simple mathematical analysis is not available for more complex room shapes, but although they cannot be predicted easily, resonant frequencies still exist. For example, a change in the shape of a room from rectangularity shifts the frequencies of the normal modes, making them extremely difficult to compute, although the total number of modes remains essentially the same, assuming the room volume remains constant.

1.1.2 Steady-State Sound Field. When a constant sound source begins to operate in a quiet architectural enclosure, it will initially emit energy in all directions and the sound pressure level will increase until it exponentially approaches a steady-state value in which the sound energy being removed from the space in each frequency band is equal to the sound energy produced by the source. The process is complicated by interference between the waves reflected from the room surfaces and the waves emitted directly from the source, thus producing spatial standing waves and also time-domain unevenness in the growth of the sound field which is sometimes heard as audible "beats." At steady state, the source excites normal modes. The degree of mode excitation within each frequency band depends on the acoustic power of the source, the source location with respect to any standing-wave patterns, source acoustic impedance, and the bandwidth of each mode. The direct field exists close to the sound source and the energy flow is away from the source. The steady-state energy density of the direct field is

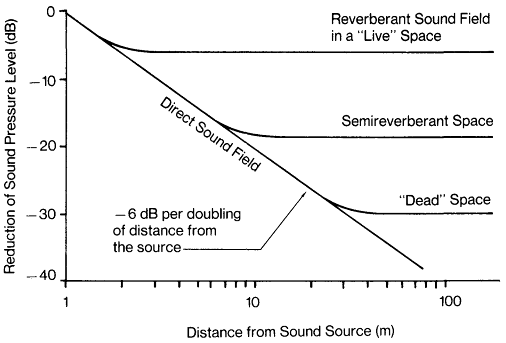

FIG. 1. Effect of sound absorbing boundary surfaces on the reverberant sound field in an enclosure. The direct field in a reverberant (or "live") space dominates for only a short distance out from the sound source, whereas in a highly absorptive (or "dead") space the direct field can predominate for long distances from the sound source.

$$D_0 = WQ_\theta / 4\pi r^2 c, \tag{6}$$

where D_0 is the energy density of the direct field (in W s m^{-3}), W is the acoustic power output of the source (in W), Q_θ is the directivity factor of the source in a particular direction θ (dimensionless), and r is the distance from the source (in m).

As the distance from the source increases the energy density of the direct sound field becomes equal to, and eventually less than, that of the reverberant field. In the reverberant field all of the sound waves have been reflected at least once from the boundary surfaces of the enclosure. The more absorptive the boundary surfaces are, the greater the reduction of the reflected sound energy that will occur, as indicated in Fig. 1. The steady-state energy density of the reverberant field is defined as

$$D_R = 4W/cR, \tag{7}$$

where D_R is the energy density of the reverberant field (in W s m^{-3}), R is the room constant, defined as

$$R = S\bar{\alpha}/(1-\bar{\alpha}), \tag{8}$$

where S is the total surface area of the room (in m^2) and $\bar{\alpha}$ is the average absorption coefficient, defined as

$$\bar{\alpha} = \frac{S_1\alpha_1 + S_2\alpha_2 + \cdots + S_n\alpha_n}{S_1 + S_2 + \cdots + S_n}. \tag{9}$$

At a certain distance from the source, the contributions to the sound pressure level from both the direct and reverberant fields will be equal. This distance is defined as the "room radius," r_r, and is equal to

$$r_r = (RQ_\theta/16\pi)^{1/2}. \tag{10}$$

Architecturally significant reduction, i.e., greater than 3 dB, of the sound level at a distance less than the room radius from an omnidirectional source cannot be achieved by adding sound absorbing material to the space since the direct sound predominates.

1.1.3 Decay of the Sound Field. When the sound source in an enclosure is stopped, the sound will persist for a time, as determined by the volume of the space and the amount of sound absorption present (see Sec. 1.4). The direct sound from the sound source will die away first, and the various components of the reverberant field will disappear one by one as the end of each field passes the observation point. The component waves will continue to impinge on the various boundary surfaces of the enclosure with the energy of the sound field being, for a continuum of modes, continuously and exponentially absorbed. During this decay, modes with the slowest decay rates dominate, and, for frequencies with widely spaced modes, this decay may result in very noticeable beats, "boominess," or "hollowness." The total energy in the enclosure at any instant equals the average energy density D_R times the room volume V. The number of times per second that a given sound wave will impinge upon a room boundary surface will depend on the average distance traveled between boundaries. This average distance is called the mean free path of the enclosure, which can be approximated by

$$4V/S, \tag{11}$$

where V is the room volume (in m^3) and S is the total surface area (in m^2). Thus the number of reflections occurring in 1 s will be equal to the speed of sound, c, divided by the mean free path.

Assuming a diffuse sound field in the enclosure, after a length of time the energy of the reverberant field will be reduced by numerous encounters with the boundary surfaces in a continuous process. Therefore, the reverberant sound field decays typically in small steps, beginning the instant that the last of the direct field is reflected from the boundary surfaces of the enclosure. The stepwise sound field decay is approximately exponential at a rate given by

$$1.086\,\frac{c}{V}\left(\sum_{i=1}^{n} S_i \ln(1-\alpha_i)\right)\quad \text{dB/s}, \tag{12}$$

where S_i is the surface area of each material in the enclosure (in m^2) and α_i is the absorption coefficient of each material.

A diffuse sound field is defined as one in which the sound pressure level is the same throughout, and it is equally probable that sound waves are traveling in every direction. This characteristic also ensures that the average energy density is the same at all points. In reality, a completely diffuse sound field cannot exist; however, the concept of a diffuse sound field is useful in spaces that are not highly absorptive, and in fact, near-diffuse sound fields can be achieved.

1.2 Sound Reflections

Sound reflections are the return of sound waves from the boundary surfaces of an enclosure and are essential for achieving good hearing conditions in a space, such as an auditorium. The signal strength, direction of arrival, time of arrival, and frequency content of the reflected sound are important factors, and in large spaces they provide the distinctive acoustical "signature," good or bad, associated with the space.

1.2.1 Geometrical Reflections. When a sound wave strikes a uniform boundary surface that is large compared with the wavelength of the sound, the reflection can be considered to be specular, and the ray can be traced similar to the reflection of light as used in geometrical optics. Analogous to light rays, sound rays are reflected from hard plane surfaces in accordance with the laws of reflection, i.e., the angle of the incident ray equals the angle of the reflected ray. Similarly, sound rays striking a curved surface will be focused or dispersed depending on whether the surface is concave or convex, as shown in Fig. 2. This approach is commonly used for investigating the effects of various shapes of proposed spaces on the distribution of sound within that space. For the most part, the use of concave surfaces as sound reflecting ele-

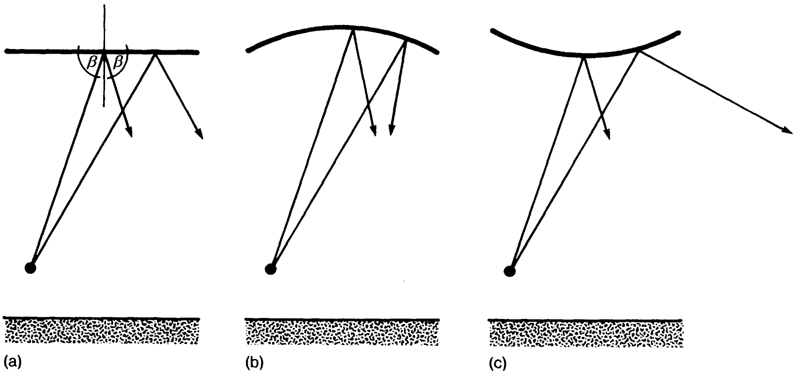

FIG. 2. Sound reflection characteristics from various types of boundary surfaces in an enclosure. The reflection patterns are similar to light reflectance in geometrical optics in that the angle of incidence of a sound wave is equal to the angle of reflection from a hard, plane surface (a), is focused from a concave surface (b), and is diffused from a convex surface (c).

ments should be avoided since this shape will cause focusing effects, time-smearing of transient sounds, discrete echoes, and nonuniform distribution of sound. It is often tempting for architects to use this shape for the rear wall of an auditorium since it follows the curve of the seating which is laid out in concentric arcs. Other examples of architectural spaces that typically exhibit focusing effects are those with barrel vaults or domed ceilings. Convex surfaces, on the other hand, disperse the reflected wave and are useful for achieving a diffuse sound field in the space. Caution must be used, however, in the application of the laws of reflection since this simplification of the behavior of sound is only valid for sound at the mid and high frequencies. In general, the minimum dimension of a surface should be on the order of at least two to four times the wavelength of the incident sound in order to achieve reflection. Surfaces smaller than this will not provide reflection, but rather diffraction of the incident sound wave.

1.2.2 Diffraction and Diffusion. When a sound wave strikes an object of finite size some of the energy is reflected, some is absorbed or transmitted, and, in general, some gets around the object, i.e., is diffracted. The extent of the diffraction and its scattering pattern depends on the relationship between the wavelength of the sound and the size of the object. In performance spaces the diffraction effects that accompany the reflection of sound are important and necessary. The architectural and decorative treatment of a room, such as columns, beams, balcony faces, statuary, niches, alcoves, etc., provides discontinuities in the boundaries of the space, and the pattern of the sound field distribution is altered by the scattering of the sound. This adds to the diffusion in the space, which helps to establish a more uniform distribution of the sound, ensures a perception of smooth growth and decay of the sound field, and improves the subjective degree of "liveness" of the room. Another means of increasing the diffusion of the sound in a space is through the use of randomly distributed areas of sound absorptive material on the boundary surfaces. Both diffusion and diffraction can be achieved by this means due to phase shifts in the diminished sound wave reflected from the absorbing material and from sound diffraction due to the edge effect (see Sec. 1.3.2).

An interesting development regarding diffraction and diffusion in broad directional patterns for use in performance spaces began in the 1970s with the use of number theory by Schroeder. Diffraction grating designs were developed for both two- and three-dimensional sound diffraction and diffusion, based on real or complex periodic number sequences fashioned from quadratic residues, primitive roots, primitive polynomials in finite number fields, the Legendre symbol, the index function, the Zech logarithm, etc. These diffusing elements consist of a periodic array of wells of equal width, but different depths, separated by thin dividers. The well-depth sequences provided by the diffraction grating achieve both a time distribution of the backscattered sound as well as a uniform angular dispersion over a broad, designable frequency range.

1.3 Sound Absorption

Sound absorption is the primary factor in reducing noise and controlling reverberation in a space. Sound absorption can occur both at the boundary surfaces of a space and by the air contained within the enclosure. At the boundary surfaces absorption is achieved by converting the acoustic energy of a sound wave into heat through thermal lag and viscous drag. When a sound wave encounters a boundary surface a portion of the energy is absorbed, the amount depending on the surface material, and the remaining energy is reflected back to the space. The amount of sound absorption of a material is defined in terms of its absorption coefficient α, which is a ratio of the sound energy absorbed to the sound energy incident upon that surface. A perfect absorber would have an absorption coefficient of 1, while a perfect reflector would have an absorption coefficient of 0. The unit of sound absorption, $S\alpha$, is called a sabin, which is dimensionless, and is equal to the area of a sound absorbing material times its sound absorption coefficient at each frequency of concern. The total sound absorption in a space, therefore, is equal to the sum of the products of the areas of all of the surfaces and materials, and their absorption coefficients, i.e.,

$$\sum S\alpha = S_1\alpha_1 + S_2\alpha_2 + \cdots + S_n\alpha_n, \qquad (13)$$

where $\Sigma S\alpha$ is the total sound absorption (in sabins); and $S_1\alpha_1, S_2\alpha_2, \ldots, S_n\alpha_n$ are the areas of each material in the space times its absorption coefficient.

The absorption coefficient of a material will vary with the angle of incidence of the sound wave. However, most published absorption coefficients for building materials are obtained from measurements in reverberation chambers which are designed to achieve a near-diffuse reverberant sound field, and therefore the reported absorption coefficients are for near-random incidence of sound. From these measurements, the absorption coefficients for materials are obtained for six standard octave band-center frequencies; 125, 250, 500, 1000, 2000, and 4000 Hz. In current practice, some manufacturers of sound absorbing materials do not report the absorption coefficients for their products, but rather publish a single-number rating called the noise reduction coefficient (NRC), which is the arithmetic average (to the nearest increment of 0.05) of the absorption coefficients at 250, 500, 1000, and 2000 Hz. The NRC can be used to select sound absorbing materials for noncritical spaces or for general noise control applications, but should not be used in the design of critical or acoustically sensitive spaces.

A common misconception continues to exist throughout the building industry regarding which materials to use for sound absorption and which for sound isolation. Sound absorption and sound isolation are entirely different functions and require materials with entirely different physical characteristics. Sound absorption typically requires a lightweight, porous material, which allows the air molecules to move in and out freely, but retarded mostly by viscous drag. Sound isolation, on the other hand, requires a heavy, impervious barrier to block air movement. Applying a sound absorbing material to the surface of a wall will reduce the reverberation in the space, but will not provide any meaningful increase in the amount of sound isolation provided by the wall itself.

1.3.1 Sound Absorbing Properties of Materials. All materials absorb sound to some degree. The three basic mechanisms through which sound absorption can be achieved, using standard building materials, are porous materials, resonant panels, and resonant air cavities. Each of these types provides absorption in a different manner and as a result has distinctive absorption characteristics. The generalized sound absorption characteristics of the three types of absorbing mechanisms are shown in Fig. 3.

1.3.1.1 Porous Absorber. Porous, fibrous materials are by far the most commonly used type of sound absorption in architectural acoustics design and include such standard finish materials as carpet, drapes, upholstered furniture, acoustical tile, etc. This type of material is characterized by its pores, which are exposed to the air of a room. Sound absorption is achieved when the air

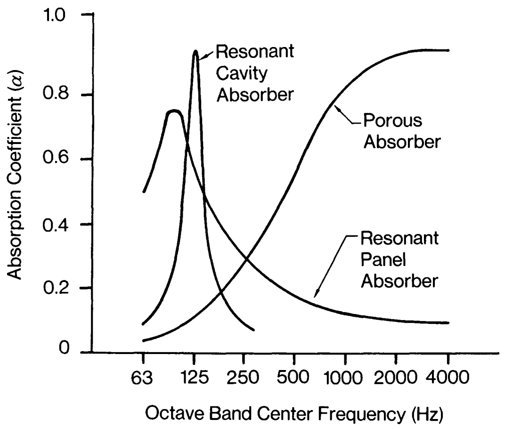

FIG. 3. Typical sound absorption characteristics of standard building materials. Porous materials absorb acoustic energy over a broad frequency range. Resonant absorbers, such as panel absorbers and cavity absorbers, absorb acoustic energy over narrow frequency ranges near their resonant frequencies.

pressure at the material increases and decreases due to successive sound waves which force the air molecules in the connected pores both to vibrate and also to undergo heating and cooling through compression. This rapid motion of the air molecules results in the loss of acoustic energy due to conversion to heat through viscous, linear friction. Another damping mechanism is irreversible heat conduction from the air into the material and back. The latter is significant at low frequencies in closed cavities, such as within walls. The amount of sound absorption achieved in each type of porous material is determined by such physical properties as thickness, density, porosity, fiber or pore orientation, and flow resistance. Of these properties, flow resistance and thickness are usually the most important. As a sound wave encounters a porous material the amplitude of the air particle vibration is progressively damped by friction against the sides of the pores, thus acting as an acoustic resistance. The specific flow resistance of a layer of porous material is defined as

$$R_1 = \Delta p / Tu, \tag{14}$$

where R_1 is the specific flow resistance (in rayls m^{-1}) (the unit "rayl" is equal to $\mathrm{N\,s\,m^{-3}}$), Δp is the air-pressure differential between the two sides of the material (in $\mathrm{N\,m^{-2}}$), T is the thickness of the material (in m), and u is the apparent particle velocity through the sample (in $\mathrm{m\,s^{-1}}$), calculated using the face area of the material and not the actual flow area. If R_1 is too small, insufficient friction will result and little absorption will occur. If the value of R_1 is too great, the particle velocity is reduced and too much reflection will occur at the face of the material due to too large an impedance mismatch. This is the reason why painting a porous material can significantly decrease its sound absorbing performance. It is interesting to note that in architectural acoustics applications, typical sound levels produce airflows small enough that essentially all sound absorption is through viscous and thermal losses, and is well described by linear equations. Turbulent dissipation, on the other hand, involves drag which is proportional to the square of the particle velocity and, if significant, can result in audible frequency distortion of the sound field. Experimentally, this distortion becomes audible with some materials at particle velocities associated with sound levels above approximately 120 dB, which are not typically encountered in architectural acoustics situations.

The sound absorbing performance of a porous material can be increased at the mid and lower frequencies by increasing the thickness of the material, as indicated in Fig. 4. Maximum sound absorption will occur in a porous absorber when the airflow, or particle velocity, is at a standing-wave maximum or antinode. This occurs when the distance from the wall is equal to one-quarter wavelength, $\lambda/4$. Thus, in order to absorb low-frequency energy the absorber must either be very thick or else be mounted $\lambda/4$ in front of a rigid wall.

1.3.1.2 Resonant Panel Absorber. Absorption can also be achieved by constructing a resonant panel system which consists of a thin, impervious, flexible material mounted at some distance out from a rigid wall. A sound wave incident on the flexible surface will cause it to resonate, and thereby absorb sound, at a characteristic frequency. At frequencies other than near the resonant frequency the absorption is poor. Sound absorption with this type of system is achieved by converting the sound energy incident on the panel into mechanical energy and heat. The resonant frequency of this system is determined by the panel stiffness, the stiffness of its supports, panel thickness, mass, and depth of air space. If the panel material is thin and

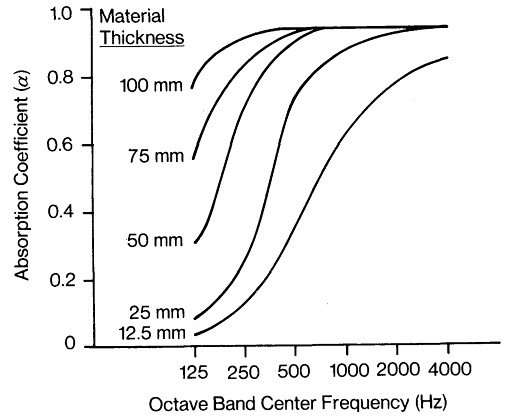

FIG. 4. Effect of thickness on the sound absorbing characteristics of porous materials. Absorption is most effective when the thickness of the porous material is equal to at least one-quarter wavelength of the sound. Thus the lowest frequency at which a material can effectively absorb acoustic energy decreases as the thickness of the material increases, or as the material is moved away from the wall.

flexible the resonant frequency can be approximated by

$$f_{\mathrm{res}}=60/\sqrt{Md}, \tag{15}$$

where M is the surface mass of the panel (in kg m^{-2}) and d is the depth of air space (in m). Increasing either the mass of the panel or the depth of the air space will lower the resonant frequency of the system. Resonant panel absorbers are most practical for absorption in the lower frequencies, i.e., 200 Hz and below, and generally will be thinner than a porous absorber of similar performance in the same frequency band. The frequency bandwidth over which the resonant panel absorber will provide effective absorption depends on the amount of damping within the system. A heavily damped system will act over a wider frequency range, but the amount of absorption provided at the resonant frequency will be less. Few resonant panel absorbers are commercially available, and typically must be designed and constructed as required for a specific installation. It can be noticed that spaces built with large areas of thin wood paneling on the walls are often unintentionally weak in low-frequency "bass" energy, resulting in a sound quality which is acoustically "bright" and lacking in "warmth." This is due to the excess absorption of the wood paneling acting as efficient resonant absorbers at the lower frequencies.

1.3.1.3 Resonant Air Cavity Absorber.

The third type of absorber is a resonant air cavity, volume resonator, or Helmholtz resonator, which consists of an enclosed volume of air connected to the room by a small opening or neck. Sound energy in the room near the resonant frequency will cause the air in the restricted neck to vibrate. Energy is absorbed primarily by friction of the air particles that pump back and forth along the neck. Architecturally, the neck of this type of absorber is usually either a round hole or a slot.

With this type of absorber, increasing the resistance to air movement by adding a porous material, either to the neck or to the air cavity, is a standard practice. The primary reason for this is that some sound energy is transferred into the air cavity which stores it instead of dissipating it. When the sound in the room is stopped the stored resonant energy is reradiated back into the room, thus prolonging the room reverberation. Adding a porous material to this type of resonator also has the effect of increasing the frequency range over which it will provide effective absorption, but as with the resonant panel absorber, this reduces the peak absorption at the damped resonant frequency.

The resonant frequency of an undamped Helmholtz resonator with a circular neck can be approximated by

$$f_{\mathrm{res}}=(c/2\pi)\sqrt{S/Vl}, \tag{16}$$

where c is the speed of sound (in m s^{-1}), S is the cross-sectional area of the neck (in m^2), l is the length of the neck (in m), and V is the volume of the enclosed air volume (in m^3).

As with the resonant panels, the architectural resonant air cavity provides useful absorption primarily at the lower frequencies. This type of absorber also has a somewhat limited application, but several products are commercially available in the form of structural masonry units that can be used for wall constructions. The two major types of masonry units currently available are ceramic blocks with holes leading into the enclosed air chamber or cell, and concrete blocks with slots leading into the cell. Both of these products can be provided with a porous absorbing material in the cells. These products can withstand moisture and other adverse weather conditions, and are therefore useful for some industrial, exterior locations such as enclosures for transformers and mechanical equipment.

1.3.2 Measurement Procedures. The absorption coefficients of acoustical materials are typically obtained by measuring the time rate of decay of the sound energy density in a certified reverberation room with and without a test specimen present. The procedures required for measuring the absorption coefficients are fairly strict and must follow those established by the American Society for Testing and Materials (ASTM), Designation C423, "Standard Test Method for Sound Absorption and Sound Absorption Coefficients by the Reverberation Room Method," or the International Organization for Standardization (ISO), Recommendation R354, "Measurements of Absorption Coefficients in a Reverberation Room." The ASTM standard requires that the minimum volume of the room shall not be less than $V=4\lambda^3$ based on the center frequency of the lowest one-third octave frequency band at which measurements are to be made. For the one-third octave band centered on 125 Hz, for which the wavelength λ is 2.75 m, this requires a minimum room volume of 82 m^3. The ISO recommendation is for a room volume larger than 180 m^3, preferably as close to 200 m^3 as possible. In order to achieve a near-diffuse reverberant sound field in the room, a number of angled sound reflective panels are required. These can be both fixed, which are hung and distributed at random angles, and moving, on a rotating shaft or other mechanism.

The size of the sample to be tested is standardized, as are the proportions or aspect ratio, so that test specimens can be compared on an equal basis. For the ASTM standard the size of the test specimen is 6.7 m^2, in a shape of 2.44 m $\times$2.74 m. For the ISO procedure the recommended specimen size is between 10 and 12 m^2, in a rectangular shape with the ratio of the sides between 0.7 and 1. The size and aspect ratio are specified because a test specimen with a narrow rectangular shape will generate excessive diffraction effects at the perimeter, or "edge effects," resulting in an unrealistically high absorption coefficient.

The reverberation time is measured in the test chamber with and without the presence of the test specimen. The absorption coefficient of the test specimen is then determined by dividing the excess absorption by the area of the test specimen. Note that since the sound absorption of a material depends not only on the physical properties of the material itself, but also on the manner in which the material is mounted or installed, the mounting used for the test specimen must also be known. According to ASTM Designation E795, "Standard Practice for Mounting Test Specimens During Sound Absorption Tests," there are eight standard mounting configurations that can be used for determining the absorption coefficients of a material. For example, most manufacturers of acoustical ceiling board products test their materials in a configuration approximating a typical suspended ceiling with an air space of 400 mm between the face of the material and backing surface (type E-400 mounting). This same ceiling board product will provide significantly different absorption coefficients, particularly much less at the lower frequencies, when tested in a mounting configuration where the material is adhered directly to a surface (type B mounting). It is important to use the absorption coefficients determined from the mounting configuration closest to that condition in which the material will actually be used.

Even with the strict requirements for the design of a reverberation room and standardized measurement procedures, the measured absorption coefficients will vary somewhat between testing laboratories due to such factors as microphone positions, loudspeaker positions, test specimen position, room geometry, and diffuser geometry. Another peculiarity that occurs in the measurement of absorption coefficients is that the value can exceed unity for a highly absorptive material. This is caused by diffraction effects at the edges of the material, i.e., the previously noted "edge effect," which increases the apparent absorption coefficient. The ASTM standard recommends that no adjustments be made to absorption coefficients greater than 1, but requires that the data be reported as measured.

Table 1. Sound absorption coefficients for common building materials and furnishings.

[a] These values are for the floor area occupied by the seating or audience (in m^2), and include an "edge effect" equal in area to a strip 0.5 m wide for each aisle bordering the seating area.

1.3.3 Absorption Coefficients. Table 1 lists typical absorption coefficients of common building materials and furnishings.

1.3.4 Noise Reduction by Sound Absorbing Materials. The installation of sound absorptive materials at the boundary surfaces of an enclosure can shorten the reverberation time, lower the level of the reverberant sound field, and help to localize the noise to the region of its source, i.e., its direct sound field. As indicated in Eq. (7), increasing the amount of absorption in a space decreases the energy density of the steady-state reverberant field. However, the level is never significantly reduced in the direct field closer to the noise source than the room radius [see Eq. (10)]. Noise reduction provided by the addition of sound absorbing material to a space can be determined by

$$D = 10 \log_{10}(A_2/A_1), \qquad (17)$$

where D is the amount of noise reduction (in dB), A_1 is the total amount of sound absorption before treatment (in sabins), and A_2 is the total amount of sound absorption after treatment (in sabins).

1.3.5 Air Absorption. In large enclosures sound energy can be absorbed by the air itself, particularly at the higher sound frequencies. For reverberation time calculations (see Sec. 1.4) the amount of sound absorption provided by the air must be included in the total absorption for the enclosure, the total absorption being the sum of all absorbing features, including those due to the losses at the boundary surfaces and the furnishings in the space. If an enclosure is small the number of reflections from the boundary surfaces is large, while the distance traveled by the sound waves between the boundaries is small. In this situation air absorption is typically not as important as the boundary absorption and can usually be ignored. However, if the enclosure is very large, for the same number of reflections from the boundary surfaces, the distance traveled by the sound waves through the air is much greater and the energy loss, or absorption, can be significant.

Air can absorb acoustic energy by two methods: classical absorption, which is caused by heat conduction and air viscosity; and molecular absorption, which is due to rotational and vibration relaxation of the air molecules. In architectural acoustics situations, the amount due to classical absorption is insignificant. The amount of absorption due to molecular absorption, however, can range from negligible amounts below 1000 Hz to large amounts in large spaces and at high frequencies. In practice, air absorption is typically considered for the octave band-center frequencies at 2000 Hz and above.

There are several methods used for predicting the amount of air absorption, which include such variables as room volume, air temperature, humidity, and frequency. Not all of these prediction methods are in agreement. The classic study, which empirically

Table 2. Molecular absorption of sound in air per cubic meter of room volume (at 20 °C).

Relative humidity	Octave band-center frequency 2 kHz	4 kHz	8 kHz
30%	0.012	0.038	0.136
50%	0.010	0.024	0.086
70%	0.009	0.021	0.060

determined the amount of absorption provided by air, was completed by Harris in 1966. The results of this study are summarized in Table 2 and show the amount of sound absorption provided by the air based on the volume of the enclosure and relative humidity.

1.4 Reverberation Time

Reverberation time is perhaps the most widely recognized term from the field of architectural acoustics. Sound which is generated in an enclosed space is repeatedly reflected by its boundary surfaces where it is absorbed, transmitted, or reflected. Once the sound source has ceased, a fraction of the acoustic energy is lost at each reflection. The time that it takes the sound energy to decrease by a factor of one million, or the sound pressure by a factor of 1000, i.e., 60 dB, is defined as the reverberation time, T_{60}. The reverberation time is therefore controlled by the volume of the space, i.e., the larger the enclosure, the farther the sound must travel between reflections, and the type and amount of sound absorption in the space, i.e., the higher the absorption coefficient, the greater the decibel loss per reflection.

1.4.1 Reverberation Equations. The three most commonly used reverberation equations, Sabine, Eyring, and Fitzroy, are discussed below.

1.4.1.1 Sabine Equation. Reverberation time was first defined by Sabine from his empirical work, beginning in 1895, on the acoustics of the then new lecture hall in the Fogg Art Museum at Harvard University. His work established the quantitative relationship between the room volume and the sound absorption provided by the room's finish materials, furnishings, and occupants. The Sabine equation for reverberation time is

$$T_{60}=0.161\,V/\Sigma S\alpha, \qquad (18)$$

where T_{60} is the reverberation time (in s), V is the room volume (in m^3), and $\Sigma S\alpha$ is the total sound absorption in the room (in sabins).

Note that the unit of sound absorption, $S\alpha$, is called the sabin in honor of Sabine's pioneering work.

1.4.1.2 Eyring Equation. For noncritical design situations, the Sabine equation predicts reverberation times with adequate accuracy. However, the equation is not completely accurate, particularly in spaces where the total absorption is very large, such as in broadcast studios or other acoustically "dead" spaces. In 1930, Eyring developed an equation that is a more accurate expression than the Sabine equation, based on multiple sound reflections at the enclosure's surfaces and uniform distribution of the sound absorption:

$$T_{60}=0.07V/[-S\log_{10}(1-\bar{\alpha})], \qquad (19)$$

where S is the total surface area of the room (in m^2) and $\bar{\alpha}$ is the average absorption coefficient.

1.4.1.3 Fitzroy Equation. Both the Sabine and Eyring equations assume uniform absorption at all surfaces as well as a diffuse sound field in the space. These conditions are rarely achieved in practice and the equations are not accurate in such nondiffuse spaces where pairs of surfaces are sound reflective and others are absorptive, as in a typically furnished space with carpeted floor, acoustical tile ceiling, and hard walls. In 1959, Fitzroy expanded the Eyring equation to take such uneven distributions of sound absorbing surfaces into account. This equation apportions the reverberation time between the three major axes of a rectangular space which exhibit decay rates dependent on the average absorption of the pair of surfaces in each axis:

$$\begin{aligned}T_{60}=&\frac{x}{S}\left(\frac{0.07V}{-S\log_{10}(1-\bar{\alpha}_x)}\right)\\&+\frac{y}{S}\left(\frac{0.07V}{-S\log_{10}(1-\bar{\alpha}_y)}\right)\\&+\frac{z}{S}\left(\frac{0.07V}{-S\log_{10}(1-\bar{\alpha}_z)}\right),\end{aligned} \qquad (20)$$

where x is the total side wall area (in m^2); y is the total ceiling and floor area (in m^2); z is the total front and rear wall area (in m^2); S is the total surface area of the room (i.e., $x+y+z$)

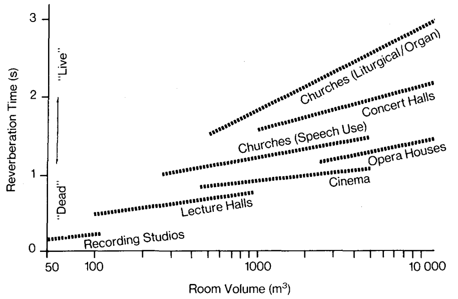

FIG. 5. Approximate range of optimum reverberation times at 500 Hz for fully occupied spaces as a function of the volume and use of the space. The shorter reverberation times in dead spaces provide a high degree of speech intelligibility. Longer reverberation times in live spaces provide "warmth" for music performance.

(in m^2); and $\overline{\alpha}_x$, $\overline{\alpha}_y$, and $\overline{\alpha}_z$ are the average absorption coefficients for the areas x, y, and z, respectively.

1.4.2 Design Criteria for Enclosed Spaces. There are no uniformly accepted values for the "ideal" reverberation time in any type of space. In general, however, a space that is to be used for speech should have a fairly short reverberation time to ensure good articulation and intelligibility. A space to be used for music performance should have a longer reverberation time to achieve adequate "blend" and "richness" of sound. The ranges of reverberation times generally considered acceptable for various types of spaces are shown in Fig. 5. However, since there are no absolute or "perfect" reverberation times for any space, these values should be considered as general guidelines. The values shown are for the reverberation times at mid-frequency, i.e., 500 Hz. For most performance spaces, they should be longer at the lower frequencies and somewhat shorter at the higher frequencies. For spaces which require a high degree of articulation, such as recording studios, music practice rooms, etc., the reverberation times should be fairly constant over the frequency range from 63 to 4000 Hz.

Although reverberation time is an important acoustical characteristic of enclosed spaces, it can be a notoriously unreliable descriptor of overall subjective quality. Comparably sized spaces can have identical reverberation times but, due to numerous other acoustical characteristics, one space can be well regarded while the other considered unsatisfactory. This is because the reverberation time essentially only describes the decay constant of the reverberant energy in the enclosure. Other factors such as reflection characteristics, ratio of early to reverberant energy, sound level, and directional distribution patterns are also important for achieving overall good acoustical characteristics of a space (see Sec. 1.5).

1.4.3 Assisted Resonance Systems. Assisted resonance is a term used to describe various methods of creating an artificial reverberation time in a space by electroacoustic means. This type of system has been used, with varying degrees of success, in performance spaces which require longer reverberation times to compensate for insufficient volume or shape dictated by nonacoustical criteria of the space. This approach has also been used as a specific design element for multiple-use spaces which must accommodate various functions requiring differing reverberation times.

One of the first large performance spaces to use assisted resonance, in this case as a remedial measure, was the Royal Festival Hall in London. Originally opened in 1951, an assisted resonance system was installed during renovation work in 1965 to compensate for the "dryness" associated with the acoustics of the hall. This system is based on regenerated reverberation in which multiple channels, each consisting of a microphone, amplifier, and loudspeaker, are located at pressure maxima for the particular modes whose reverberation needs to be "assisted." The signal for each channel is adjusted to be in phase around the loop, and the gain is adjusted to be approximately 6 dB below the feedback level. The microphones are located towards the rear of the hall, i.e., in the reverberant field, and the loudspeakers near the front. This provides the required time delay so that the reinforced sound occurs later than the direct sound. To achieve appropriate frequency filtering each microphone is installed in a tunable Helmholtz resonator located above the ceiling, with the neck extending into the hall and the bottom of the neck flush with the underside of the ceiling.

One advantage to this type of system is that, since each loudspeaker is operating at only one frequency, the frequency response uniformity of the loudspeaker is not critical.

The disadvantage is the large number of channels required. In Festival Hall there are 172 channels, covering the range of frequencies from approximately 60 to 700 Hz. As a general guideline for this type of system, Parkin, the designer of the system at the Royal Festival Hall, indicates that a system should consist of at least 100 channels. Using this number, a 100% increase in the reverberation time can be achieved at the lower frequency range and approximately a 60% increase at the mid to high frequencies, i.e., up to approximately 2000 Hz.

A second method of electroacoustic enhancement of reverberation is called ambiophony. This system uses microphones to pick up sound close to the source; the signal is mixed and passed through a time-delay element, such as a tape loop, reverberation plate, reverberation chamber, or digital delay device, and then transmitted back to the hall by numerous loudspeakers. The time delays and amplification of the signal from the various loudspeakers must be adjusted and evaluated subjectively until the desired increase in the reverberation time and "natural" sound quality are achieved. The major disadvantage to this type of system is the requirement for locating microphones close to the source, i.e., a very large number of microphones is required for an orchestral performance in a concert hall. This requirement has both practical and aesthetic drawbacks which are generally not acceptable to either typical performing groups or audiences.

A more recent development is the electronic reflected energy system (ERES), which takes a signal from a single microphone located in the sound field near the stage area. The signal is processed through amplifiers, equalizers, and delay systems, and then distributed to loudspeakers located at various positions in the auditorium. The signal is modified and the loudspeakers located so as to simulate sound reflections comparable to those of natural reflections in a performance space, including early reflections, lateral reflections, and reverberant energy. The processed sound provided by this system has a frequency range from approximately 100 to 6000 Hz. The advantage of this type of system is that the acoustical characteristics of a multipurpose space can be quickly modified to accommodate the requirements of various conflicting performance types.

1.5 Auditorium and Enclosure Design

The traditional acoustical characteristics that must be considered in the design of almost any type of indoor or outdoor performance space can be summarized by the following basic requirements:

1. quiet background, which ensures that the wanted signal is not masked by intruding noise from mechanical equipment systems, exterior sources, etc.;
2. adequate loudness and distribution, which ensures that an appropriate sound level of the source signal is achieved at the listening areas, typically through proper shaping of the enclosure surfaces providing reflected energy of suitable strength, direction, frequency content, and the appropriate balance of early to reverberant energy; and
3. reverberation time, to achieve appropriate decay characteristics.

1.5.1 Sound Reflection Design. There are many different approaches and design philosophies to auditorium design. Since the late 1950s, significant research has been completed both in the design of actual spaces and in simulated spaces. However, there is little consensus among designers and researchers on the relative importance of the various factors in auditorium design. Some of the major aspects regarding reflected sound characteristics are summarized below.

1.5.1.1 Early versus Reverberant Sound. The major area of discussion that continues regarding these two critical portions of the sound field is the appropriate balance between the amount and character of the early-arriving sound to the amount of reverberant sound energy. In general, the early sound, i.e., arriving at the listener within 50–80 ms after the direct sound, provides clarity and articulation. Too much early energy produces a harsh, "hi-fi" quality to the sound. The reverberant sound in a space provides blend and richness to the sound quality. Excessive reverberant energy, however, produces a muddy or indistinct sound quality. Establishment of an optimum pattern of early sound reflections should include such parameters as frequency content, energy content relative to the reverberant sound field, time and direction of arrival, etc. To achieve proper early sound reflections, appropriately designed and oriented reflecting surfaces near the performers are required. Note that if two sounds arrive within 10 ms of each other they cannot be distinguished as separate sounds by a normal listener. Further, if a reflected sound arrives within 40 ms of the direct sound, it is also not perceived separately, but rather produces a change of quality and increase in the perceived loudness of the original sound. This is called the Haas precedence effect.

1.5.1.2 Lateral Reflections. The other major factor that has been extensively discussed and researched for the past decade is the proper value of lateral sound reflections in performance spaces, including energy content, frequency content, time of arrival, and angle of arrival. It has been established that the subjective quality of auditory "spaciousness" is a direct function of lateral reflections. This subjective quality consists of such perceptual attributes as spatial impression, spatial responsiveness, apparent source width, envelopment, etc. For the formation of auditory spaciousness binaural dissimilarity of the sound at the listener's position is required, including both interaural arrival time and level differences. Subjectively, interaural coherence is highly positively correlated with the width of the hall, the side walls being the primary source of lateral reflections. This is also one of the major reasons why the early, "classical" European concert hall is well regarded as having good acoustical characteristics. This space, typically classified as a "shoebox" shape, consists of a rectangular space with a high ceiling, which provides adequate reverberant energy, and a narrow width, which provides early, strong lateral reflections from the close side walls.

1.5.2 Subjective Preference Scaling. As a means for establishing the relationship between the objective physical properties of the sound field and the subjective properties as heard by the listener, various subjective preference and evaluation scales have been developed. The main purpose of this type of study is to establish the desired acoustical characteristics of a performance space during the design phase of a project rather than having to correct any deficiencies after construction. This work was initially begun by Beranek in the early 1960s and included such subjective preference parameters as clarity, warmth, intimacy, loudness, balance, etc. More recently, extensive work has been carried out by Barron (1971), Ando (1985), and others to study the relationship of such subjective and objective parameters as preferred listening level, delay time of early sound reflections, reverberation time, and the magnitude of interaural cross correlation. These studies typically involve head-related stereophony, in which either sound fields are recorded in actual performance spaces, or special recordings of musical works are recorded in anechoic chambers. The microphones are located in the ears of a dummy human head to achieve highly accurate reproduction of the sound field, and the recordings therefore include such effects as diffraction of the signal caused by the head and outer ear configuration, time and level differences of the signal at the left and right ear, etc. These recorded data can be reproduced, simulated, or modified using digital computers to achieve direct comparisons of sound fields of various spaces, with subjective measures using paired comparison tests to establish multivariate scaling preferences.

1.5.3 Model Testing and Computer Simulation. Another design tool for studying the acoustical characteristics of a performance space is through the use of scale model testing and computer simulation. The very early acoustical model testing consisted of two-dimensional models such as ripple tanks, in which the paths of sound waves are represented by water wavelets, or optical models, in which the boundary surfaces are constructed of an optically reflecting material for light reflection to simulate sound rays. The use of scale models for actual acoustical measurements was first developed in the 1930s; however, current techniques can provide highly accurate objective evaluation of the acoustical characteristics of spaces. Typically, the preliminary work on a performance space model is completed in a model built at 1:50 scale. Since frequency scales in a linear manner, all elements of the acoustical model can be similarly scaled, including dimensions, wavelength, frequency, absorption coefficients, and time. This scaling factor requires careful selection of the materials used for the finishes of the space in order to achieve acceptably accurate sound absorption coefficients. The most difficult factor to achieve is the appropriate degree of air absorption. To compensate for the excess absorption of air in the scale models some researchers use models filled with nitrogen as the medium, others dry the air to approximately 2% relative humidity to minimize absorption.

After the initial design studies are completed, another model at 1:10 scale is commonly used to refine the objective measurements. The sound source used for the studies is typically an impulse source such as a spark discharge. The signal is measured using $\frac{1}{8}$-in.-diam or $\frac{1}{4}$-in.-diam condenser microphones, often located in a scaled, miniature dummy head (see Sec. 1.5.2), and the signal is processed using analog-to-digital converters and digital signal processing. Use of this type of system can provide accurate information on such acoustical design parameters as the ratio of early to late energy, lateral energy, echograms, reverberation time, loudness levels, etc. The use of scale models, combined with the signal processing capabilities of digital computers, is considered by many researchers to be far more accurate than simulation techniques that use a digital computer alone to calculate the sound field of a performance space. This is primarily due to the lack of proper algorithms for simulating scattering on diffusing surfaces.

2. SOUND ISOLATION

In architectural acoustics, intruding noise sources from both the exterior and interior of a building must be considered. Control of the transmission of intruding noise is of critical importance in the design of spaces, and the amount of noise reduction or transmission loss that must be achieved depends on such factors as the level of the intruding noise; transmission paths, i.e., airborne or structure-borne; frequency content of intruding noise; and the design criteria or level of ambient noise allowable in the space of concern. For noise-reduction design purposes, the type of intruding noise at a space must first be categorized by its primary transmission path, i.e., through the air or through the building structure. The basic sound isolation problem is to reduce the sound pressure level of the intruding noise by sound isolation techniques appropriate to the type of intruding signal.

2.1 Airborne-Sound Isolation

A basic example of airborne-sound isolation can be shown by two spaces located side by side with a wall separating them. In the source room, a noise source produces a reverberant sound field which, when it encounters the boundary surfaces, will be either absorbed, reflected, or transmitted. The amount of sound energy not absorbed or reflected back to the source room will propagate through the wall, the amount depending on the acoustic impedance of the wall compared to that of the air. At the boundary of the adjacent space, the relative impedances of the wall and the air will again determine the percentage of energy transmitted into the receiving room.

2.1.1 Transmission Coefficient and Transmission Loss. Airborne-sound isolation is essentially the reduction of energy transmitted from one space to another. One way to express this is by the flow of sound energy, or transmission coefficient τ, which is defined as the ratio of transmitted acoustic energy to the incident acoustic energy. For a given angle of an incident plane wave in an infinitely large panel, the transmission coefficient is given by

$$\begin{aligned}\tau(\Theta)&=I_t/I_i\\&=\left\{\left[1+\eta\left(\frac{\omega\rho_s}{2\rho c}\cos\Theta\right)\left(\frac{\omega^2B}{c^4\rho_s}\sin^4\Theta\right)\right]^2\right.\\&\quad+\left[\left(\frac{\omega\rho_s}{2\rho c}\cos\Theta\right)\right.\\&\quad\left.\left.\times\left(1-\frac{\omega^2B}{c^4\rho_s}\sin^4\Theta\right)\right]^2\right\}^{-1},\end{aligned}\tag{21}$$

where $\tau(\Theta)$ is the transmission coefficient, I_t is the sound intensity of the transmitted energy (in W m^{-2}), I_i is the sound intensity of the incident energy (in W m^{-2}), η is the composite plate loss factor (dimensionless), ω is angular frequency (in rad s^{-1}), $\rho_s=\rho_m t$ is the plate surface density (in kg m^{-2}), ρ_m is the density of the plate material (in kg m^{-3}), t is the thickness of the plate (in m), ρ is the density of the air (in kg m^{-3}), c is the speed of sound in air (in m s^{-1}), Θ is the incident angle (in degrees), and B is the plate bending stiffness per unit width (in N m).

A forcing sound field consisting of an incident plane wave is not typically encountered in practice, since the sound field in a space is more commonly a diffuse field. In this situation the total transmitted intensity is

$$I_t = \int_\Omega \tau(\Theta)\ I_i \cos\Theta\ d\Omega. \qquad (22)$$

The integration is over a hemisphere of solid angle Ω, where

$$d\Omega = \cos\Theta\ d\Theta\ d\Phi. \qquad (23)$$

Since the sound intensity of the incident energy is the same for all plane waves in a diffuse field, and the transmission coefficient is independent of the polar angle Φ, an average transmission coefficient is defined by

$$\overline{\tau} = \frac{\int_0^{\Theta_{\mathrm{lim}}} \tau(\Theta)\ \cos\Theta\ \sin\Theta\ d\Theta}{\int_0^{\Theta_{\mathrm{lim}}} \cos\Theta\ \sin\Theta\ d\Theta}, \qquad (24)$$

where Θ_{lim} is the limiting angle of incidence of the sound field which, for random incidence, is taken as $\pi/2$ or 90°.

To rate the sound isolating properties of a structure, the difference between the incident intensity level and the transmitted intensity level is used. This difference is called the transmission loss, TL, or sound reduction index, R (in dB), and is defined as

$$R = 10\ \log_{10}(1/\overline{\tau}). \qquad (25)$$

Commonly, it is found that a wall assembly will consist of several elements of different sizes and different sound isolating capabilities, such as a wall containing a door and windows. To determine the average transmission loss of this compound assembly the transmission coefficients of each element are averaged. The resultant value is the composite transmission loss of the overall assembly, and is defined as

$$R_{\mathrm{comp}} = 10\ \log_{10} \frac{S_1 + S_2 + \cdots + S_n}{S_1\tau_1 + S_2\tau_2 + \cdots + S_n\tau_n}, \qquad (26)$$

where R_{comp} is the composite transmission loss (in dB); S_1, S_2, ..., S_n are the areas of the various elements (in m^2); and τ_1, τ_2, ...,τ_n are the transmission coefficients of the various elements (dimensionless).

2.1.2 Homogeneous Walls. Sound transmission through a wall varies with frequency and is dependent upon the transverse vibration velocity response of the wall. A generalized transmission-loss curve for a single-layer, homogeneous partition, such as a window or concrete floor, is shown in Fig. 6 together with the frequency regions affected by the stiffness, resonances, mass, and coincidence effects.

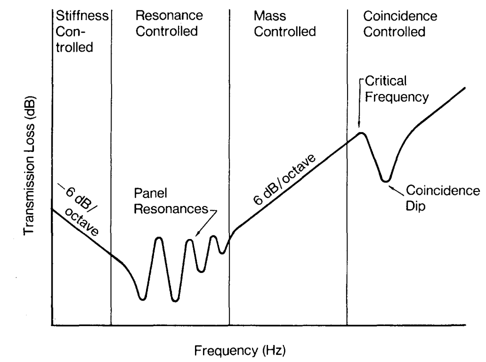

FIG. 6. Generalized sound transmission-loss curve of a single-layer, homogeneous partition mounted in an immobile frame. Different physical characteristics of a material control its effectiveness as a sound insolator in different parts of the frequency spectrum. The sound transmission of most common materials used to construct partitions in buildings is controlled by mass and the coincidence effect. The effects of stiffness and resonance are typically at frequencies below the range of human hearing.

2.1.2.1 Stiffness-Controlled Transmission Loss. At very low frequencies, below the lowest resonant frequency, the panel transmission loss R is considered to be stiffness controlled. The transmission loss increases with decreasing frequency at 6 dB per halving of frequency. However, for walls, floors, and ceilings, the lowest resonance is usually between about 5 and 15 Hz, and generally lower than 10 Hz for large single-pane windows. Thus, stiffness- controlled transmission loss is rarely a factor in architectural acoustics, perhaps with the exception of small panels such as a window in a door.

2.1.2.2 Resonance-Controlled Transmission Loss. At and near the fundamental resonant frequency, the transmission loss is at its lowest, limited only by damping. In practice, this frequency, usually from 5 to 15 Hz, is rarely an acoustic problem, with the possible exceptions of interference to neighbors by amplified music and structural response to ground vibration or sonic booms. The first few resonances above the fundamental resonant frequency can also reduce the transmission loss, but are usually not as strongly excited.

For a simply supported panel, i.e., with fixed edges, the resonant frequency due to bending waves is

$$f_{\text{res}}=\frac{\pi}{2}\left(\frac{B}{\rho_s}\right)^{1/2}\left[\left(\frac{m}{l_x}\right)^2+\left(\frac{n}{l_y}\right)^2\right], \tag{27}$$

where B is the bending stiffness of the panel per unit width (in N m), ρ_s is the mass per unit area of the panel material (in kg m^{-2}), m and n are integers (both finite), and l_x and l_y are the panel edge lengths (in m).

2.1.2.3 Mass Law. At a frequency above approximately twice the lowest resonant frequency, the transmission loss of a simple partition becomes dependent primarily on surface density and is said to be mass controlled. In this frequency region the vibrational response of the wall to sound is resisted primarily by the wall's inertia, and the panel acts as if it consists of many small masses connected only by a limp membrane. The sound energy transmission obeys the "mass law," which states that for each doubling of mass per unit area, or for each doubling of frequency, the transmission loss is increased by 6 dB. The mass law can be approximated by

$$R=20\log_{10}(Mf)-48, \tag{28}$$

where M is the surface mass of the partition (in kg m^{-2}) and f is the frequency of the incident sound (in Hz).

This equation gives the theoretical maximum sound transmission loss for random incidence and should only be used as an approximation.

2.1.2.4 Critical Frequency. For a given angle of incidence of an airborne sound wave there is a particular frequency at which the projected wavelength of incident sound matches the bending wavelength of the flexural wave of the wall. When this matching occurs, the incident energy is readily accepted and radiated, i.e., transmitted, with the only limit in energy transmission due to damping. The minimum frequency at which this matching occurs is for 90° incident sound, and is called the critical frequency, f_c, defined as

$$f_c=\frac{c^2}{2\pi}\left(\frac{\rho_s}{B}\right)^{1/2}, \tag{29}$$

where ρ_s is the mass per unit area of the material (in kg m^{-2}) and B is the bending stiffness per unit width (in N m).

This "coincidence effect" or "coincidence dip" particularly limits the performance of gypsum board constructions and glass windows between 2 and 4 kHz. To control the coincidence effect in the latter, a laminated glass utilizing an inner, plastic damping layer can be used for single panes of glass. In double-glazed assemblies, glass of different thicknesses can be used to achieve critical frequencies with less overlap.

The relationship described by the mass law between sound transmission loss, frequency, and mass can only be used at frequencies up to about one-half of the critical frequency, which is the lowest frequency at which the coincidence effect begins to lessen the transmission loss. Above about ten times the critical frequency for common building materials, the thickness of the panel becomes significant and vibrations other than transverse become significant.

2.1.3 Multiple-Skin Walls. To achieve any significant improvement in the sound transmission loss of a homogeneous or solid wall requires increasing its mass, since, in the most important frequency range of 50–2000 Hz, architectural materials such as glass, concrete, and masonry are "mass controlled." Adding mass to achieve an adequate degree of sound isolation, however, becomes both inefficient acoustically and uneconomical in current building technology. Some of the disadvantages of increasing the mass of a wall include increased wall thickness, with resultant loss of available floor space, and limited effectiveness, due to the law of diminishing returns. Using massive walls on the upper floors of a high-rise building will also significantly increase the cost of the building, since the design of the structural support system must also be made more massive to support this added weight, particularly if lateral seismic forces are anticipated. A high degree of transmission loss can be achieved, however, using lighter weight wall types, such as a stud wall, consisting of multiple layers of material. A stud wall is perhaps the most common type of wall assembly used in the building industry today. It consists of layers of material, typically gypsum board or plaster, installed on each side of a supporting member or stud, usually of metal or wood, typically spaced 40 or 60 cm apart. With this type of wall there are two major paths for transmission of sound energy: airborne radiation from the first panel to the second panel through the air of the stud cavity; and structure-borne transmission of vibrational energy from the first panel to the second panel through direct connection at the studs.

At low frequencies the trapped air of the stud space couples the two leaves of the wall together with a compliance (spring), and therefore, there is a resonant frequency. The frequency at which this mass-air-mass resonance occurs can be determined by

$$f_{\mathrm{res}}=60\left(\frac{w_1 w_2}{w_1+w_2}\,d\right)^{-1/2}, \qquad (30)$$

where f_{res} is the resonant frequency of the air cavity (in Hz), w_1 and w_2 are the surface masses of the leaves of the wall (in kg m^{-2}), and d is the width of air space (in m).

This resonance can be significant, and in practice, the mass-air-mass resonance should be designed to be below 100 Hz so that for leaves of low mass, a wide cavity is required. For a typical wood stud wall, there are also other resonances, usually ranging from 50 to 350 Hz. Note that in order to reduce the effect of the resonances of the wall, a porous sound absorbing material should be installed in the air cavity.

Transmission through the studs and around the fixed edges becomes an important factor when sound isolation greater than a sound transmission class (STC) (see Sec. 2.1.5) rating of 50 is required. Up to this level standard, single-stud walls can be used and the amount of isolation required can be achieved by varying the mass of the leaves and width of air space. Above approximately STC 50, it is usually necessary to vibration isolate the two sides of the wall from each other. One method is to stagger the studs, using a double row of studs, one supporting each side, installed on a common plate. The sound isolation of this type of assembly is limited, however, by the common, fixed top and bottom edges, which limit the vibration isolation. Higher sound isolation can be achieved by constructing a double-stud-wall assembly which consists of a double row of studs, each on its own separate edge plates, so that the two rows of studs are better vibration isolated from each other. Typical sound transmission loss curves for single-stud, staggered-stud, and double-stud walls are shown in Fig. 7.

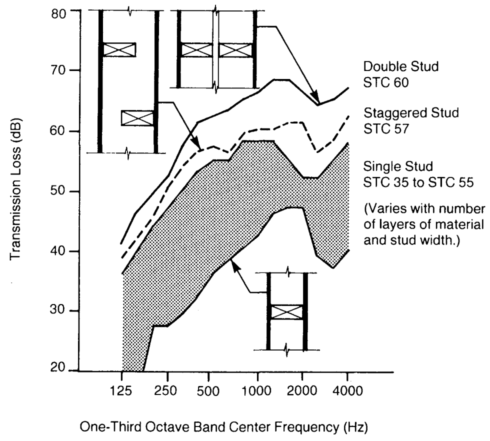

FIG. 7. Typical sound transmission-loss curves for single-stud walls (shaded region), staggered-stud wall (dashed line), and double-stud wall (solid line). Transmission loss increases with the depth of air space between the two leaves of the wall, the degree of isolation of the wall leaves, the number of layers of wall material, and the presence of sound absorbing material in the stud cavity.

Another method of isolation is to use metal studs instead of wood studs. A metal stud is somewhat like the letter "*C*" in cross section, and provides added resilience over that of a wood stud. In common practice, most high-rise buildings use metal studs.

2.1.4 Flanking Transmission. In sound isolation situations it is necessary to consider the total amount of sound energy transmitted to a space by all sound paths, not just through the common barrier. The total degree of sound isolation between spaces is typically limited, not by how much sound is transmitted through the intervening partition, but by how much sound is transmitted by every path, through *and around* the partition. The transmission of sound by indirect paths is called flanking transmission. For a given degree of sound isolation, the most economical construction can be achieved when all paths transmit approximately the same amount of sound energy. Typical sound flanking paths in construction systems include the following: unsealed joints between construction elements, ventilation grilles, interconnecting duct work, common corridors, continuous plenum space above suspended-ceiling systems, electrical outlet boxes located back to back on opposite sides of a wall, wall furnaces, and pipe penetrations.

A very small hole or crack can seriously reduce the effectiveness of a sound isolating construction. Since a hole has a transmission loss of near zero, it takes a very small percentage of hole-to-total wall area to negate the airborne sound isolation of the wall, considering that a residential wall may be required to reduce incident sound energy by 50 dB, or a factor of 100 000. The sound flanking paths must therefore be carefully sealed to achieve the full sound isolating capabilities of the construction assembly. Such leaks can be controlled by inserting solid, impervious barriers in the openings or, at the smaller cracks and holes, by filling with resilient materials and sealants to achieve an airtight closure.

2.1.5 Sound Transmission Class. For convenience in selecting or comparing the airborne sound isolation provided by various building assemblies, a single-number rating system called the sound transmission class (STC) is used. In general, the higher the STC rating the more efficient the construction is for isolating sound. The STC rating is determined by comparing the measured transmission-loss values of an assembly at the 16 one-third octave band-center frequencies from 125 to 4000 Hz with a standard reference contour, which is adjusted based on standard rules. The STC rating system is widely used throughout the U.S. building industry for airborne-sound isolation design and evaluation. However, selecting a building assembly solely on its STC rating does not always ensure a satisfactory degree of sound isolation. The STC rating system was originally developed to evaluate the isolation provided by construction for speech privacy situations. It is therefore not a reliable predictor for situations in which low-frequency isolation, i.e., below 125 Hz, is required, such as for mechanical equipment noise sources, or live or reproduced music.

2.2 Structure-Borne Sound Isolation

The other major transmission path of noise in buildings is as vibration directly through a rigid building structure. The resulting radiated noise is called "structure-borne sound." Structures commonly transmit vibration as shear, flexural (bending), and compressional waves. Structure-borne sound can be generated both by sources which act mechanically on the structure, such as the impact of footsteps, or cupboard doors, as well as by acoustic excitation from airborne sound. The energy may be felt as vibration if the level is high enough. Structure-borne sound may be particularly troublesome where lightweight, lightly damped radiating panels are rigidly attached to the vibrating structure, often far removed from the original source. Structure-borne energy is readily transmitted long distances with little attenuation through typical buildings. This is particularly true if the structural system consists of continuous timber, steel, or concrete framing members or large areas of rigid frame and panel assemblies with only small discontinuities to reflect or absorb energy. It is generally more effective to reduce the impacting or vibrating forces at their source, such as by providing resilient floor finishes, vibration isolation devices on mechanical and electrical equipment, resilient supports for plumbing and piping, etc. If it is necessary to achieve a high degree of impact noise reduction at acoustically sensitive spaces, more elaborate constructions are required, including specially designed, resiliently mounted double, or "floated," floors or resiliently suspended ceiling systems. Placement of vibration breaks in the structure is used most often in wood-frame floors of multifamily dwellings.

2.2.1 Impact Insulation Class. Since the sound generated by impact sources depends on the interaction between a specific source and a particular building structure, it is generally not possible to calculate the airborne noise levels that will be transmitted to an adjacent space. In practice, the degree of impact noise reduction required is specified for that particular type of occupancy based on excitation of the construction by a standardized impact force. In order to compare the effectiveness of various floor-ceiling assemblies for isolating an impact noise source, a single-number rating system is used, the impact insulation class (IIC), which is similar in concept to the sound transmission class rating for airborne sound isolation. The IIC rating is determined by comparing the normalized impact sound pressure level, L_n, in the space below the floor-ceiling assembly being tested against a standard reference spectrum contour. The measured impact-sound pressure-level data are generated using a standard impact-noise source called a "tapping machine," which produces a series of uniform impacts at a uniform rate on the test floor assembly (see Sec. 2.3.2). The IIC ratings should be used with caution, however, since it has been found that evaluations of various floor coverings on test floor constructions using the standard tapping machine do not always provide accurate assumptions for use of the same floor coverings on other floor constructions. In addition, because of its lightweight design, the tapping-machine impact source does not simulate the weight or characteristics of a human walker. Therefore, the "creaks" and "booms" of a flexible floor assembly caused by such footstep excitation is typically not reflected in the single-number IIC rating. Note, however, that at present the tapping-machine impact source is the only standardized device allowable for determining IIC ratings of floor-ceiling assemblies.

2.3 Measurement Procedures

2.3.1 Airborne-Sound Isolation. The transmission-loss values of a building assembly can be obtained by either laboratory or field testing, with the measurement procedures for each specified by various standards. Laboratory measurements are governed nationally, such as by the American Society for Testing and Materials (ASTM) Designation E90, "Standard Method for Laboratory Measurement of Airborne Sound Transmission Loss of Building Partitions," and also by the International Organization for Standardization (ISO) Recommendation R140, "Field and Laboratory Measurements of Airborne and Impact Sound Transmission." The sound reduction index R, or transmission loss (TL), is the ratio of incident to transmitted acoustic energy, and is measured by inserting the test specimen in an opening between two reverberant rooms whose minimum volume is 80 m^3 for the ASTM standard and 50 m^3 for the ISO standard (100 m^3 desirable). The volume and shape of the rooms are designed to achieve a diffuse sound field. Diffusing panels, both stationary and rotating, are also required (see Sec. 1.3.2). The minimum dimension of the test specimen is 2.4 m and the recommended overall size is 10 m^2. There is no specific minimum area requirement for the test specimen because various building elements are tested, e.g., walls, doors, windows, etc., and it is not possible to standardize the size.

In the source room, a near-diffuse sound field is generated and the space-average sound pressure levels L in both the source and receiving rooms are measured. The numerical difference between the measured sound pressure levels provides the noise reduction D at each test frequency:

$$D=L_1-L_2, \tag{31}$$

where L_1 is the average sound pressure level in the source room (in dB) and L_2 is the average sound pressure level in the receiving room (in dB).

The noise reduction represents the sound isolation achieved by the test specimen in that specific configuration, which includes the effects of specimen size and of receiving room absorption. So that the specimen can be compared with similar specimens from other test facilities, corrections are applied to the measured data to negate the effects of the size and absorption by converting the noise-reduction (D) data to transmission-loss (R) values by

$$R=D+10\log_{10}(S/A), \tag{32}$$

where S is the area of the test specimen (in m^2) and A is the sound absorption in the receiving room (in metric sabins). The single-number STC rating of the test specimen is determined from the transmission-loss values ranging from 125 to 4000 Hz (see Sec. 2.1.5).

Field measurements are also controlled by standards, such as ASTM Designation E336, "Standard Test Method for Measurement of Airborne Sound Insulation in Buildings," and ISO R140. However, because it is generally not possible to perform measurements in the field under the same ideal conditions encountered in laboratory test facilities, the sound isolation data can be measured and reported somewhat differently from the laboratory measurements. When measurements are performed between two spaces in the field, the measured noise-reduction values can be corrected for specimen size and absorption to determine the field transmission-loss (R_F) values at each frequency, and the field sound transmission class (FSTC) obtained for that specimen. In this situation the R_F and FSTC values apply to that specific construction assembly tested and are theoretically independent of the surroundings, quality of installation, and other acoustical characteristics of the space. However, the same measured noise-reduction data can also be reported to be measured without corrections and, in this case, the noise isolation class (NIC) rating is obtained. The NIC is determined from the noise-reduction data in exactly the same manner that the STC rating is determined from the adjusted transmission-loss values. The difference between the two rating systems is that the NIC rating provides information on the total amount of airborne sound isolation actually existing between the two rooms, taking into account *all* sound transmission paths, while the FSTC rating evaluates only the performance of a specific building assembly, independent of its surroundings.

2.3.2 Impact-Sound Isolation. As with airborne sound, the measurement procedures for impact-sound isolation are controlled by strict standards. For laboratory measurements these include ASTM Designation E492, "Standard Method of Laboratory Measurement of Impact Sound Transmission through Floor-Ceiling Assemblies Using the Tapping Machine." For field measurements, ASTM E1007 is used. The method for measuring impact noise and determining impact-sound isolation is significantly different from the methods used for airborne-sound isolation. For airborne sound the amount of sound isolation is determined by measuring the difference in sound pressure levels between the source room and receiving room. The greater the difference, the better the isolation. For impact isolation the sound pressure level in the source room is not important, but rather the average impact-sound pressure level L in the space below the floor-ceiling assembly being tested is important. It is measured at the 16 one-third octave band center frequencies from 100 to 3150 Hz by using a tapping machine as the source (see Sec. 2.2.1). The test specimen is inserted in an opening between two reverberant rooms similar to those used for airborne-sound isolation testing, but with the rooms located one above the other instead of side by side. The recommended minimum size of the test specimen is 9.3 m^2. Since the spectrum and level of the measured impact-sound pressure levels depend on the sound absorption in the receiving room, the average impact-sound pressure levels are normalized to a reference absorption, so that the results can be compared with those obtained in other spaces with different amounts of absorption by

$$L_n = L_r - 10 \log_{10}(A_0/A), \tag{33}$$

where L_n is the normalized impact-sound pressure level (in dB), L_r is the average impact-sound pressure level in the receiving room (in dB), A_0 is the reference absorption equal to 10 metric sabins, and A is the sound absorption in the receiving room (in metric sabins).

The single-number impact insulation class (IIC) rating is determined from the normalized L_n data by comparing them to a standard reference contour, similar to the method used to determine the sound transmission class (STC) rating for airborne-sound isolation. The higher the IIC rating, the more efficient the floor-ceiling assembly is for isolating impact sound.

GLOSSARY

Air Absorption: Absorption of sound energy caused by molecular relaxation of air molecules. Air absorption is significant only in large rooms and at sound frequencies of 2000 Hz and above.

Airborne Sound: Sound radiated initially into and transmitted through the air rather than through the structure of a building.

Ambient Noise: The all-encompassing noise associated with a given environment, being usually a composite of sounds from many sources near and far.

Anechoic Room: A room whose boundaries absorb effectively all incident sound, thereby providing essentially a free-field condition within a specified range of frequencies.

Architectural Acoustics: The area of acoustics that deals with the effects of sound and vibration in buildings and its effects on the building users. The main concerns in architectural acoustics are room acoustics, sound isolation, and mechanical equipment noise and vibration control.

Assisted Resonance: Artificial enhancement of sound reflections and reverberation time by electronic means.

Critical Frequency: The frequency at which the acoustic wavelength in air exactly matches a transverse bending wavelength of a sound isolating structure.

Dead Room: A space that is characterized by an unusually large amount of sound absorption.

Decibel (dB): A dimensionless, logarithmic unit denoting the ratio of a quantity to a reference quantity of the same kind, both proportional to energy or power, and given by 10 $\log_{10}(q_1/q_{\text{ref}})$. Examples of quantities include sound power, sound intensity, sound pressure squared, and particle or vibration velocity squared. For systems adequately described by linear equations, force-like quantities, such as sound pressure, acceleration, and force at levels usually found in architectural acoustics are usually used directly. For example, sound pressure (in dB) is

$$L_P = 10 \log_{10}(P^2/P_{\text{ref}}^2) = 20 \log_{10}(P/P_{\text{ref}}),$$

where P and P_{ref} are root mean square (rms) pressures. A commonly used approximation substitutes linear averages, zero-to-peak, and other wave-form descriptors for the rms. (Strictly speaking, a decibel is one-tenth of a bel, but the latter is now rarely used.)

Diffraction: The change in the direction of a sound wave, other than by reflection or refraction, which occurs when the wave encounters an obstacle or nonhomogeneity in a medium.

Diffuse Sound Field: A theoretical sound field in an enclosure in which the time average of the mean square sound-pressure level is the same throughout and the flow of energy in all directions is equally probable.

Direct Sound Field: The field of unreflected sound that exists close to a sound source.

Echo: In architectural acoustics, a wave of sound that has been reflected or otherwise returned with an adequately uniform and long delay and with sufficient magnitude to be detected as a sound that is distinct from the directly transmitted sound and its smoothly decaying reverberation.

Edge Effect: The excess or increased sound absorption of a test sample relative to what would be measured for an arbitrarily large sample of the same material. This effect is due to diffraction effects at the sample's edges or to discontinuities in the surface impedance.

Energy Density: The sound energy at a point in a sound field contained in a given infinitesimal part of the medium divided by the volume of that part of the medium.

Flanking Transmission: The transmission of sound from one space to another by indirect paths rather than directly through an intervening construction.

Helmholtz Resonator: A resonant acoustic device consisting of an air cavity connected to a larger space by a relatively small opening or neck.

Impact Insulation Class (IIC): A single-number rating used to evaluate the impact-sound isolating performance of a floor-ceiling construction system.

Live Room: A space that is characterized by an unusually small amount of sound absorption.

Loudness: The subjective response of human hearing to sound levels. The perception of loudness also depends on the frequency and wave form of the sound.

Masking: The ability of one sound to inhibit the perception of another sound. Also, the use of an unobtrusive background noise to cover other intruding sounds.

Mass-Air-Mass Resonance: The resonant system comprising the enclosed air between the two leaves of a partition and the mass of the two leaves. This resonance can result in a pronounced dip in the sound transmission loss, usually at low frequencies.

Mass Law: The sound transmission loss of a panel structure will increase by 6 dB for every doubling of mass per unit area. The mass law is reasonably accurate only in the absence of significant resonances and in the frequency region above twice the lowest resonant frequency and below one-half the critical frequency.

Mean Free Path: The average distance that a sound travels between successive reflections in an enclosure.

Natural Frequency: A frequency of free oscillation of an undamped system. The natural frequencies are the frequencies of the normal modes of vibration. See also resonance frequency.

Noise Isolation Class (NIC): A single-number rating used to evaluate the airborne-sound isolating performance of a completed construction system, determined from the measured noise-reduction values. See also sound transmission class.

Noise Reduction (NR): The reduction in level of a sound by any of several means. Also, the measured difference, in a specified frequency band, between the average sound pressure levels in two enclosed spaces due to a source in one of them and measured without adjustment for sound absorption or flanking noise paths. See also transmission loss.

Noise Reduction Coefficient (NRC): The arithmetic average of the sound absorbing coefficients of a material at 250, 500, 1000, and 2000 Hz, rounded to the nearest 0.05.

Octave: The interval between two sound frequencies having a ratio of two.

Octave Band: A frequency range that is one octave wide. Standard octave bands are designated by their center frequencies.

Pink Noise: A random or pseudorandom broadband noise whose spectrum level decreases with increasing frequency to yield constant time-averaged energy per constant percentage bandwidth, such as one-third or whole octaves. See also white noise.

Pitch: The subjective response of the human hearing mechanism to the perceived dominant frequency of a sound. The perception of pitch also depends on the sound pressure level and wave form of the sound.

Pure Tone: A simple sound whose instantaneous wave form is that of a sine wave, i.e., consisting of only one frequency.

Quadratic Residue Diffusor: A sound diffusing element consisting of a reflection phase grating that provides wide angles of sound dispersion within its designed frequency range.

Resonance Frequency: Frequency of oscillation at which the response of the system peaks. See also natural frequency.

Reverberant Sound Field: The sound field in an enclosure in which all of the sound waves have been reflected at least once from the boundary surfaces.

Reverberation: The persistence of sound in an enclosed space, as a result of multiple reflections or scattering, after the sound source has stopped.

Reverberation Time (T_{60}): The time in seconds required for the mean square sound pressure level of a sound originally in a steady state and within a specified frequency band to decay by 60 dB after the sound source has stopped.

Room Acoustics: The study of sound in an enclosure, including the sound in the air and the effects on the sound by the enclosure.

Room Modes: The normal modes of acoustic vibration in an enclosure that describe standing waves that may occur near the characteristic natural frequencies based on the size and shape of the enclosure.

Room Radius (r_r): The nominal distance from an ideally uniform sound source in an enclosure at which the sound pressure levels of both the direct and reverberant sound fields are equal.

Sabin ($S\alpha$): The dimensionless unit measure of sound absorption. A metric sabin is equal to the absorption provided by one square meter of a perfect absorber (i.e., one with an absorption coefficient of 1.0).

Sound Absorption: The change of sound energy into some other form, usually heat, in passing through a medium, including air, or striking a material or object.

Sound Absorption Coefficient (α): The fraction of incident sound energy absorbed by a material. Unless otherwise specified, a diffuse sound field is assumed.

Sound Intensity: The average sound power transmitted in a specified direction and location through a plane perpendicular to the specified direction and normalized to a unit area.

Sound Isolation: The use of building materials or construction systems to reduce the transmission of sound. Also, the degree of reduction achieved, as measured according to various standardized methods and expressed using corresponding standardized ratings.

Sound Power Level (L_w): The total sound energy per unit of time, such as produced by a sound source, usually expressed in decibels. For airborne sound, this is equal to 10 $\log_{10}$ of the ratio of the power of a sound in watts to the standard reference power of 10^{-12} W.

Sound Pressure Level (L_p): As used in architectural acoustics, a value expressed in decibels. For airborne sound, equal to 20 $\log_{10}$ of the time average of the root mean square of the instantaneous sound pressure divided by the reference pressure of 20 μPa.

Sound Reduction Index (R): See transmission loss.

Sound Reflection: The return of sound energy from a discontinuity in a medium, such as a boundary surface.

Sound Transmission Class (STC): A single-number rating used to evaluate the airborne-sound isolating performance of a specific construction element, determined from the transmission-loss values by standardized procedures. See also noise isolation class.

Standing Waves: See room modes.

Steady-State Sound Field: The sound field in an enclosure in which the time-averaged sound pressure level at any point is constant.

Structure-Borne Sound: That portion of sound in a room that has been transmitted from elsewhere through a solid medium, such as a building structure, rather than only through air.

Subjective Preference Scaling: Any of various systems used either to evaluate or relate objective physical properties of the sound field with subjective characteristics in music performance spaces.

Threshold of Audibility: The minimum sound pressure level at which a person can hear a sound of a given frequency. In children without auditory pathology, the threshold is about 20 μPa or 0 dB at 2000 Hz.

Threshold of Pain: The minimum sound pressure level at which a person begins to sense pain in the ear from sounds of high intensity. Pain or a tickling sensation is reported at 140 dB, while sounds at 120 dB are discomforting.

Transmission Coefficient (τ): The ratio of transmitted acoustic energy to the incident acoustic energy in airborne-sound isolation situations. This varies with frequency and angle of incidence.

Transmission Loss (R): The ratio, expressed in decibels, of the incident to transmitted airborne sound of a specified angle of incidence and a specified frequency content as it passes through a building construction. Strictly speaking, transmission loss must be determined in accordance with standardized procedures which take into account the size of the construction and the amount of sound absorption present. This is also called the sound reduction index.

Weighting Network: An electronic network that modifies the frequency response of a standard sound level meter, usually to enable it to approximate the subjective spectral response of human hearing to various sounds. Most frequently used is the "A" network, with the sound level designated as dBA.

White Noise: A broadband noise whose energy per unit bandwidth remains constant at all frequencies within the total bandwidth. See also pink noise.

INTRODUCTION

Acoustics, the science of waves of a mechanical nature, is typically concerned with small-amplitude phenomena that can be described to a good approximation in terms of linear differential equations. The analysis that accompanies most applications of acoustics consequently draws upon a linearized theory, briefly referred to as linear acoustics. The present article presents the underlying principles of linear acoustics, and discusses some general applications of the theory.

The reason why one chooses to view acoustics as a linear phenomenon, unless there are strong indications of the importance of nonlinear behavior, is the intrinsic conceptual simplicity brought about by the principle of superposition. Thus, for example, a complicated sound field caused by several sources can be regarded as a sum of fields, each of which is caused by an individual source. Moreover, if one has some assurance that the governing equations have time-independent coefficients, then the concept of frequency has great utility. Waves of each frequency propagate independently, so one can analyze the generation and propagation of each frequency separately, and then combine the result.

Nevertheless, linear acoustics should be always regarded as an approximation, and the understanding of nonlinear aspects of acoustics is of increasing importance in modern applications (see ACOUSTICS, NONLINEAR). Consequently, part of the task of the present article is to explain in what sense linear acoustics is an approximation. An extensive discussion of the extent to which the linearization approximation is valid is not attempted, but a discussion is given of the manner in which the linear equations result from nonlinear equations that are regarded as more nearly exact.

The historical origins (Hunt, 1978) of linear acoustics reach back to antiquity, to Pythagoras and Aristotle (Lindsay, 1972) and to other ancient civilizations. The mathematical theory began with Mersenne, Galileo, and Newton, and developed into its more familiar form during the time of Euler and Lagrange (Truesdell, 1955). Prominent contributors during the 19th century include Poisson, Laplace, Cauchy, Green, Stokes, Helmholtz, Kirchhoff, and Rayleigh. The last-named's book, *The Theory of Sound* (Rayleigh, 1878), is still widely read and quoted today. The subject is now a mature mainstay of applied physics, with a seemingly unbounded realm of application, and with a voluminous and ever growing scientific and technical literature. The maturity of linear acoustics, its long history, and its voluminous literature can at times be intimidating to a researcher, but the basic principles can be expressed relatively concisely, and the diversity of novel applications continues to afford ample opportunity for creative contributions.

1. BASIC EQUATIONS OF CONTINUUM MECHANICS

1.1 Mass, Momentum, and Energy Equations

The primary equations governing sound are those that account for conservation of mass and energy, and for changes in momentum. These may be written in the form of either partial differential equations or integral equations. The former version is the customary starting point for the derivation of approximate equations for linear acoustics. Extensive discussions of the equations of continuum mechanics can be found in texts by Thompson (1972), Fung (1965), Shapiro (1953), Batchelor (1967), Truesdell (1966), and Landau and Lifshitz (1959), and in the encyclopedia article by Truesdell and Toupin (1960).

The conservation of mass is described by the partial differential equation,

$$\frac{\partial \rho}{\partial t}+\nabla\cdot(\rho\mathbf{v})=0, \tag{1}$$

and the generalization of Newton's second law to a continuum is described by Cauchy's equation of motion, which is written in Cartesian coordinates as

$$\rho\frac{D\mathbf{v}}{Dt}=\sum_{ij}\mathbf{e}_i\frac{\partial\sigma_{ij}}{\partial x_j}+\mathbf{g}\rho. \tag{2}$$

Here the Eulerian description is used with each field variable regarded as a function of actual spatial position coordinates and time. The quantity ρ is the density of matter, mass per unit volume; $\mathbf{v}$ is the particle or fluid velocity; the σ_{ij} are the Cartesian components of the stress tensor. The quantities $\mathbf{e}_i$ are the unit vectors in a Cartesian coordinate system. The second term on the right-hand side of Eq. (2) is a body-force term associated with gravity, with $\mathbf{g}$ representing the vector acceleration due to gravity. In some instances, it may be appropriate to include body-force terms associated with external electromagnetic fields, but such are excluded from consideration in the present article. The time derivative operator on the left-hand side of Eq. (2) is Stokes's total time derivative operator (Stokes, 1845),

$$\frac{D}{Dt}=\frac{\partial}{\partial t}+\mathbf{v}\cdot\nabla, \tag{3}$$

with the two terms corresponding to (i) the time derivative as would be seen by an observer at rest and to (ii) the convective time derivative. This total time derivative applied to the particle velocity field yields the particle acceleration field, so the right-hand side of Eq. (2) can be regarded as the apparent force per unit volume on an element of the continuum.

The stress tensor's Cartesian component σ_{ij} can be regarded as the ith component of the surface force per unit area on a segment of the surface of a small element of the continuum, when the unit outward normal to the surface is in the jth direction. This surface force is caused by interactions with the neighboring particles just outside the surface or by the transfer of momentum due to diffusion of molecules across the surface. Considerations of the net torque that such surface forces would exert on a small element, and the requirement that the angular acceleration of the element be finite in the limit of very small element dimensions, lead to the conclusion

$$\sigma_{ij}=\sigma_{ji}, \tag{4}$$

so the stress tensor is symmetric.

The equations described above are supplemented by an energy conservation relation,

$$\rho\frac{D}{Dt}\left(\frac{1}{2}v^2+u\right)=\sum_{ij}\frac{\partial}{\partial x_j}(\sigma_{ij}v_i)+\rho\mathbf{g}\cdot\mathbf{v}-\nabla\cdot\mathbf{q}, \tag{5}$$

which involves the internal energy u per unit mass and the heat flux vector $\mathbf{q}$. The latter has the interpretation that its dot product with any unit vector represents the heat energy flowing per unit time and per unit area across any internal surface with the corresponding unit normal. An alternative version,

$$\rho\frac{Du}{Dt}=\sum_{ij}\sigma_{ij}\frac{\partial v_i}{\partial x_j}-\nabla\cdot\mathbf{q}, \tag{6}$$

of the energy equation results when the vector dot product of $\mathbf{v}$ with Eq. (2) is subtracted from Eq. (5). [In carrying through the derivation, one recognizes that $\mathbf{v}\cdot\{\rho D\mathbf{v}/Dt\}$ is $\frac{1}{2}\rho Dv^2/Dt$.]

1.2 Newtonian Fluids

The above equations apply to both fluids and solids. Additional equations needed to complete the set must take into account the properties of the materials that make up the continuum. Air and water, for example, are fluids, and their viscous behavior corresponds to that for Newtonian fluids, so that the stress tensor is given by

$$\sigma_{ij}=\sigma_n\delta_{ij}+\mu\phi_{ij}, \tag{7}$$

which involves the rate-of-shear tensor,

$$\phi_{ij}=\frac{\partial v_i}{\partial x_j}+\frac{\partial v_j}{\partial x_i}-\frac{2}{3}\,\nabla\cdot\mathbf{v}\delta_{ij}. \tag{8}$$

The quantity σ_n that appears here is the average normal stress component and μ is the shear viscosity, while δ_{ij} is the Kronecker delta, equal to unity if the two indices are equal and otherwise equal to zero.

1.3 Equilibrium Thermodynamics

Further specification of the equations governing sound requires some assumptions concerning the extent to which equilibrium or near-equilibrium thermodynamics applies to acoustic disturbances. In the simplest idealization, which neglects relaxation processes, one assumes that the thermodynamic variables describing the perturbations are related just as for quasiequilibrium processes, so one can use an equation of state of the form

$$s=s(u,\rho^{-1}), \tag{9}$$

which has the corresponding differential relation (Landau, Lifshitz, and Pitaevskii, 1980)

$$T\,ds=du+pd(\rho^{-1}) \tag{10}$$

in accordance with the second law of thermodynamics. Here s is the entropy per unit mass, T is the absolute temperature, and p is the absolute pressure. The reciprocal of the density, which appears in the above relations, is recognized as the specific volume.

For the case of an ideal gas with temperature-independent specific heats, which is a common idealization for air, the function in Eq. (9) is given by

$$s=(R_0/M)\,\ln(u^{1/(\gamma-1)}\rho^{-1})+s_0. \tag{11}$$

Here, s_0 is independent of u and ρ^{-1}, while M is the average molecular weight (average molecular mass in atomic mass units), and R_0 is the universal gas constant (equal to Boltzmann's constant divided by the mass of an atomic mass unit), equal to 8314 J/kg K. The quantity γ is the specific-heat ratio, equal to approximately 7/5 for diatomic gases, to 5/3 for monatomic gases, and to 9/7 for polyatomic gases whose molecules are not collinear. For air, γ is 1.4 and M is 29.0. [The expression given here for entropy neglects the contribution of internal vibrations of diatomic molecules, which cause the specific heats and γ to depend slightly on temperature. When one seeks to explain the absorption of sound in air, a nonequilibrium entropy (Pierce, 1978) is used which depends on the fractions of O_2 and N_2 molecules that are in their first excited vibrational states in addition to the quantities u and ρ^{-1}.]

For other substances, a knowledge of the first and second derivatives of s, evaluated at some representative thermodynamic state, is sufficient for most linear acoustics applications.

1.4 Bulk Viscosity and Thermal Conductivity

The average normal stress must equal the negative of the thermodynamic pressure that enters into Eq. (10), when the fluid is in equilibrium. Consideration of the requirement that the equations be the same regardless of the choice of directions of the coordinate axes plus the assumption of a Newtonian fluid lead to the relation (Stokes, 1845)

$$\sigma_n=-p+\mu_B\nabla\cdot\mathbf{v} \tag{12}$$

which involves the bulk viscosity μ_B. Also, the Fourier model for heat conduction (Fourier, 1822) requires that the heat flux vector $\mathbf{q}$ be proportional to the gradient of the temperature,

$$\mathbf{q}=-\kappa\nabla T, \tag{13}$$

where κ is the coefficient of thermal conduction.

Transport Properties of Air. Regarding the values of the viscosities and the thermal conductivity that enter into the above expressions, the values for air are approximated by

(Hilsenrath, 1960; Sutherland, 1893; Greenspan, 1959)

$$\mu_S=\mu_0\left(\frac{T}{T_0}\right)^{3/2}\frac{T_0+T_S}{T+T_S}, \tag{14}$$

$$\mu_B=0.6\mu_S, \tag{15}$$

$$\kappa=\kappa_0\left(\frac{T}{T_0}\right)^{3/2}\frac{T_0+T_A e^{-T_B/T_0}}{T+T_A e^{-T_B/T}}. \tag{16}$$

Here T_S is 110.4 K, T_A is 245.4 K, T_B is 27.6 K, T_0 is 300 K, μ_0 is 1.846×10^{-5} kg/(m s), and κ_0 is 2.624×10^{-2} W/(m K).

Transport Properties of Water. The corresponding values of the viscosities and the thermal conductivity of water are given by (Horne, 1969; Pinkerton, 1947)

$$\mu_S=1.002\times 10^{-3}e^{-0.0248\Delta T}, \tag{17}$$

$$\mu_B=3\mu_S, \tag{18}$$

$$\kappa=0.597+0.0017\Delta T-7.5\times 10^{-6}(\Delta T)^2. \tag{19}$$

The quantities that appear in these equations are understood to be in mks units, and ΔT is the temperature relative to 283.16 K (10 °C).

1.5 Navier–Stokes–Fourier Equations

The assumptions represented by Eqs. (9), (10), (12), and (13) cause the governing continuum mechanics equations to reduce to

$$\frac{\partial\rho}{\partial t}+\nabla\cdot(\rho\mathbf{v})=0, \tag{20}$$

$$\rho\frac{D\mathbf{v}}{Dt}=-\nabla p+\nabla(\mu_B\nabla\cdot\mathbf{v})+\sum_{ij}\mathbf{e}_i\frac{\partial}{\partial x_j}(\mu\phi_{ij})+\mathbf{g}\rho, \tag{21}$$

$$\rho T\frac{Ds}{Dt}=\frac{1}{2}\mu\sum_{ij}\phi_{ij}^2+\mu_B(\nabla\cdot\mathbf{v})^2+\nabla\cdot(\kappa\nabla T), \tag{22}$$

which are known as the Navier–Stokes–Fourier equations for compressible flow.

1.6 Thermodynamic Coefficients

An implication of the existence of an equation of state of the form of Eq. (9) is that any thermodynamic variable can be regarded as a function of any other two (independent) thermodynamic variables. The pressure p, for example, can be regarded as a function of ρ and T, or of s and ρ. In the expression of differential relations, such as that which gives dp as a linear combination of ds and $d\rho$, it is helpful to express the coefficients in terms of a relatively small number of commonly tabulated quantities. A standard set of such quantities includes the square of the sound speed.

$$c^2=\left(\frac{\partial p}{\partial\rho}\right)_s, \tag{23}$$

the specific heat at constant pressure,

$$c_p=T\left(\frac{\partial s}{\partial T}\right)_p, \tag{24}$$

the specific heat at constant volume,

$$c_v=T\left(\frac{\partial s}{\partial T}\right)_\rho, \tag{25}$$

and the coefficient of thermal expansion,

$$\beta=\rho\left(\frac{\partial(1/\rho)}{\partial T}\right)_p. \tag{26}$$

(The subscripts on the partial derivatives indicate the independent thermodynamic quantities that are kept fixed during the differentiation.)

The coefficients that are given here are related by the thermodynamic identity,

$$\gamma-1=T\beta^2c^2/c_p, \tag{27}$$

where γ is the specific-heat ratio,

$$\gamma=c_p/c_v. \tag{28}$$

In terms of the thermodynamic coefficients defined above, the differential relations of principal interest in acoustics are

$$d\rho=\frac{1}{c^2}\,dp-\left(\frac{\rho\beta T}{c_p}\right)ds, \tag{29}$$

$$dT=\left(\frac{T\beta}{\rho c_p}\right)dp+\left(\frac{T}{c_p}\right)ds. \tag{30}$$

Thermodynamic Coefficients for an Ideal Gas. For an ideal gas, which is the common idealization for air, it follows from Eqs. (9) and (10) (with the abbreviation R for R_0/M) that the thermodynamic coefficients are given by

$$c^2=\gamma RT=\gamma p/\rho, \tag{31}$$

$$c_p=\gamma R/(\gamma-1), \tag{32}$$

$$c_v=R/(\gamma-1), \tag{33}$$

$$\beta=1/T. \tag{34}$$

For air, R is 287 J/kg K and γ is 1.4, so c_p and c_v are 1005 and 718 J/kg K, respectively. A temperature of 293.16 K and a pressure of 10^5 Pa yield a sound speed of 343 m/s and a density ρ of 1.19 kg/m^3.

Thermodynamic Properties of Water. For pure water, the sound speed is approximately given in mks units by (Wilson, 1959)

$$c=1447+4.0\Delta T+1.6\times 10^{-6}p. \tag{35}$$

Here c is in meters per second, ΔT is temperature relative to 283.16 K (10 °C), and p is absolute pressure in pascals. The pressure and temperature dependence of the density is approximately given by (Horne, 1969)

$$\rho\approx 999.7+0.048\times 10^{-5}p-0.088\Delta T$$

$$-0.007(\Delta T)^2, \tag{36}$$

the coefficient of thermal expansion is given by

$$\beta\approx(8.8+0.022\times 10^{-5}p+1.4\Delta T)\times 10^{-5}, \tag{37}$$

and the coefficient of specific heat at constant pressure is approximately given by

$$c_p\approx 4192-0.40\times 10^{-5}p-1.6\Delta T. \tag{38}$$

The specific-heat ratio is very close to unity, the deviation described by

$$(\gamma-1)/\gamma\approx 0.0011(1+\Delta T/6+0.0024$$

$$\times 10^{-5}p)^2 \tag{39}$$

The values for sea water are somewhat different, because of the presence of dissolved salts. An approximate expression for the speed of sound in sea water is given by (Wilson, 1960)

$$c\approx 1490+3.6\Delta T+1.6\times 10^{-6}p+1.3\Delta S. \tag{40}$$

Here ΔS is the deviation of the salinity in parts per thousand from a nominal value of 35.

1.7 Ideal Compressible Fluids

If viscosity and thermal conductivity are neglected at the outset, then the Navier-Stokes equation, Eq. (21), reduces to

$$\rho\frac{D\mathbf{v}}{Dt}=-\nabla p+\mathbf{g}\rho, \tag{41}$$

which is known as the Euler equation. The energy equation, Eq. (22), reduces to the isentropic flow condition

$$\frac{Ds}{Dt}=0. \tag{42}$$

Moreover, the latter in conjunction with the differential equation of state, Eq. (29), yields

$$\frac{Dp}{Dt}=c^2\frac{D\rho}{Dt}. \tag{43}$$

The latter combines with the conservation-of-mass relation, Eq. (1), to yield

$$\frac{Dp}{Dt}+\rho c^2\nabla\cdot\mathbf{v}=0. \tag{44}$$

In many applications of acoustics, it is these equations that are used as a starting point.

1.8 Elastic Solids

For analyses of acoustic wave propagation in solids, the idealization of a linear elastic isotropic solid (Crandall, Dahl, and Lardner, 1978; Landau and Lifshitz, 1970; Love, 1944; Fung, 1965; Achenbach, 1975; Lindsay, 1960) is often used. The solid-particle displacements are regarded as sufficiently small that convective time derivatives can be neglected, so the Cauchy equation, given previously by Eq. (2), reduces, with the omission of the invariably negligible gravity term, to an equation whose ith Cartesian component is

$$\rho\frac{\partial^2\xi_i}{\partial t^2}=\sum_{j=1}^{3}\frac{\partial\sigma_{ij}}{\partial x_j}. \tag{45}$$

Here ρ is the ambient density; $\xi_i(\mathbf{x},t)$ is the ith Cartesian component of the displacement of the particle nominally at $\mathbf{x}$. This displacement is measured relative to the particle's ambient position.

The stress tensor components σ_{ij} are taken to be linearly dependent on the strain components,

$$\epsilon_{ij}=\frac{1}{2}\left(\frac{\partial\xi_i}{\partial x_j}+\frac{\partial\xi_j}{\partial x_i}\right). \tag{46}$$

The linear stress-strain relation for an isotropic elastic solid has the form

$$\sigma_{ij}=2\mu_{\mathrm{L}}\,\epsilon_{ij}+\lambda_{\mathrm{L}}\delta_{ij}\sum_{k=1}^{3}\epsilon_{kk}, \tag{47}$$

which involves two Lamé constants λ_{L} and μ_{L} (the latter being the same as the shear modulus G). These are related to the elastic modulus E and Poisson's ratio ν by

$$\lambda_L = \nu E/(1+\nu)(1-2\nu), \tag{48}$$

$$\mu_L = G = E/2(1+\nu). \tag{49}$$

In this idealized and simplified model of acoustic propagation in solids, the conservation of mass and energy is not explicitly invoked. The density that appears on the left-hand side of Eq. (45) is regarded as time independent, and as what is appropriate for the undisturbed state of the solid. Values of the elastic properties of solids can be found in various reference books. Steel, for example, has an elastic modulus E of the order of 20×10^{10} N/m^2, a Poisson's ratio ν of the order of 0.27, and a density ρ of the order of 7.8×10^3 kg/m^3.

2. EQUATIONS OF LINEAR ACOUSTICS

2.1 The Linearization Process

Sound results from a time-varying perturbation of the dynamic and thermodynamic variables that describe the medium. The quantities appropriate to the ambient medium are customarily represented (Pierce, 1989) by the subscript 0, and the perturbations are represented by a prime on the corresponding symbol. Thus one expresses the total pressure as

$$p = p_0 + p', \tag{50}$$

with corresponding expressions for fluctuations in specific entropy, fluid velocity, and density. The linear equations that govern acoustical disturbances are then determined by the first-order terms in the expansion of the governing nonlinear equations in the primed variables. The zeroth-order terms cancel out completely because the ambient variables should themselves correspond to a valid state of motion of the medium. Thus, for example, the linearized version of the conservation-of-mass relation in Eq. (1) is

$$\frac{\partial\rho'}{\partial t} + \nabla\cdot(\mathbf{v}_0\rho' + \mathbf{v}'\rho_0) = 0. \tag{51}$$

The possible forms of the linear equations differ in complexity according to what is assumed about the medium's ambient state and according to what dissipative terms are included in the original governing equations. In the establishment of a rationale for using simplified models, it is helpful to think in terms of the orders of magnitude and characteristic scales of the coefficients in more nearly comprehensive models. If the spatial region of interest has bounding dimensions that are smaller than any scale length over which the ambient variables vary by a respectable fraction, then it may be appropriate to idealize the coefficients in the governing equations as if the ambient medium were spatially uniform or homogeneous. Similarly, if the characteristic wave periods or propagation times are much less than characteristic time scales for the ambient medium, then it may be appropriate to idealize the coefficients as being time independent. Examination of orders of magnitude of terms suggests that the ambient velocity may be neglected if it is much less than the sound speed c. The first-order perturbation to the gravitational force term can be ordinarily neglected (Bergmann, 1946) if the previously stated conditions are met and if the quantity g/c is sufficiently less than any characteristic frequency of the disturbance. Analogous inferences can be made about thermal conductivity and viscosity. However, the latter may be important (Cremer, 1948) in the interaction of acoustic waves in fluids with adjacent solid bodies.

A discussion of the restrictions on using linear equations and of neglecting second-order and higher terms in the primed variables is outside the scope of the present article, but it should be noted that one regards p' as small (Pierce, 1989) if it is substantially less than $\rho_0 c^2$, and $|\mathbf{v}'|$ as small if it is much less than c, where c is the sound speed defined via Eq. (23). It is not necessary that p' be much less than p_0, and it is certainly not necessary that $|\mathbf{v}'|$ be less than $|\mathbf{v}_0|$.

2.2 Linearized Equations for an Ideal Fluid

The customary equations for linear acoustics neglect dissipation processes and consequently can be derived from the equations for flow of a compressible ideal fluid, given in Eqs. (41)–(44). If one neglects gravity at the outset, and assumes that the ambient fluid velocity is zero, then the ambient pressure is constant. In such a case, Eq. (44) leads after linearization to

$$\frac{\partial p}{\partial t} + \rho c^2 \nabla\cdot\mathbf{v} = 0, \tag{52}$$

and the Euler equation, Eq. (41), leads to

$$\rho\frac{\partial \mathbf{v}}{\partial t}=-\nabla p. \tag{53}$$

Here a common notational convention is used to delete primes and subscripts. The density ρ is understood to be the ambient density ρ_0, while p and $\mathbf{v}$ are understood to be the acoustically induced perturbations to the pressure and fluid velocity.

These two coupled equations for p and $\mathbf{v}$ remain applicable when the ambient density and sound speed vary with position.

2.3 The Wave Equation

A single partial differential equation for the acoustic part of the pressure results when one takes the time derivative of Eq. (52) and then uses Eq. (53) to reexpress the time derivative of the fluid velocity in terms of pressure. The resulting equation is

$$\nabla\cdot\left(\frac{1}{\rho}\nabla p\right)-\frac{1}{\rho c^2}\frac{\partial^2 p}{\partial t^2}=0. \tag{54}$$

If the ambient density is independent of position, then this reduces to

$$\nabla^2 p-\frac{1}{c^2}\frac{\partial^2 p}{\partial t^2}=0, \tag{55}$$

which is what is ordinarily termed the wave equation of linear acoustics. Often this is written as

$$\Box^2 p=0 \tag{56}$$

in terms of the d'Alembertian operator defined by

$$\Box^2=\nabla^2-c^{-2}\partial^2/\partial t^2. \tag{57}$$

2.4 Wave Equations for Isotropic Elastic Solids

When the ambient density and the Lamé constants are independent of position, the Cauchy equation and the stress-strain relations described by Eqs. (45)–(47) can be combined into the single vector equation

$$\frac{\partial^2 \boldsymbol{\xi}}{\partial t^2}=(c_1^2-c_2^2)\nabla(\nabla\cdot\boldsymbol{\xi})+c_2^2\nabla^2\boldsymbol{\xi}. \tag{58}$$

Here the quantities c_1 and c_2 are defined by

$$c_1^2=(\lambda_\mathrm{L}+2\mu_\mathrm{L})/\rho, \tag{59}$$

$$c_2^2=\mu_\mathrm{L}/\rho. \tag{60}$$

Because any vector field may be decomposed into a sum of two fields, one with zero curl and the other with zero divergence, one can set the vector $\boldsymbol{\xi}$ equal to

$$\boldsymbol{\xi}=\nabla\Phi+\nabla\times\boldsymbol{\Psi} \tag{61}$$

in terms of a scalar and a vector potential. This expression will satisfy Eq. (58) identically, provided the two potentials separately satisfy

$$\nabla^2\Phi-\frac{1}{c_1^2}\frac{\partial^2\Phi}{\partial t^2}=0, \tag{62}$$

$$\nabla^2\boldsymbol{\Psi}-\frac{1}{c_2^2}\frac{\partial^2\boldsymbol{\Psi}}{\partial t^2}=0. \tag{63}$$

Both of these equations are of the form of the simple wave equation of Eq. (55). The first corresponds to longitudinal wave propagation, and the second corresponds to shear wave propagation. The quantities c_1 and c_2 are referred to as the dilatational and shear wave speeds, respectively.

If the displacement field is irrotational, so that the curl of the displacement vector is zero (as is so for sound in fluids), then each component of the displacement field satisfies Eq. (62). If the displacement field is solenoidal, so that its divergence is zero, then each component of the displacement satisfies Eq. (63).

2.5 Linearized Equations for a Viscous Fluid

For the restricted but relatively widely applicable case when the Navier–Stokes–Fourier equations are presumed to hold and the characteristic scales of the ambient medium and the disturbance are such that the ambient flow is negligible, and the coefficients are idealizable as constants, the linear equations have the form appropriate for a disturbance in a homogeneous, time-independent, nonmoving medium, these equations being

$$\frac{\partial \rho'}{\partial t}+\rho_0\nabla\cdot\mathbf{v}'=0, \tag{64}$$

$$\rho_0\frac{\partial \mathbf{v}'}{\partial t}=-\nabla p'+\left(\frac{1}{3}\mu+\mu_B\right)\nabla(\nabla\cdot\mathbf{v}')+\mu\nabla^2\mathbf{v}', \tag{65}$$

$$\rho_0 T_0 \frac{\partial s'}{\partial t} = \kappa \nabla^2 T', \tag{66}$$

$$\rho' = \frac{1}{c^2} p' - \left(\frac{\rho \beta T}{c_p}\right)_0 s', \tag{67}$$

$$T' = \left(\frac{T\beta}{\rho c_p}\right)_0 p' + \left(\frac{T}{c_p}\right)_0 s'. \tag{68}$$

The primes on the perturbation field variables are needed here to distinguish them from the corresponding ambient quantities.

2.6 Acoustic, Entropy, and Vorticity Modes

In general, any solution of the linearized equations for a fluid with viscosity and thermal conductivity can be regarded (Kirchhoff, 1868; Cremer, 1948; Kovasznay, 1953; Pierce, 1989) as a sum of three basic types of solutions. The common terminology for these is (i) the acoustic mode, (ii) the entropy mode, and (iii) the vorticity mode. Thus, with appropriate subscripts denoting the various fundamental mode types, one writes the fluid velocity perturbation in the form

$$\mathbf{v}' = \mathbf{v}_{\mathrm{ac}} + \mathbf{v}_{\mathrm{ent}} + \mathbf{v}_{\mathrm{vor}} \tag{69}$$

with similar decompositions for the other field variables. The decomposition is intended to be such that, for waves of constant frequency, each field variable's contribution from any given mode satisfies a partial differential equation that is second order [rather than of some higher order as might be derived from Eqs. (64)–(68)] in the spatial derivatives. That such a decomposition is possible follows from a theorem (Wu, 1956; Courant, 1937) that any solution of a partial differential equation of, for example, the form

$$(\nabla^2 + \lambda_1)(\nabla^2 + \lambda_2)(\nabla^2 + \lambda_3)\psi = 0 \tag{70}$$

can be written as a sum,

$$\psi = \psi_1 + \psi_2 + \psi_3, \tag{71}$$

where the individual terms each satisfy second-order differential equations of the form

$$(\nabla^2 + \lambda_i)\psi_i = 0. \tag{72}$$

This decomposition is possible providing no two of the λ_i are equal. Thus one has replaced the seemingly formidable problem of solving a sixth-order partial differential equation by that of solving three second-order partial differential equations

Linear acoustics is primarily concerned with solutions of the equations that govern the acoustic mode, while conduction heat transfer is primarily concerned with solutions of the equations that govern the entropy mode. However, the simultaneous consideration of all three solutions is often necessary when one seeks to satisfy boundary conditions at solid surfaces. The decomposition becomes relatively simple when the characteristic angular frequency is sufficiently small that

$$\omega \ll \rho c^2 / (\tfrac{4}{3}\mu + \mu_B), \tag{73}$$

$$\omega \ll \rho c^2 c_p / \kappa. \tag{74}$$

These conditions are invariably well met in all applications of interest. For air the right-hand sides of the two inequalities correspond to frequencies of the order of 10^9 Hz, while for water they correspond to frequencies of the order of 10^{12} Hz. If the inequalities are not satisfied, it is also possible that the Navier–Stokes–Fourier model is not appropriate, since the latter presumes that the variations are sufficiently slow that the medium can be regarded as being in quasithermodynamic equilibrium.

The acoustic mode and the entropy mode are both characterized by the vorticity (curl of the fluid velocity) being identically zero. (This characterization is consistent with the theorem that any vector field can be decomposed into a sum of a field with zero divergence and a field with zero curl.) In the limit of zero viscosity and thermal conductivity [which is a limit consistent with Eqs. (73) and (74)], the acoustic mode is characterized by zero entropy perturbations, while the entropy mode is a static entropy perturbation, with zero pressure perturbation. These identifications allow the approximate equations governing the various modes to be developed in the limit for which the inequalities are valid. In carrying out the development, it is convenient to use an expansion parameter defined by

$$\epsilon = \omega\mu / \rho_0 c^2, \tag{75}$$

where ω is a characteristic angular frequency, or equivalently, the reciprocal of a characteristic time for the perturbation. In the ordering, ϵ is regarded as small, μ_B/μ and $\kappa/\mu c_p$

are regarded as of order unity, and all time derivative operators are regarded as of order ω.

Acoustic Mode. To zeroth order in ϵ, the acoustic mode is what results when the thermal conductivity and the viscosities are identically zero and the entropy perturbation is also zero. In such a case, the relations of Eqs. (52) and (53) are valid and one obtains the wave equation of Eq. (55). All of the field variables in the acoustic mode satisfy this wave equation to zeroth order in ϵ. This is so because the governing equations have constant coefficients.

When one wishes to take into account the corrections that result to first order in ϵ, the entropy perturbation is no longer regarded as identically zero, but its magnitude can be deduced by replacing the T' that appears in Eq. (66) by only the first term in the sum of Eq. (68), the substitution being represented by

$$T_{\mathrm{ac}}=(T_0\beta/\rho_0 c_p)p_{\mathrm{ac}}. \tag{76}$$

To the same order of approximation one may use the zeroth-order wave equation, Eq. (55), to express the right-hand side of Eq. (66) in terms of a second-order time derivative of the acoustic-mode pressure. The resulting equation can then be integrated once in time with the constant of integration set equal to zero, because the acoustic mode's entropy perturbation must vanish when the corresponding pressure perturbation is identically zero. Thus one obtains the acoustic-mode entropy as

$$s_{\mathrm{ac}}\approx\frac{\kappa\beta}{\rho_0^2 c^2 c_p}\frac{\partial p_{\mathrm{ac}}}{\partial t} \tag{77}$$

correct to first order in ϵ.

This expression for the entropy perturbation is substituted into Eq. (67) and the resulting expression for ρ_{ac} is substituted into the conservation-of-mass relation, represented by Eq. (64), so that one obtains

$$\frac{\partial p_{\mathrm{ac}}}{\partial t}-\frac{(\gamma-1)\kappa}{\rho_0 c^2 c_p}\frac{\partial^2 p_{\mathrm{ac}}}{\partial t^2}+\rho_0 c^2\nabla\cdot\mathbf{v}_{\mathrm{ac}}=0. \tag{78}$$

The vorticity in the acoustic mode is zero,

$$\nabla\times\mathbf{v}_{\mathrm{ac}}=0, \tag{79}$$

so the momentum balance equation, Eq. (65), simplifies to one where the right-hand side is a gradient. Then with an appropriate substitution for the divergence of the fluid velocity from Eq. (78), one finds that the momentum-balance equation to first order in ϵ takes the form

$$\rho_0\frac{\partial\mathbf{v}_{\mathrm{ac}}}{\partial t}=-\nabla\left[p_{\mathrm{ac}}+\frac{1}{\rho_0 c^2}\left(\frac{4}{3}\mu+\mu_B\right)\frac{\partial p_{\mathrm{ac}}}{\partial t}\right]. \tag{80}$$

The latter and Eq. (78), in a manner similar to that in which the wave equation of Eq. (54) is derived, yield the dissipative wave equation represented by

$$\nabla^2 p_{\mathrm{ac}}-\frac{1}{c^2}\frac{\partial^2 p_{\mathrm{ac}}}{\partial t^2}+\frac{2\delta_{\mathrm{cl}}}{c^4}\frac{\partial^3 p_{\mathrm{ac}}}{\partial t^3}=0. \tag{81}$$

The quantity δ_{cl}, defined by

$$\delta_{\mathrm{cl}}=(1/2\rho_0)\left[\tfrac{4}{3}\mu+\mu_B+(\gamma-1)(\kappa/c_p)\right], \tag{82}$$

is a constant that characterizes the "classical" dissipation in the acoustic mode.

Entropy Mode. For the entropy mode, the pressure perturbation vanishes to zeroth order in ϵ, while the entropy perturbation does not. Thus for this mode, Eqs. (67) and (68) approximate in zeroth order to

$$\rho_{\mathrm{ent}}=-(\rho\beta T/c_p)_0 s_{\mathrm{ent}}, \tag{83}$$

$$T_{\mathrm{ent}}=(T/c_p)_0 s_{\mathrm{ent}}. \tag{84}$$

The latter, when substituted into the energy equation, Eq. (66), yields the diffusion equation of conduction heat transfer,

$$\frac{\partial s_{\mathrm{ent}}}{\partial t}=\frac{\kappa}{\rho_0 c_p}\nabla^2 s_{\mathrm{ent}}. \tag{85}$$

All of the entropy-mode field variables, including T_{ent}, satisfy this diffusion equation to lowest order in ϵ.

The mass-conservation equation, with an analogous substitution from Eq. (83) and another substitution from Eq. (85), integrates to

$$\mathbf{v}_{\mathrm{ent}}=(\beta T_0\kappa/\rho_0 c_p^2)\nabla s_{\mathrm{ent}}, \tag{86}$$

so there is a weak fluid flow caused by entropy or temperature gradients in the entropy mode. The substitution of this expression for the fluid velocity into the linearized Navier–Stokes equation, Eq. (65), subsequently yields a lowest-order expression for the entropy-mode contribution to the pressure perturbation, this being

$$p_{\mathrm{ent}}=\frac{\beta T_0}{c_p}\left(\frac{4}{3}\mu+\mu_B-\frac{\kappa}{c_p}\right)\frac{\partial s_{\mathrm{ent}}}{\partial t}. \tag{87}$$

Vorticity Mode. For the vorticity mode, the divergence of the fluid velocity is identically zero,

$$\nabla\cdot\mathbf{v}_{\text{vor}}=0. \tag{88}$$

The mass-conservation equation, Eq. (64), and the thermodynamic relations, Eqs. (67) and (68), consequently require that all of the thermodynamic field quantities with subscript "vor" are zero. The Navier–Stokes equation, Eq. (65), accordingly requires that each component of the fluid velocity associated with this mode satisfy the vorticity diffusion equation

$$\rho_0\frac{\partial\mathbf{v}_{\text{vor}}}{\partial t}=\mu\nabla^2\mathbf{v}_{\text{vor}}. \tag{89}$$

2.7 Boundary Conditions at Interfaces

For the model of a fluid without viscosity or thermal conduction, such as is governed by Eqs. (52) through (56), the appropriate boundary conditions at an interface are that the normal component of the fluid velocity be continuous and that the pressure be continuous. At a rigid nonmoving surface, the normal component must consequently vanish, but no restrictions are placed on the tangential component of the velocity. The model also places no requirements on the value of the temperature at a solid surface.

When viscosity is taken into account, no matter how small it may be, the model demands additional boundary conditions. An additional condition invariably imposed is that the tangential components of the velocity also be continuous, the rationale (Lamb, 1932) being that a fluid should not slip any more freely with respect to an interface than it does with itself; this lack of slip is invariably observed (Shapiro, 1961) when the motion is examined sufficiently close to an interface. Similarly, when thermal conduction is taken into account, the rational interpretation of the model requires that the temperature be continuous at an interface. Newton's third law requires that the shear stresses exerted across an interface be continuous and the conservation of energy requires that the normal component of the heat flux be continuous.

The apparent paradox, that tiny but nonzero values of the viscosity and thermal conductivities should drastically alter the basic nature of the boundary conditions at an interface, is resolved by acoustic boundary-layer theory. Under normal circumstances, disturbances associated with sound are almost entirely in the acoustic mode except in oscillating acoustic boundary layers near interfaces. In these boundary layers, a portion of the disturbance is in the entropy and vorticity modes. These modes make minor contributions to the total perturbation pressure and normal velocity component, but, respectively, have temperature and tangential velocity components that are comparable to those of the acoustic mode. The boundary and continuity conditions can be satisfied by the sum of the three mode fields, but not by the acoustic-mode field alone. However, the entropy- and vorticity-mode fields typically die out rapidly with distance from an interface. The characteristic decay lengths when the disturbance has an angular frequency ω are (Pierce, 1989)

$$l_{\text{vor}}=(2\mu/\omega\rho)^{1/2}, \tag{90}$$

$$l_{\text{ent}}=(2\kappa/\omega\rho c_p)^{1/2}. \tag{91}$$

Given that the parameter ϵ in Eq. (75) is much less than unity, these lengths are much shorter than a characteristic wavelength. If they are, in addition, much shorter than the dimensions of the space to which the acoustic field is confined, then the acoustic boundary layer has a minor effect on the acoustic field outside the boundary layer. However, because dissipation of energy can occur within such boundary layers, the existence of a boundary layer can have a long-term accumulative effect. This can be manifested by the larger attenuation of sound waves propagating in pipes (Lambert, 1951) and in the finite *Q*'s (quality factors) of resonators.

3. WAVES OF CONSTANT FREQUENCY

3.1 General

One of the principal terms used in describing sound is that of frequency. Although certainly not all acoustic disturbances are purely sinusoidal oscillations of a quantity (such as pressure or displacement) that oscillates with constant frequency about a mean value, it is usually possible to characterize (at least to an order of magnitude) any such disturbance by one or a limited number of representative frequencies, these being the reciprocals of the characteristic time scales. Such a description is highly useful, because it gives one some insight into what detailed physical effects are relevant and what instrumentation is applicable. The simplest sort of acoustic signal would be one where a quantity such as the fluctuating part p of the pressure is oscillating with time t as

$$p=A\sin(\omega t+\phi). \tag{92}$$

Here the amplitude A and phase constant ϕ are independent of t (but possibly dependent on position). The quantity ω is called the angular frequency and has the units of radians divided by time (for example, rad/s or simply s^{-1} when the unit of time is the second). The number f of repetitions per unit time is what one normally refers to as the frequency (without a modifier), such that $\omega=2\pi f$. The value of f in hertz (abbreviated Hz) is the frequency in cycles (repetitions) per second.

The human ear responds (Fletcher, 1940) almost exclusively to frequencies between roughly 20 Hz and 20 kHz. Consequently, sounds composed of frequencies below 20 Hz are said to be infrasonic; those composed of frequencies above 20 kHz are said to be ultrasonic. The scope of acoustics, given its general definition, is not limited to only audible frequencies.

3.2 Spectral Density

The term frequency spectrum is often used in relation to sound. Often the use is somewhat loose, but there are circumstances for which the terminology can be made precise. If the fluctuating physical quantity p associated with the acoustic disturbance is a sum of sinusoidal disturbances, the nth having rms amplitude p_n and frequency f_n, no two frequencies being the same, then the set of mean squared amplitudes can be taken as a description of the spectrum of the signal. Also, if the sound is made up of many different frequencies, then one can use the sum of the p_n^2 that correspond to those frequencies within a given specified frequency band as a measure of the strength of the signal within that frequency band. This sum divided by the width of the frequency band often approaches a quasilimit as the bandwidth becomes small but with the number of included terms still being moderately large, with this quasilimit being a definite smooth function of the center frequency of the band. This quasilimit is called the spectral density p_f^2 of the signal. Although an idealized quantity, it can often be repetitively measured to relatively high accuracy; instrumentation for "measurement" of spectral densities or of integrals of spectral densities over specified frequency bands (such as octaves) is widely available commercially.

The utility of the spectral density concept rests on the principle of superposition and on a version of Parseval's theorem which states that, when the signal is a sum of discrete frequency components, then if averages are taken over a sufficiently long time interval,

$$(p^2)_{\text{av}}=\sum p_n^2. \tag{93}$$

Consequently, in the quasilimit corresponding to the spectral density description, one has the mean squared pressure expressed as an integral over spectral density,

$$(p^2)_{\text{av}}=\int_0^\infty p_f^2(f)\,df. \tag{94}$$

The spectral density at a given frequency times a narrow bandwidth centered at that frequency is interpreted as the contribution to the mean squared acoustic pressure from that frequency band.

If the signal is a linear response to a source (or excitation) characterized by some time variation $s(t)$ with spectral density $s_f^2(f)$, then the spectral density of the response is

$$p_f^2(f)=|H_{ps}(2\pi f)|^2 s_f^2(f), \tag{95}$$

where the proportionality factor $|H_{ps}(2\pi f)|^2$ is the square of the absolute magnitude of a transfer function which is independent of the excitation but which does depend on frequency. For any given frequency, this transfer function can be determined from the response to a known sinusoidal excitation with the same frequency. Thus the analysis for constant-frequency excitation is fundamental, even when the situation of interest may involve broadband excitation.

3.3 Complex-Number Representation

Insofar as the governing equations are linear with coefficients independent of time, disturbances that vary sinusoidally with time propagate without change of frequency. Such sinusoidally varying disturbances of constant frequency have the same repetition period (reciprocal of frequency) at every point, but the phase will in general vary from point to point.

When one considers a disturbance of fixed frequency or one frequency component of a multifrequency disturbance, it is convenient to use a complex-number representation, such that each field amplitude is written as (Rayleigh, 1878; Bouwkamp, 1946)

$$p=\mathrm{Re}(\hat{p}\,e^{-i\omega t}). \tag{96}$$

Here $\hat{p}$ is called the complex amplitude of the acoustic pressure and in general varies with position.

If one inserts expressions such as that of Eq. (96) into a homogeneous linear ordinary or partial differential equation with real time-independent coefficients, the result can always be written in the form

$$\mathrm{Re}(\Phi e^{-i\omega t})=0, \tag{97}$$

where the quantity Φ is an expression depending on the complex amplitudes and their spatial derivatives, but not depending on time. The requirement that Eq. (97) should hold for all values of time consequently can be satisfied if and only if

$$\Phi=0. \tag{98}$$

Moreover, the form of the expression Φ can be readily obtained from the original equation with a simple prescription: replace all field variables by their complex amplitudes and replace all time derivatives using the substitution

$$\frac{\partial}{\partial t}\rightarrow -i\omega. \tag{99}$$

Thus, for example, the linear acoustic equations given by Eqs. (52) and (53) reduce to

$$-i\omega\hat{p}+\rho c^2\nabla\cdot\hat{\mathbf{v}}=0, \tag{100}$$

$$-i\omega\rho\hat{\mathbf{v}}=-\nabla\hat{p}. \tag{101}$$

The wave equation in Eq. (55) reduces to

$$\nabla^2\hat{p}+k^2\hat{p}=0, \tag{102}$$

which is the Helmholtz equation (Helmholtz, 1860; Birkhoff, 1973) for the complex pressure amplitude.

4. PLANE WAVES

4.1 Plane Waves in Fluids

A solution of the wave equation that plays a central role in many acoustical concepts is that of a plane traveling wave, which is such that all acoustic field quantities vary with time and with one Cartesian coordinate, taken here as x, but are independent of y and z. The Laplacian reduces thus to a second partial derivative with respect to x and the d'Alembertian can be expressed as the product of two first-order operators, so that the wave equation takes the form

$$\left(\frac{\partial}{\partial x}-\frac{1}{c}\frac{\partial}{\partial t}\right)\left(\frac{\partial}{\partial x}+\frac{1}{c}\frac{\partial}{\partial t}\right)p=0. \tag{103}$$

The solution of this equation is a sum of two expressions, each of which is such that operation by one of the two factors in Eq. (103) yields zero. Such a solution is represented by

$$p(x,t)=f(x-ct)+g(x+ct), \tag{104}$$

where f and g are two arbitrary functions. The argument combination $x-ct$ of the first term is such that the function f with that argument represents a plane wave traveling forward in the $+x$ direction at a velocity c. The second term in Eq. (104) similarly represents a plane wave traveling backwards, in the $-x$ direction, also at a velocity c. For a traveling plane wave, not only the shape but also the amplitude is conserved during propagation. A typical situation for which wave propagation can be adequately described with traveling plane waves is that of low-frequency sound propagation in a duct. Diverging or converging (focused) waves can often be approximately regarded as planar within regions of restricted extent.

The fluid velocity that corresponds to the plane-wave solution above has y and z components that are identically zero, but the x component, in accordance with Eqs. (52) and (53), is

$$v_x=\frac{1}{\rho c}\,f(x-ct)-\frac{1}{\rho c}\,g(x+ct). \tag{105}$$

The general rule that emerges from this is that, for a plane wave propagating in the direction corresponding to unit vector $\mathbf{n}$, the acoustic part of the pressure is

$$p=f(\mathbf{n}\cdot\mathbf{x}-ct) \tag{106}$$

for some generic function f of the indicated argument, while the acoustically induced fluid velocity is

$$\mathbf{v}=(\mathbf{n}/\rho c)p. \tag{107}$$

Because the fluid velocity is in the same direction as that of the wave propagation, such waves are said to be longitudinal. (Electromagnetic plane waves in free space, on the other hand, are transverse.)

For a plane wave traveling along the $+x$ axis at a velocity c, the form of Eq. (106) implies that one can represent a constant-frequency acoustic pressure disturbance by the expression

$$p=|P|\cos[k(x-ct)+\phi_0]=\mathrm{Re}(Pe^{ik(x-ct)}) \tag{108}$$

with the angular frequency identified as

$$\omega=ck. \tag{109}$$

Alternatively, if the complex-amplitude representation of Eq. (96) is used, one writes the complex amplitude of the acoustic pressure as

$$\hat{p}=Pe^{ikx}, \tag{110}$$

where P is a complex number related to the constants that appear in Eq. (108) as

$$P=|P|e^{i\phi_0}. \tag{111}$$

Here $|P|$ is the amplitude of the disturbance, ϕ_0 is a phase constant, and k is a constant termed the wave number. The wavelength λ is the increment in propagation distance x required to change the argument of the cosine by 2π radians, so

$$k=2\pi/\lambda. \tag{112}$$

Also, the increment in t required to change the argument by 2π is the period T, which is the reciprocal of the frequency f, so one has

$$\lambda=c/f. \tag{113}$$

4.2 Plane Waves in Solids

Plane acoustic waves in isotropic elastic solids (Landau and Lifshitz, 1970) have properties similar to those of waves in fluids. Dilatational (or longitudinal) plane waves are such that the curl of the displacement field vanishes, so the displacement vector must be parallel to the direction of propagation. A comparison of Eq. (62) with the wave equation of Eq. (55) indicates that such a wave must propagate with the speed c_1 determined by Eq. (59). Thus, a wave propagating in the $+x$ direction has no y and z components of displacement, and has an x component described by

$$\xi_x=F(x-c_1t), \tag{114}$$

where F is an arbitrary function. The stress components can be deduced from Eqs. (46), (47), (59), and (60). These equations as well as symmetry considerations require, for a dilatational wave propagating in the x direction, that the off-diagonal elements of the stress tensor vanish. The diagonal elements are given by

$$\sigma_{xx}=\rho c_1^2F'(x-c_1t), \tag{115}$$

$$\sigma_{yy}=\sigma_{zz}=\rho(c_1^2-2c_2^2)F'(x-c_1t). \tag{116}$$

(Here the primes denote derivatives with respect to the total argument.)

The divergence of the displacement field in a shear wave is zero, so a plane shear wave must cause a displacement perpendicular to the direction of propagation. Shear waves are therefore transverse waves. Equation (63), when considered in a manner similar to that described above for the wave equation for waves in fluids, leads to the conclusion that plane shear waves must propagate with speed c_2. A plane shear wave polarized in the y direction and propagating in the x direction will have only a y component of displacement, given by

$$\xi_y=F(x-c_2t). \tag{117}$$

The only nonzero stress components are the shear stresses

$$\sigma_{yx}=\rho c_2^2F'(x-c_2t)=\sigma_{xy}. \tag{118}$$

5. ATTENUATION OF SOUND

5.1 General

Plane waves of constant frequency propagating through bulk materials have amplitudes that typically decrease exponentially with increasing propagation distance, such that the magnitude of the complex pressure amplitude varies as

$$|\hat{p}(x)| = |\hat{p}(0)| e^{-\alpha x}. \tag{119}$$

The quantity α is the plane-wave attenuation coefficient and has the units of nepers per meter (Np/m); it is an intrinsic frequency-dependent property of the material. This exponential decrease of amplitude is called attenuation or absorption of sound and is associated with the transfer of acoustic energy to the internal energy of the material.

5.2 Classical Absorption

The attenuation of sound due to the classical processes of viscous energy absorption and thermal conduction is derivable (Kirchhoff 1868) from the dissipative wave equation, Eq. (81), given previously for the acoustic mode. Dissipative processes enter into this equation through a parameter δ_{cl}, which is defined by Eq. (82). To determine the attenuation of waves governed by such a dissipative wave equation, one sets the perturbation pressure equal to

$$p_{\mathrm{ac}} = Pe^{-i\omega t}e^{ikx}, \tag{120}$$

where P is independent of position and k is a complex number. Such a substitution, with reasoning such as that which leads from Eq. (97) to Eq. (98), yields an algebraic equation that can be nontrivially (amplitude not identically zero) satisfied only if k satisfies the relation

$$k^2 = (1/c^2)\,\omega^2 + i(2\delta_{\mathrm{cl}}\omega^3/c^3). \tag{121}$$

The root that corresponds to waves propagating in the plus x direction is that which evolves to Eq. (109) in the limit of no absorption, and for which the real part of k is positive. Thus to first order in δ_{cl}, one has the complex wave number

$$k = \omega/c + i(\delta_{\mathrm{cl}}\omega^2/c^3). \tag{122}$$

The attenuation coefficient is the imaginary part of this, in accordance with Eq. (119), so

$$\alpha_{\mathrm{cl}} = \delta_{\mathrm{cl}}\omega^2/c^3. \tag{123}$$

This is termed the classical attenuation coefficient for acoustic waves in fluids and is designated by the subscript "cl." The distinguishing characteristic of this classical attenuation coefficient is its quadratic increase with increasing frequency.

5.3 Relaxation Processes

For many substances, including air and sea water, the variation of absorption coefficient with frequency is not quadratic (Beyer and Letcher, 1969; Markham, Beyer, and Lindsay, 1951; Lindsay, 1974), and the classical model is insufficient to predict the magnitude of the absorption coefficient. The substitution of a different value of the bulk viscosity is insufficient to remove the discrepancy, because such would still yield the quadratic frequency dependence. The successful theory to account for such discrepancies is in terms of relaxation processes. The physical nature of the relaxation processes varies from fluid to fluid, but general theory in terms of irreversible thermodynamics (Meixner, 1943, 1952a,b) yields appropriate equations.

The equation of state for the instantaneous (rather than equilibrium) entropy is written as

$$s = s(u, \rho^{-1}, \xi), \tag{124}$$

where ξ represents one or more internal variables. The differential relation of Eq. (10) is replaced by

$$T\,ds = du + p\,d(\rho^{-1}) + \sum_{\nu} A_\nu d\xi_\nu, \tag{125}$$

where the affinities A_ν are defined by this equation. These vanish when the fluid is in equilibrium with a given specified internal energy and density. The pressure p is the same as entered into the expression, Eq. (12), for the average normal stress, and the T is the same as entered into the Fourier law, Eq. (13), of heat conduction. The mass-conservation law, Eq. (1), and the Navier–Stokes equation, Eq. (21), remain unchanged, but the energy equation, expressed in Eq. (22) in terms of entropy, is replaced by the entropy balance equation

$$\rho\frac{Ds}{Dt} + \nabla\cdot\frac{\mathbf{q}}{T} = \sigma_s. \tag{126}$$

Here the quantity σ_s, which indicates the rate of irreversible entropy production per unit volume, is given by

$$T\sigma_s=\mu_B(\nabla\cdot\mathbf{v})^2+\frac{1}{2}\mu\sum_{ij}\phi_{ij}^2+\frac{\kappa}{T}(\nabla T)^2$$
$$+\rho\sum_\nu A_\nu\frac{D\xi_\nu}{Dt}. \tag{127}$$

One needs, in addition, relations that specify how the internal variables ξ_ν relax to their equilibrium values. The simplest assumption, and one which is substantiated for air and sea water, is that these relax independently according to the rule (Herzfeld and Rice, 1928)

$$\frac{D\xi_\nu}{Dt}=-\frac{1}{\tau_\nu}(\xi_\nu-\xi_{\nu,\mathrm{eq}}). \tag{128}$$

The relaxation times τ_ν that appear here are positive and independent of the internal variables.

When the linearization process is applied to the nonlinear equations for the model just described of a fluid with internal relaxation, one obtains the set of equations

$$\frac{\partial\rho'}{\partial t}+\rho_0\nabla\cdot\mathbf{v}'=0, \tag{129}$$

$$\rho_0\frac{\partial\mathbf{v}'}{\partial t}=-\nabla p'+(\tfrac{1}{3}\mu+\mu_B)\nabla(\nabla\cdot\mathbf{v}')+\mu\nabla^2\mathbf{v}', \tag{130}$$

$$\rho_0T_0\frac{\partial s'}{\partial t}=\kappa\nabla^2T', \tag{131}$$

$$\rho'=\frac{1}{c^2}p'-\left(\frac{\rho\beta T}{c_p}\right)_0s'+\sum_\nu(\xi'_\nu-\xi'_{\nu,\mathrm{eq}})a_\nu, \tag{132}$$

$$T'=\left(\frac{T\beta}{\rho c_p}\right)_0p'+\left(\frac{T}{c_p}\right)_0s'+\sum_\nu(\xi'_\nu-\xi'_{\nu,\mathrm{eq}})b_\nu, \tag{133}$$

$$\frac{\partial\xi'_\nu}{\partial t}=-\frac{1}{\tau_\nu}(\xi'_\nu-\xi'_{\nu,\mathrm{eq}}), \tag{134}$$

$$\xi'_{\nu,\mathrm{eq}}=m_\nu s'+n_\nu p'. \tag{135}$$

Here a_ν, b_ν, m_ν, and n_ν are constants whose values depend on the ambient equilibrium state.

For absorption of sound, the interest is in the acoustic mode, and so approximations corresponding to those discussed in the context of Eqs. (73)–(81) can be made here also. The quantities a_ν and b_ν are treated as small, so that one obtains, to first order in ϵ and in these quantities, a wave equation of the form

$$\nabla^2p_{\mathrm{ac}}-\frac{1}{c^2}\frac{\partial^2}{\partial t^2}\left(p_{\mathrm{ac}}-\frac{2\delta_{\mathrm{cl}}}{c^2}\frac{\partial p_{\mathrm{ac}}}{\partial t}\right.$$
$$\left.-2\sum_\nu\frac{(\Delta c)_\nu}{c}\tau_\nu\frac{\partial p_\nu}{\partial t}\right)=0. \tag{136}$$

The auxiliary internal variables that enter here satisfy the supplemental relaxation equations

$$\frac{\partial p_\nu}{\partial t}=-\frac{1}{\tau_\nu}(p_\nu-p_{\mathrm{ac}}). \tag{137}$$

Here the notation is such that the p_ν are given in terms of previously introduced quantities by

$$p_\nu=\xi'_\nu/n_\nu. \tag{138}$$

The sound-speed increments that appear in Eq. (136) represent the combinations

$$(\Delta c)_\nu=\tfrac{1}{2}a_\nu n_\nu c^2. \tag{139}$$

Equations (136) and (137) are independent of the explicit physical interpretation of the relaxation processes. Insofar as acoustic propagation is concerned, any relaxation process is characterized by two parameters, the relaxation time τ_ν and the sound-speed increment $(\Delta c)_\nu$. The various parameters that enter into the irreversible thermodynamics formulation of Eqs. (132)–(135) affect the propagation of sound only as they enter into the values of the relaxation time and the sound-speed increments. The replacement of internal variables by quantities p_ν with the units of pressure implies no assumption as to the precise nature of the relaxation process.

The attenuation of plane waves governed by Eqs. (136) and (137) is determined when one inserts substitutions of the form of Eq. (120) for p_{ac} and the p_ν. The relaxation equations yield the relations

$$\hat{p}_\nu=\frac{1}{1-i\omega\tau_\nu}\hat{p}_{\mathrm{ac}}. \tag{140}$$

When inserted into the complex amplitude version of Eq. (136), these yield the dispersion relation

$$k^2=\frac{\omega^2}{c^2}\left(1+i\frac{2\omega\delta_{\mathrm{cl}}}{c^2}+\sum_\nu\frac{2(\Delta c)_\nu}{c}\frac{i\omega\tau_\nu}{1-i\omega\tau_\nu}\right). \tag{141}$$

To first order in the small parameters, δ_{cl} and $(\Delta c)_\nu$, this yields the complex wave number

$$k=\frac{\omega}{c}\left(1+i\frac{\omega\delta_{\mathrm{cl}}}{c^2}+\sum_{\nu}\frac{(\Delta c)_{\nu}}{c}\frac{i\omega\tau_{\nu}}{1-i\omega\tau_{\nu}}\right), \tag{142}$$

which corresponds to waves propagating in the $+x$ direction. The attenuation coefficient, determined by the imaginary part of Eq. (142), can be written

$$\alpha=\alpha_{\mathrm{cl}}+\sum_{\nu}\alpha_{\nu}. \tag{143}$$

The first term is the classical attenuation determined by Eq. (123). The remaining terms correspond to the incremental attenuations produced by the separate relaxation processes, these being

$$\alpha_{\nu}=\frac{(\Delta c)_{\nu}}{c^2}\frac{\omega^2\tau_{\nu}}{1+(\omega\tau_{\nu})^2}. \tag{144}$$

Any such term increases quadratically with frequency at low frequencies, as would be the case for classical absorption (with an increased bulk viscosity), but it approaches a constant value at high frequencies.

The labeling of the quantities $(\Delta c)_{\nu}$ as sound-speed increments follows from an examination of the real part of the complex wave number, given by

$$k_R=\frac{\omega}{c}\left(1-\sum_{\nu}\frac{(\Delta c)_{\nu}}{c}\frac{(\omega\tau_{\nu})^2}{1+(\omega\tau_{\nu})^2}\right). \tag{145}$$

The ratio of ω to k_R is identified as the phase velocity v_{ph} of the wave. In the limit of low frequencies, the phase velocity predicted by Eq. (145) is the quantity c, which is the sound speed for a quasiequilibrium process. In the limit of high frequencies, however, to first order in the $(\Delta c)_{\nu}$, the phase velocity approaches the limit

$$v_{\mathrm{ph}}\rightarrow c+\sum_{\nu}(\Delta c)_{\nu}. \tag{146}$$

Consequently, each $(\Delta c)_{\nu}$ corresponds to the net increase in phase velocity of the sound wave that occurs when the frequency is increased from a value small compared to the relaxation frequency to one large compared to the relaxation frequency. Here the term relaxation frequency is used to denote the reciprocal of the product of 2π with the relaxation time.

5.4 Attenuation of Sound in Air

In air, the relaxation processes that affect sound attenuation are those associated with the internal vibrations of the diatomic molecules O_2 and N_2. The ratio of the number of molecules in the ground and first excited vibrational states is a function of temperature when the gas is in thermodynamic equilibrium, but during an acoustic disturbance the redistribution of this ratio to what is appropriate to the concurrent gas temperature is not itself instantaneous. The knowledge that the relaxation processes are vibrational relaxation processes and that only the ground and first excited states are appreciably involved allows the sound-speed increments to be determined from first principles. One need only determine the difference in sound speeds resulting from the two assumptions: (i) that the distribution of vibrational energy is frozen, and (ii) that the vibrational energy is always distributed as for a gas in total thermodynamic equilibrium. The resulting sound-speed increments are (Pierce, 1978)

$$\frac{(\Delta c)_{\nu}}{c}=\frac{(\gamma-1)^2}{2\gamma}\frac{n_{\nu}}{n}\left(\frac{T_{\nu}^*}{T}\right)^2 e^{-T_{\nu}^*/T}, \tag{147}$$

where n is the total number of molecules per unit volume and n_{ν} is the number of molecules of the type corresponding to the designation parameter ν. The quantity T is the absolute temperature, and T_{ν}^* is a characteristic temperature, equal to the energy jump ΔE between the two vibrational states divided by Boltzmann's constant. The value of T_1^* (corresponding to O_2 relaxation) is 2239 K, and the value of T_2^* (corresponding to N_2 relaxation) is 3352 K. For air the fraction n_1/n of molecules that are O_2 is 0.21, while the fraction n_2/n of molecules that are N_2 is 0.78. At a representative temperature of 20 °C, the calculated value of $(\Delta c)_1$ is 0.11 m/s, while that for $(\Delta c)_2$ is 0.023 m/s.

Because relaxation in a gas is caused by two-body collisions, the relaxation times at a given absolute temperature must vary inversely as the absolute pressure. The relatively small (and highly variable) number of water vapor molecules in the air has a significant effect on the relaxation times, because collisions of diatomic molecules with H_2O molecules are much more likely to cause a transition between one internal vibrational quantum state and another. Semiempirical expressions for the two relaxation times for air are given by (Evans, Bass, and Sutherland, 1972; Bass, Sutherland, and Zuckerwar, 1990)

$$\frac{p_{\mathrm{ref}}}{p}\frac{1}{2\pi\tau_1}=24+4.04\times 10^6 \times h\left(\frac{0.02+100h}{0.391+100h}\right), \tag{148}$$

$$\frac{p_{\mathrm{ref}}}{p}\frac{1}{2\pi\tau_2}=\left(\frac{T_{\mathrm{ref}}}{T}\right)^{1/2}(9+2.8\times 10^4 he^{-F}), \tag{149}$$

$$F=4.17[(T_{\mathrm{ref}}/T)^{1/3}-1]. \tag{150}$$

The subscript 1 corresponds to O_2 relaxation, and the subscript 2 corresponds to N_2 relaxation. The quantity h is the fraction of the air molecules that are H_2O molecules; the reference temperature is 293.16 K; and the reference pressure is 10^5 Pa. The value of h can be determined from the commonly reported relative humidity (RH) (expressed as a percentage) and the vapor pressure of water at the local temperature according to the defining relation

$$h=10^{-2}(\mathrm{RH})p_{\mathrm{VP}}(T)/p. \tag{151}$$

However, as is indicated in Eqs. (148) and (149), the physics of the relaxation process depends on the absolute humidity and has no direct involvement with the value of the vapor pressure of water. A table of the vapor pressure of water may be found in various references; some representative values in pascals are 872, 1228, 1705, 2338, 4243, and 7376 at temperatures of 5, 10, 15, 20, 30, and 40 °C.

5.5 Attenuation of Sound in Seawater

The relaxation processes contributing to the attenuation of sound are associated with dissolved boric acid $B(OH)_3$ (subscript 1) and magnesium sulfate $MgSO_4$ (subscript 2). From approximate formulas derived by Fisher and Simmons (1977) from a combination of experiment and theory one extracts the identifications

$$\delta_{\mathrm{cl}}/c^3=1.42\times 10^{-15}F(T_C)G(P_{\mathrm{atm}}) \tag{152}$$

with

$$F(T_C)=1-4.24\times 10^{-2}T_C+8.53\times 10^{-4}T_C^2 -6.23\times 10^{-6}T_C^3, \tag{153a}$$

$$G(P_{\mathrm{atm}})=1-3.84\times 10^{-4}P_{\mathrm{atm}} +7.57\times 10^{-8}P_{\mathrm{atm}}^2, \tag{153b}$$

$$(\Delta c)_1/c^2=1.64\times 10^{-9}(1+2.29\times 10^{-2}T_C -5.07\times 10^{-4}T_C^2)(S/35), \tag{154}$$

$$(\Delta c)_2/c^2=8.94\times 10^{-9}(1+0.0134T_C) \times(1-10.3\times 10^{-4}P_{\mathrm{atm}} +3.7\times 10^{-7}P_{\mathrm{atm}}^2)(S/35), \tag{155}$$

$$1/2\pi\tau_1=1320Te^{-1700/T}, \tag{156}$$

$$1/2\pi\tau_2=15.5\times 10^6 Te^{-3052/T}. \tag{157}$$

Here T_C is temperature in degrees C, T is absolute temperature, while P_{atm} is the absolute pressure in atmospheres; S is the salinity in parts per thousand (which is typically of the order of 35 for seawater). All of the quantities on the left-hand sides of these equations are in mks units.

6. ACOUSTIC INTENSITY AND POWER

6.1 General

A complete set of linear acoustic equations, regardless of the idealization incorporated into its formulation, usually yields a corollary (Kirchhoff, 1877; Pierce, 1989) of the form

$$\frac{\partial w}{\partial t}+\nabla\cdot\mathbf{I}=-\mathscr{D}, \tag{158}$$

where the terms are quadratic in the acoustic field amplitudes, the quantity w contains one term that is identifiable as a kinetic energy of fluid motion per unit volume, and the quantity $\mathscr{D}$ is either zero or positive. Such a relation is interpreted as a statement of energy conservation. The quantity w is the energy density, or energy per unit volume associated with the wave disturbance, while the vector quantity $\mathbf{I}$ is an intensity vector or energy flux vector. Its interpretation is such that its dot product with any unit vector represents the energy flowing per unit area and time across a surface whose normal is in that designated direction. The quantity $\mathscr{D}$ is interpreted as the energy that is dissipated per unit time and volume.

This interpretation of an equation such as Eq. (158) as a conservation law follows when one integrates both sides over an arbitrary fixed volume V within the fluid and reexpresses the volume integral of the divergence of $\mathbf{I}$ by a surface integral by means of Gauss's theorem. Doing this yields

$$\frac{\partial}{\partial t}\int_V w\,dV+\int_S \mathbf{I}\cdot\mathbf{n}\,dS$$
$$=-\int_V \mathscr{D}\,dV, \tag{159}$$

where $\mathbf{n}$ is the unit normal vector pointing out of the surface S enclosing V. This relation states that the net rate of increase of "acoustical energy" within the volume must equal the "acoustic power" flowing into the volume across its confining surface minus the energy that is being dissipated per unit time within the volume.

6.2 Acoustic Energy Density and Intensity

For the ideal case, when there is no ambient velocity and when viscosity and thermal conduction are neglected, the energy corollary results from Eqs. (52) and (53). The derivation begins with one's taking the dot product of the fluid velocity $\mathbf{v}$ with Eq. (53), and then using vector identities and Eq. (52) to reexpress the right-hand side as the sum of a divergence and a time derivative. The result yields the identification of the energy density as

$$w=\tfrac{1}{2}\rho v^2+\tfrac{1}{2}(1/\rho c^2)p^2, \tag{160}$$

and yields the identification of the acoustic intensity as

$$\mathbf{I}=p\mathbf{v}. \tag{161}$$

For this ideal case, there is no dissipative term on the right-hand side. The corollary of Eq. (158) remains valid even if the ambient density and sound speed should vary from point to point.

The first term in the expression for w is recognized as the acoustic kinetic energy per unit volume, and the second term is identified as the potential energy per unit volume due to compression of the fluid.

For a plane progressive wave, it follows from Eqs. (106) and (107) that the kinetic and potential energies are the same (Rayleigh, 1878) and that the energy density is given by

$$w=(1/\rho c^2)p^2. \tag{162}$$

The intensity becomes

$$\mathbf{I}=\mathbf{n}(p^2/\rho c). \tag{163}$$

For such a case, the intensity and the energy density are related by

$$\mathbf{I}=c\mathbf{n}w. \tag{164}$$

This yields the interpretation that the energy in a sound wave is moving in the direction of propagation with the sound speed. Consequently, the sound speed can be regarded as an energy propagation velocity. (This is in accord with the fact that sound waves in this idealization are nondispersive, so the group and phase velocities are the same.)

6.3 Acoustic Power

Many sound fields can be idealized as being steady, such that long-term time averages are insensitive to the duration and the center time of the averaging interval. Constant-frequency sounds and continuous noises fall into this category. For such sounds, the time derivative of the acoustic energy density will average out to zero over a sufficiently long time period, so the acoustic energy corollary of Eq. (158), in the absence of dissipation, yields the time average relation

$$\nabla\cdot\mathbf{I}_{\text{av}}=0. \tag{165}$$

This implies that the time-averaged vector intensity field is solenoidal in regions that do not contain acoustic sources. This same relation holds for any frequency component of the acoustic field or for the net contribution to the field from any given frequency band. In the following discussion, the intensity $\mathbf{I}_{\text{av}}$ is understood to refer to such a time average for some specified frequency band.

The relation of Eq. (165) yields the integral relation

$$\int_S \mathbf{I}_{\text{av}}\cdot\mathbf{n}\,dS=0, \tag{166}$$

which is interpreted as a statement that the net acoustic power flowing out of any region not containing sources must be zero on the time average and for any given frequency band.

For a closed surface which encloses one or more sources, such that the governing linear acoustic equations do not apply at every point within the volume, the reasoning above allows one to define the time-averaged net acoustic power of these sources as

$$\mathscr{P}_{\mathrm{av}}=\int_S \mathbf{I}_{\mathrm{av}}\cdot\mathbf{n}\, dS, \tag{167}$$

where the surface S encloses the sources. It follows from Eq. (166) that the acoustic power of a source computed in such a manner will be the same for any two choices for the surface S, provided that both surfaces enclose the same source and no other sources. The value of the integral is independent of the size and of the shape of S. This result is of fundamental importance for the measurement of source power. Instrumentation to measure the time-averaged intensity directly has become widely available in recent years and is often used in determining the principal noise sources in complicated environments.

6.4 Rate of Energy Dissipation

For the circumstances in which viscosity, thermal conduction, and internal relaxation are to be taken into account, the linear acoustic equations for the acoustic mode, which yield the dissipative wave equation of Eq. (136) and the relaxation equations described by Eq. (137), yield (Pierce, 1978) an energy corollary of the form of Eq. (158). To a satisfactory approximation the energy density and intensity remain as given by Eqs. (160) and (161). The energy dissipation per unit volume is no longer zero, but is instead

$$\mathscr{D}_{\mathrm{av}}=2\frac{\delta_{\mathrm{cl}}}{\rho c^4}\left(\frac{\partial p}{\partial t}\right)^2+2\sum_{\nu}\frac{(\Delta c)_{\nu}}{\rho c^3}\tau_{\nu}\left(\frac{\partial p_{\nu}}{\partial t}\right)^2 . \tag{168}$$

For constant-frequency plane waves propagating in the x direction, the time average of the time derivative of the energy density is zero, and the time averages of $\mathbf{I}$ and $\mathscr{D}$ will both be quadratic in the wave amplitude $|\hat{p}|$. The identification of the attenuation coefficient α must then be such that

$$\mathscr{D}_{\mathrm{av}}=2\alpha I_{\mathrm{av}}. \tag{169}$$

The magnitude of the acoustic intensity decreases with propagation distance x as

$$I_{\mathrm{av}}(x)=I_{\mathrm{av}}(0)e^{-2\alpha x}. \tag{170}$$

This identification of the attenuation coefficient is consistent with that given in Eq. (143).

6.5 Energy Corollary for Elastic Waves in Solids

An energy conservation corollary of the form of Eq. (158) also holds for sound in solids. The appropriate identifications for the energy density w and the components I_i of the intensity are

$$w=\frac{1}{2}\rho\sum_i\left(\frac{\partial\xi_i}{\partial t}\right)^2+\frac{1}{2}\sum_{i,j}\epsilon_{ij}\sigma_{ij}, \tag{171}$$

$$I_i=-\sum_j\sigma_{ij}\frac{\partial\xi_j}{\partial t}. \tag{172}$$

7. CYLINDRICAL AND SPHERICAL WAVES

7.1 Spherical Waves

A type of propagation of fundamental importance is that of a spherically symmetric wave spreading out radially from a source in an unbounded medium. The symmetry implies that the acoustic field variables are functions of only the radial coordinate r and time t. The Laplacian then reduces to

$$\nabla^2 p=\frac{\partial^2 p}{\partial r^2}+\frac{2}{r}\frac{\partial p}{\partial r}=\frac{1}{r}\frac{\partial^2(rp)}{\partial r^2}, \tag{173}$$

so the wave equation of Eq. (55) takes the form

$$\frac{\partial^2(rp)}{\partial r^2}-\frac{1}{c^2}\frac{\partial^2(rp)}{\partial t^2}=0. \tag{174}$$

The solution of this is given by

$$p(r,t)=r^{-1}f(r-ct)+r^{-1}g(r+ct). \tag{175}$$

Causality considerations (no sound before source is turned on) lead to the conclusion that the second term on the right-hand side of Eq. (175) is not an appropriate solution of the wave equation when the source is concentrated near the origin. The expression

$$p(r,t)=r^{-1}f(r-ct), \tag{176}$$

which describes the acoustic pressure in an outgoing spherically symmetric wave, has the property that listeners at different radii will receive (with a time shift corresponding to the propagation time) wave forms of the same shape, but of different amplitudes. The factor of $1/r$ is characteristic of spherical spreading and implies that the peak waveform amplitudes in a spherical wave decrease with radial distance as $1/r$.

Spherical waves of constant frequency have complex amplitudes governed by the Helmholtz equation, Eq. (102), with the Laplacian given as stated in Eq. (173). The complex pressure amplitude corresponding to Eq. (176) has the form of

$$p=Ar^{-1}e^{ikr}. \tag{177}$$

The fluid velocity associated with an outgoing spherical wave is purely radial and has the form

$$v_r=(1/\rho c)[-r^{-2}F(r-ct)+r^{-1}f(r-ct)]. \tag{178}$$

Here the function F is such that its derivative is the function f that appears in Eq. (176). Because the first term (a near-field term) decreases as the square rather than the first power of the reciprocal of the radial distance, the fluid velocity asymptotically approaches

$$v_r\rightarrow p/\rho c, \tag{179}$$

which is the same as the plane-wave relation of Eq. (107).

For outgoing spherical waves of constant frequency, the complex amplitude of the fluid velocity is

$$\hat{v}_r=\frac{1}{\rho c}\left(1-\frac{1}{ikr}\right)\hat{p}. \tag{180}$$

7.2 Cylindrical Waves

For cylindrically symmetric waves, there is no dependence on the azimuthal angle θ or on the axial coordinate z, so the Laplacian in cylindrical coordinates reduces to

$$\nabla^2=\frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial}{\partial r}\right), \tag{181}$$

where r is here the radial distance from the z axis. Consequently, the wave equation of Eq. (55) takes the form

$$\frac{\partial^2(r^{1/2}p)}{\partial r^2}-\frac{1}{c^2}\frac{\partial^2(r^{1/2}p)}{\partial t^2}+\frac{r^{1/2}p}{4r^2}=0. \tag{182}$$

and the Helmholtz equation of Eq. (102) takes the form

$$\frac{d^2\hat{p}}{dr^2}+\frac{1}{r}\frac{d\hat{p}}{dr}+k^2\hat{p}=0. \tag{183}$$

The solution of the latter that corresponds to an outgoing wave is a Hankel function of the first kind (Morse and Feshbach, 1953),

$$p=AH_0^{(1)}(kr). \tag{184}$$

For waves that are not of constant frequency, the wave-form shapes of outward propagating waves governed by the cylindrical wave equation, Eq. (182), tend to distort with increasing propagation distance, especially so at small r. However, at larger values of r it is often a good approximation to neglect the last term in that equation, so one obtains the approximate solution

$$p(r,t)\approx f(r-ct)/r^{1/2}, \tag{185}$$

which is similar to the expression of Eq. (176) for an outgoing spherical wave, only here the amplitude drops off with r as $r^{-1/2}$.

The latter approximate expression is consistent with the constant-frequency solution given by Eq. (184), since the Hankel function asymptotically approaches the limit

$$\lim_{kr\to\infty} H_0^{(1)}(kr)=\left(\frac{2}{\pi kr}\right)^{1/2}e^{-i\pi/4}e^{ikr}. \tag{186}$$

The fluid velocity induced by outgoing cylindrical waves is not as simply related to the corresponding acoustic pressure as that induced by a plane wave, although symmetry directs that the velocity must be in the appropriate radial direction when the propagation is cylindrically symmetric. For the constant-frequency case, an expression may be determined from the radial component of (101), such that the velocity is expressed in terms of the Hankel function of first order. However, a simple approximate result emerges in the limit of large radial distance r, this being the plane-wave relation of Eq. (179). (Here large r implies large compared to a characteristic wavelength, or compared to c divided by a characteristic angular frequency.)

8. SIMPLE SOURCES OF SOUND, GREEN'S FUNCTIONS

8.1 Volume Sources

Sources in acoustics are incorporated into the governing equations through either boundary conditions or source terms. Sources that are some distance from bounding surfaces and that are small compared to a wavelength can frequently be described by source terms. The simplest such source would be one which causes a net amount of mass of fluid to flow out of or into a surface that encases it. The mass passing out per unit time divided by the ambient density ρ is a quantity $Q_S(t)$ termed the source-strength function or the source volume velocity. If such a source is concentrated at a point $\mathbf{x}_0$, then the appropriate inhomogeneous wave equation which would replace Eq. (55) would be

$$\nabla^2 p - \frac{1}{c^2}\frac{\partial^2 p}{\partial t^2} = -\rho \dot{Q}_S(t)\delta(\mathbf{x}-\mathbf{x}_0), \qquad (187)$$

where $\delta(\mathbf{x})$ is the Dirac delta function, which has a volume integral of unity and which is concentrated at the point where its argument vanishes.

The solution of the above inhomogeneous wave equation for an isolated source in an unbounded region is

$$p = \frac{\rho}{4\pi r}\dot{Q}_S(t-[r/c]) = \frac{S(t-[r/c])}{r}, \qquad (188)$$

where

$$S(t) = \frac{\rho}{4\pi}\frac{d}{dt}Q_S(t) \qquad (189)$$

is called the monopole strength. The replacement of the argument by the retarded time $t - [r/c]$ accounts for the transit time lag r/c for the sound to propagate from the source to the listener.

The classic example of a monopole source is a pulsating small sphere. In such a case, $Q_S(t)$ can be taken as the time derivative of the instantaneous volume within the sphere. Thus the radiated acoustic pressure is proportional to the volume acceleration, the second derivative with respect to time of the sphere's volume, so that

$$p = \frac{\rho}{4\pi r}\left(\frac{d^2V}{dt^2}\right)_{t\to t-[r/c]}. \qquad (190)$$

This rule holds for bodies that are not necessarily spherically shaped, provided the largest dimensions are small compared to a characteristic wavelength and provided the acoustic pressure is measured at a sufficiently large distance from the source.

8.2 Small Piston in a Rigid Baffle

Another example of a volume source is that of a very small (relative to a wavelength) piston mounted in an infinite rigid baffle. If the piston has area A and outward normal velocity $v_n(t)$, then symmetry (or, equivalently, the inclusion of an image source) requires that the radiated sound be the same as from an isolated source with twice the volume velocity of the piston, so one has

$$p = (\rho/2\pi r)A\,\dot{v}_n(t-[r/c]). \qquad (191)$$

8.3 Multiple and Distributed Sources

For assemblages of sources, each concentrated at a point, the generalization of Eq. (187) is to replace the right-hand side by a sum of individual source terms; the solution to this inhomogeneous wave equation is given by

$$p = \sum_n \frac{S(t-[R_n/c])}{R_n}, \qquad (192)$$

where R_n is the distance of the listener from the nth source.

When the source is continuously distributed in space, the point-source term is replaced by a smoothly varying function, so the inhomogeneous wave equation is now of the form

$$\nabla^2 p - \frac{1}{c^2}\frac{\partial^2 p}{\partial t^2} = -\rho\,\dot{q}_S(\mathbf{x},t) = -4\pi s(\mathbf{x},t). \qquad (193)$$

Here the function q_S is termed the source-strength density (source strength per unit volume). For an unbounded medium, the solution of this latter equation is given by the definite integral

$$p(\mathbf{x},t) = \int \frac{1}{R} s(\mathbf{x}_0, t-[R/c])\,dV_0, \qquad (194)$$

where the volume integration ranges over source position $\mathbf{x}_0$, and where $R = |\mathbf{x} - \mathbf{x}_0|$ is the distance between listener and source positions.

8.4 Thermoacoustic Sources

The differential equation of Eq. (193) arises when one suddenly adds heat to a fluid (Chu, 1955; Westervelt and Larson, 1973), as with a laser or by combustion, so that the entropy s per unit mass changes according to the thermodynamic relation

$$\rho T\, Ds/Dt=h, \tag{195}$$

and so that, to first order, the equation-of-state relation, Eq. (68), yields

$$\frac{\partial p'}{\partial t}=c^2\frac{\partial p'}{\partial t}+\frac{c^2\beta}{c_p}h. \tag{196}$$

Here h is the heat added per unit time and unit volume, β is the volume expansion coefficient defined by Eq. (26), and c_p is the specific heat at constant pressure. Equation (196) changes the basic linear acoustic equations, Eqs. (52) and (53), to

$$\frac{\partial p}{\partial t}+\rho c^2\nabla\cdot\mathbf{v}=\frac{c^2\beta}{c_p}h, \tag{197}$$

$$\rho_0\frac{\partial\mathbf{v}}{\partial t}+\nabla p=0, \tag{198}$$

so the energy-conservation corollary of Eq. (158) becomes

$$\frac{\partial w}{\partial t}+\nabla\cdot\mathbf{I}=\frac{\beta}{\rho c_p}ph, \tag{199}$$

and the wave equation becomes

$$\nabla^2 p-\frac{1}{c^2}\frac{\partial^2 p}{\partial t^2}=-\frac{\beta}{c_p}\frac{\partial h}{\partial t}. \tag{200}$$

The appropriate identification for the monopole strength density function $s(\mathbf{x},t)$ in the integral expression of Eq. (194) is consequently given by

$$s(\mathbf{x},t)=\frac{1}{4\pi}\frac{\beta}{c_p}\frac{\partial h}{\partial t}. \tag{201}$$

8.5 Green's Functions

The idealization of a point source of constant frequency is of basic importance in formulating solutions to complicated acoustic radiation problems. The resulting complex pressure amplitude of the field resulting from such a single source can be expressed as a constant times a Green's function, where the Green's function is a solution of the inhomogeneous Helmholtz equation

$$(\nabla^2+k^2)G(\mathbf{x}\,|\,\mathbf{x}_0)=-4\pi\delta(\mathbf{x}-\mathbf{x}_0). \tag{202}$$

If the medium surrounding the source is unbounded, then the Green's function is the free-space Green's function, which can be identified from Eq. (188) to have the form

$$G(\mathbf{x}\,|\,\mathbf{x}_0)=R^{-1}\,e^{ikR}, \tag{203}$$

where R is the distance between the source and observation (listener) point. When external boundary conditions are imposed on the Green's function that satisfies Eq. (202), then the Green's function will have a form different from that of the free-space Green's function. However, in all such cases, the Green's function will approach $1/R$ plus a bounded function when the listener's position approaches the source point.

9. DIPOLES, QUADRUPOLES, AND SPHERICAL HARMONICS

9.1 Multipole Series

Radiation fields from sources of limited spatial extent in unbounded environments can be described in terms of either multipoles or spherical harmonics. That such descriptions are feasible can be demonstrated with the aid of the constant-frequency version of Eq. (194):

$$\hat{p}(\mathbf{x})=\int\hat{s}(\mathbf{x}_0)\frac{e^{ikR}}{R}\,dV_0, \tag{204}$$

which is the solution of the inhomogeneous Helmholtz equation with a continuous distribution of monopole sources taken into account.

The multipole series results when one expands $R^{-1}e^{ikR}$ in a power series in the coordinates of the source position $\mathbf{x}_0$ and then integrates term by term. Up through second order one obtains

$$\hat{p}=\hat{S}\,\frac{e^{ikr}}{r}-\sum_{\nu=1}^{3}\hat{D}_\nu\frac{\partial}{\partial x_\nu}\frac{e^{ikr}}{r}+\sum_{\mu,\nu=1}^{3}\hat{Q}_{\mu\nu}\frac{\partial^2}{\partial x_\mu\partial x_\nu}\frac{e^{ikr}}{r}, \tag{205}$$

where the coefficients are expressed by

$$\hat{S}=\int\hat{s}(\mathbf{x})dV, \tag{206}$$

$$\hat{D}_\nu=-\int x_\nu\hat{s}(\mathbf{x})dV, \tag{207}$$

$$\hat{Q}_{\mu\nu}=\frac{1}{2!}\int x_\mu x_\nu \hat{s}(\mathbf{x})dV. \tag{208}$$

The three terms in Eq. (205) are said to be the monopole, dipole, and quadrupole terms, respectively. The coefficients $\hat{S}$, $\hat{D}_\nu$, and $\hat{Q}_{\mu\nu}$ are similarly labeled. The D_ν are the components of a dipole moment vector, while the $Q_{\mu\nu}$ are the components of a quadrupole moment tensor. The general validity of such a description extends beyond the manner of derivation (Lamb, 1925; Lighthill, 1978) and is not restricted to sound generated by a continuous source distribution embedded in the fluid. It applies in particular to the sound radiated by a vibrating body of arbitrary shape.

9.2 Acoustically Compact Sources

If the source is acoustically compact, so that its largest dimension is much less than a wavelength, the multipole series converges rapidly, so one typically only need retain the first nonzero term. Sources exist whose net monopole strength is zero, and sources also exist whose dipole moment vector components are all zero as well. Consequently, compact sources are frequently classed as monopole, dipole, and quadrupole sources. The prototype of a monopole source is a body of oscillating volume. One for a dipole source is a rigid solid undergoing translational oscillations; another would be a vibrating plate or shell whose thickness changes negligibly. In the former case, the detailed theory shows that in the limit of sufficiently low frequency, the dipole moment vector is given by

$$\hat{D}_\nu=\hat{F}_\nu+m_d\hat{a}_{C,\nu}, \tag{209}$$

where $\hat{F}_\nu$ is associated with the force the moving body exerts on the surrounding fluid and where $\hat{a}_{C,\nu}$ is associated with the acceleration of the geometric center of the body. The quantity m_d is the mass of fluid displaced by the body.

The simplest example of a dipole source is that of a rigid sphere transversely oscillating along the z axis about the origin. If the radius of the sphere is a and if $ka \ll 1$, then the force and acceleration have only a z component, and the force amplitude is given by

$$\hat{F}_z=\tfrac{1}{2}m_d\hat{a}_{C,z}. \tag{210}$$

The dipole moment when the center velocity has amplitude $\hat{v}_C$ is consequently of the form

$$\hat{D}_z=-\tfrac{3}{2}i\omega(\tfrac{4}{3}\rho\pi a^3)\,\hat{v}_C\,. \tag{211}$$

Taking into account that the derivative of r with respect to z is cos θ, one finds the acoustic field from Eq. (205) to be given by

$$\hat{p}=-\hat{D}_z\cos\theta\frac{d}{dr}\frac{e^{ikr}}{r}\,. \tag{212}$$

When $kr \gg 1$, this approaches the limiting form

$$\hat{p}\to -ikD_z\cos(\theta)e^{ikr}/r. \tag{213}$$

The far-field intensity, in accord with Eq. (161), has a time average of $|\hat{p}|^2/2\rho c$ and is directed in the radial direction in this asymptotic limit. The drop of intensity as $1/r^2$ with increasing radial distance is the same as for spherical spreading, but the intensity varies with direction as $\cos^2\theta$.

Vibrating bodies that radiate as quadrupole sources (and which therefore have no dipole radiation) usually do so because of symmetry. Vibrating bells (Stokes, 1868) and tuning forks are typically quadrupole radiators.

A dipole source can be represented by two similar monopole sources, 180° out of phase with each other, and very close together. Since they are radiating out of phase, there is no total mass flow input into the medium. Such a dipole source will have a net acoustic power output substantially lower than that of either of the component monopoles radiating individually. Similarly, a quadrupole can be formed by two identical but oppositely directed dipoles brought very close together. If the two dipoles have a common axis, then a longitudinal quadrupole results; when they are side by side, a lateral quadrupole results. In either case, the quadrupole radiation is much weaker than that from either dipole radiating separately.

9.3 Spherical Harmonics

The closely related general description of source radiation in terms of spherical harmonics results from Eq. (204) when one inserts the expansion (Morse, 1936; Morse and Feshbach, 1953; Morse and Ingard, 1968)

$$\frac{e^{ikR}}{R}=\sum_{l=0}^{\infty}(2l+1)j_l(kr_0)h_l^{(1)}(kr)P_l(\cos\Theta), \tag{214}$$

where j_l is the spherical Bessel function and $h_l^{(1)}$ is the spherical Hankel function of order l and the first kind. (The expansion here assumes $r>r_0$; otherwise, one interchanges r and r_0 in the above equation). The quantity $P_l(\cos\Theta)$ is the Legendre function of order l; the angle Θ is that between the directions of $\mathbf{x}$ and $\mathbf{x}_0$. Alternatively, one uses the expansion

$$P_l(\cos\Theta)=\sum_{m=-l}^{l}\frac{(l-|m|)!}{(l+|m|)!}\times Y_l^m(\theta,\phi)Y_l^{-m}(\theta_0,\phi_0), \tag{215}$$

where the spherical harmonics are defined by

$$Y_l^m(\theta,\phi)=e^{im\phi}P_l^{|m|}(\cos\theta). \tag{216}$$

Here the functions $P_l^{|m|}(\cos\theta)$ are the associated Legendre functions. [The value of $P_0(\cos\Theta)$ is identically 1.]

If such an expansion is inserted into Eq. (204), and if r is understood to be sufficiently large that there are no sources beyond that radius, one has the relation

$$\hat{p}(r,\theta,\phi)=a_{00}h_0^{(1)}(kr)+\sum_{l=1}^{\infty}\sum_{m=-l}^{l}a_{lm}\times h_l^{(1)}(kr)Y_l^m(\theta,\phi) \tag{217}$$

with coefficients given by

$$a_{lm}=ik(2l+1)\frac{(l-|m|)!}{(l+|m|)!}\times\int\hat{s}(r_0,\theta_0,\phi_0)j_l(kr_0)\times Y_l^{-m}(\theta_0,\phi_0)dV_0. \tag{218}$$

The indicated volume integrations are to be carried out in spherical coordinates. The general result of Eq. (218) holds for any source of limited extent; any such wave field in an unbounded medium must have such an expansion in terms of spherical Hankel functions and spherical harmonics.

The spherical Hankel functions have the asymptotic (large r) form

$$h_l^{(1)}(kr)\rightarrow(-i)^{(l+1)}e^{ikr}/kr, \tag{219}$$

so the acoustic radiation field must asymptotically approach

$$\hat{p}\rightarrow\hat{F}(\theta,\phi)e^{ikr}/r, \tag{220}$$

where the function $\hat{F}(\theta,\phi)$ is a function of θ and ϕ that has an expansion in terms of spherical harmonics. In this asymptotic limit, the acoustic intensity is in the radial direction and given by

$$I_{r,\mathrm{av}}=\tfrac{1}{2}|\hat{F}|^2/\rho c r^2. \tag{221}$$

For fixed θ and ϕ, the time-averaged intensity must asymptotically decrease as $1/r^2$. The coefficient of $1/r^2$ in the above equation describes the far-field radiation pattern of the source, having the units of watts per steradian.

Although the two types of expansions, multipoles and spherical harmonics, are related, the relationship is not trivial. The quadrupole term in Eq. (205), for example, cannot be equated to the sum of the $l=2$ terms in Eq. (217). It is possible to have spherically symmetric quadrupole radiation, so an $l=0$ term would have to be included.

10. INTEGRAL EQUATIONS IN ACOUSTICS

10.1 The Helmholtz–Kirchoff Integral

The analysis of radiation of sound from a vibrating body of limited extent in an unbounded region is often aided by an integral corollary of the Helmholtz equation of Eq. (102) which dates back to 19th century works of Helmholtz (1860) and Kirchoff (1883). One considers a closed surface S where the outward normal component of the particle velocity has complex amplitude $\hat{v}_n(\mathbf{x}_S)$ and complex pressure amplitude $\hat{p}_S(\mathbf{x}_S)$ at a point $\mathbf{x}_S$ on the surface. For notational convenience, one introduces a quantity defined by

$$\hat{f}_S=-i\omega\rho\hat{v}_n, \tag{222}$$

where $\hat{v}_n(\mathbf{x}_S)$ is the normal component $\mathbf{n}(\mathbf{x}_S)\cdot\hat{\mathbf{v}}(\mathbf{x}_S)$ of the complex fluid velocity vector amplitude $\hat{\mathbf{v}}(\mathbf{x})$ at the surface. One can regard $\hat{f}_S$ as a convenient grouping of symbols, either as a constant times the normal velocity or as a constant times the normal acceleration, or as the normal component of the apparent body force, per unit volume, exerted on the fluid at the surface. Because of the latter identification, the use of the symbol f is appropriate. The subscript S is used to denote values appropriate to the surface.

Then, given that there are no sources outside the surface, a mathematical derivation, involving the differential equation of Eq. (202) for the free-space Green's function of

Eq. (203), involving the Helmholtz equation, and involving Gauss's theorem, yields

$$\hat{p}(\mathbf{x})=\mathscr{M}\{\mathbf{x},\hat{p}_S,\hat{f}_S\} \tag{223}$$

for the complex pressure amplitude $\hat{p}$ at a point $\mathbf{x}$ outside the surface. Here the right-hand side is given by the expression

$$\mathscr{M}=\frac{1}{4\pi}\int[\hat{f}_S(\mathbf{x}'_S)G(\mathbf{x}|\mathbf{x}'_S) + \hat{p}_S(\mathbf{x}'_S)\mathbf{n}(\mathbf{x}'_S)\cdot\{\nabla' G(\mathbf{x}|\mathbf{x}')\}_{\mathbf{x}'=\mathbf{x}'_S}]dS'. \tag{224}$$

In the integrand of this expression, the point $\mathbf{x}'_S$ (after evaluation of any requisite normal derivatives) is understood to range over the surface S, with the point $\mathbf{x}$ held fixed during the integration. The unit outward normal vector $\mathbf{n}(\mathbf{x}'_S)$ points out of the enclosed volume V at the surface point $\mathbf{x}'_S$.

In Eq. (224), the integral $\mathscr{M}$ is a function of the point $\mathbf{x}$, but a functional (function of a function) of the function arguments $\hat{p}_S$ and $\hat{f}_S$.

10.2 Integral Equations for Fields on the Surface

The functions $\hat{p}_S$ and $\hat{f}_S$ cannot be independently prescribed on the surface S. Specifying either one is a sufficient inner boundary condition on the Helmholtz equation. The corollary of Eq. (223) applies only if both functions correspond to a physically realizable radiation field outside the surface S. If this is so and if the point $\mathbf{x}$ is formally set to a point inside the enclosed volume, then analogous mathematics involving the properties of the Green's function leads to the deduction (Copley, 1968; Schenck, 1968)

$$\mathscr{M}\{\mathbf{x}_{\text{inside}},\hat{p}_S,\hat{f}_S\}=0, \tag{225}$$

which is a general relation between the surface value functions $\hat{p}_S$ and $\hat{f}_S$, holding for any choice of the point $\mathbf{x}$ inside the enclosed volume.

Equation (223) allows one to derive two additional relations (distinguished by subscripts I and II) between the surface values of $\hat{p}_S$ and $\hat{f}_S$. One results when the off-surface point $\mathbf{x}$ is allowed to approach an arbitrary but fixed surface point $\mathbf{x}_S$. For one of the terms in the integral defining the quantity $\mathscr{M}$, the limit as $\mathbf{x}$ approaches $\mathbf{x}_S$ of the integral is not the same as the integral over the limit of the integrand as $\mathbf{x}$ approaches $\mathbf{x}_S$. With this subtlety taken into account, one obtains

$$\hat{p}_S(\mathbf{x}_S)-\mathscr{L}_{\text{I}}\{\mathbf{x}_S,\hat{p}_S\}=\mathscr{H}_{\text{I}}\{\mathbf{x}_S,\hat{f}_S\}, \tag{226}$$

where the two linear operators $\mathscr{L}_{\text{I}}$ and $\mathscr{H}_{\text{I}}$ are

$$\mathscr{L}_{\text{I}}\{\mathbf{x}_S,\hat{p}_S\}=\frac{1}{2\pi}\int\hat{p}(\mathbf{x}'_S)\mathbf{n}(\mathbf{x}'_S)\cdot\{\nabla' G(\mathbf{x}_S|\mathbf{x}')\}_{\mathbf{x}'=\mathbf{x}'_S}dS', \tag{227}$$

$$\mathscr{H}_{\text{I}}\{\mathbf{x}_S,\hat{f}_S\}=\frac{1}{2\pi}\int\hat{f}(\mathbf{x}'_S)G(\mathbf{x}'_S|\mathbf{x}_S)dS'. \tag{228}$$

These linear operators operate on the surface values of $\hat{p}_S$ and $\hat{f}_S$, respectively, with the resultant in each case being a function of the position of the surface point $\mathbf{x}_S$.

The second type of surface relationship (Maue, 1949) is obtained by taking the gradient of both sides of Eq. (223), subsequently setting $\mathbf{x}$ equal to $\mathbf{x}_S+\epsilon\mathbf{n}(\mathbf{x}_S)$, where $\mathbf{x}_S$ is an arbitrary point on the surface, taking the dot product with $\mathbf{n}(\mathbf{x}_S)$, then taking the limit as ϵ goes to zero. The order of the processes, doing the integration and taking the limit, cannot be blindly interchanged, and some mathematical manipulations making use of the properties of the Green's function are necessary before one can obtain a relation in which all integrations are performed after all necessary limits are taken. The result is

$$-\mathscr{L}_{\text{II}}\{\mathbf{x}_S,\hat{p}_S\}=\hat{f}_S(\mathbf{x}_S)+\mathscr{H}_{\text{II}}\{\mathbf{x}_S,\hat{f}_S\}, \tag{229}$$

where the relevant operators are given by

$$\begin{aligned}\mathscr{L}_{\text{II}}&\{\mathbf{x},\hat{p}_S\}\\ &=[\mathbf{n}(\mathbf{x}_S)\times\nabla]\cdot\frac{1}{2\pi}\int[\mathbf{n}(\mathbf{x}'_S)\nabla'\hat{p}_S(\mathbf{x}'_S)]\\ &\quad\times G(\mathbf{x}_S|\mathbf{x}'_S)dS'+\frac{k^2}{2\pi}\int\mathbf{n}(\mathbf{x}_S)\\ &\quad\cdot\mathbf{n}(\mathbf{x}'_S)\,\hat{p}_S(\mathbf{x}'_S)G(\mathbf{x}_S|\mathbf{x}'_S)dS',\end{aligned} \tag{230}$$

$$\mathscr{H}_{\text{II}}\{\mathbf{x}_S,\hat{f}_S\}=\frac{1}{2\pi}\int\hat{f}_S(\mathbf{x}'_S)\mathbf{n}(\mathbf{x}_S)\cdot\{\nabla G(\mathbf{x}|\mathbf{x}'_S)\}_{\mathbf{x}=\mathbf{x}_S}dS'. \tag{231}$$

In regard to Eq. (230), one should note that the operator $\mathbf{n}(\mathbf{x}_S)\times\nabla$ involves only derivatives tangential to the surface, so that the integral on which it acts needs only be evaluated at surface points $\mathbf{x}_S$.

A variety of numerical techniques have been used and discussed in recent literature to solve either Eq. (225), (226), or (229), or some combination (Burton and Miller, 1971) of these for the surface pressure $\hat{p}_S$, given the surface force function $\hat{f}_S$. Once this is done, the radiation field at any external point **x** is found by numerical integration of the corollary integral relation of Eq. (223).

11. IMPEDANCE

11.1 Mechanical Impedance

The ratio of the complex amplitude of a sinusoidally varying force to the complex amplitude of the resulting velocity at a point on a vibrating object is called the mechanical impedance at that point. It is a complex number and usually a function of frequency. Other definitions (Beranek, 1972) of impedance are also in widespread use in acoustics.

11.2 Specific Acoustic Impedance

The specific acoustic impedance or unit area acoustic impedance $Z_S(\omega)$ for a surface is defined as

$$Z_S(\omega)=\hat{p}/\hat{v}_{\text{in}}, \tag{232}$$

where $\hat{v}_{\text{in}}$ is the component of the fluid velocity directed into the surface under consideration. Typically, the specific acoustic impedance, often referred to briefly as impedance without any adjective, is used to describe the acoustic properties of materials. In many cases, surfaces of materials abutting fluids can be characterized as locally reacting, so that Z_S is independent of the detailed nature of the acoustic pressure field. In particular, the locally reacting hypothesis implies that the velocity of the material at the surface is unaffected by pressures other than in the immediate vicinity of the point of interest. At a nominally motionless and passively responding surface, and when the hypothesis is valid, the appropriate boundary condition on the complex amplitude $\hat{p}$ that satisfies the Helmholtz equation is given by

$$i\omega\rho\hat{p}=-Z_S\nabla\hat{p}\cdot\mathbf{n}, \tag{233}$$

where **n** is the unit normal vector pointing out of the material into the fluid. A surface which is perfectly rigid has $|Z_S|=\infty$. The other extreme, where $|Z_S|=0$, corresponds to the ideal case of a pressure release surface. This is, for example, what is normally assumed for the upper surface of the ocean in underwater sound. Since a passive surface absorbs energy from the sound field, the time-averaged intensity component into the surface should be positive or zero. This observation leads to the requirement that the real part (specific acoustic resistance) of the impedance should always be non-negative. The imaginary part (specific acoustic reactance) may be either positive or negative.

11.3 Characteristic Impedance

For extended substances, a related definition is that of characteristic impedance Z_{char}, defined as the ratio of $\hat{p}$ to the complex amplitude $\hat{v}$ of the fluid velocity in the direction of propagation when a plane wave is propagating through the substance. As indicated by Eq. (107), this characteristic impedance is ρc, regardless of frequency and position in the field. The mks units (kg m^{-3} m/s) of specific acoustic impedance are referred to as mks rayls (after Rayleigh). The characteristic impedance of air under standard conditions is approximately 400 mks rayls, and that of water is approximately 1.5×10^6 mks rayls.

11.4 Radiation Impedance

The radiation impedance Z_{rad} is defined as $\hat{p}/\hat{v}_n$, where $\hat{v}_n$ corresponds to the outward normal component of velocity at a vibrating surface. For outward propagating spherically symmetric waves, where $\hat{p}$ is $Ar^{-1}e^{ikr}$, the surface can be taken as any sphere concentric with the origin, so the radiation impedance at radius r is given by

$$Z_{\text{rad}}=\hat{p}/\hat{v}_r=\rho c(1+i/kr)^{-1}. \tag{234}$$

The time-averaged intensity in the radial direction is therefore

$$\begin{aligned} I_{\text{av}}&=\tfrac{1}{2}\,\text{Re}(pv_r^*)\\ &=\tfrac{1}{2}\,|\hat{p}|^2\,\text{Re}(Z_{\text{rad}}^{-1})\\ &=(1/2\rho c)\,|\hat{p}|^2. \end{aligned} \tag{235}$$

The latter is the same as results for a plane wave, even though, for a spherical wave, the acoustic pressure is not in phase with the radial velocity, except in the asymptotic limit of large radial distances.

11.5 Acoustic Impedance

The term acoustic impedance Z_A is reserved (Beranek, 1972) for the ratio of $\hat{p}$ to the volume-velocity complex amplitude. Here volume velocity is the net volume of fluid flowing past a specified surface element per unit time in a specified directional sense. One may speak, for example, of the acoustic impedance of an orifice in a wall, of the acoustic impedance at the mouth of a Helmholtz resonator, and of the acoustic impedance at the end of a pipe.

12. REFLECTION, REFRACTION, AND TRANSMISSION

12.1 Reflection at a Plane Surface

When a plane wave reflects at a surface with finite specific acoustic impedance Z_S, a reflected wave is formed such that the angle of incidence θ_{I} equals the angle of reflection (law of mirrors). Here both angles are reckoned from the line normal to the surface and correspond to the directions of the two waves. If one takes the y axis as pointing out of the surface and the surface as coinciding with the $y=0$ plane, then an incident plane wave propagating obliquely in the $+x$ direction will have a complex pressure amplitude

$$\hat{p}_{\mathrm{in}}=\hat{f}\, e^{ik_x x}e^{-ik_y y}, \tag{236}$$

where $\hat{f}$ is a constant. (For transient reflection, the quantity $\hat{f}$ can be taken as the Fourier transform of the incident pressure pulse at the origin.) The two indicated wave-number components are $k_x=k\,\sin\theta_{\mathrm{I}}$ and $k_y=\cos\theta_{\mathrm{I}}$. The reflected wave has a complex pressure amplitude given by

$$\hat{p}_{\mathrm{refl}}=\mathscr{R}(\theta_I,\omega)\,\hat{f}\, e^{ik_x x}e^{ik_y y}, \tag{237}$$

where the quantity $\mathscr{R}(\theta_{\mathrm{I}},\omega)$ is the pressure-amplitude reflection coefficient.

Analysis that makes use of the boundary condition of Eq. (233) leads to the identification

$$\mathscr{R}(\theta_I,\omega)=\frac{\xi(\omega)\cos\theta_{\mathrm{I}}-1}{\xi(\omega)\cos\theta_{\mathrm{I}}+1} \tag{238}$$

for the reflection coefficient, with the abbreviation

$$\xi(\omega)=Z_S/\rho c, \tag{239}$$

which represents the ratio of the specific acoustic impedance of the surface to the characteristic impedance of the medium.

12.2 Reflection at an Interface

The above relations also apply, with an appropriate identification of the quantity Z_S, to sound reflection at an interface between two fluids with different sound speeds and densities (Green, 1838). Translational symmetry requires that the disturbance in the second fluid have the same apparent phase velocity ω/k_x (trace velocity) along the x axis as does the disturbance in the first fluid. This requirement is known as the trace velocity matching principle (Rayleigh, 1878; Pierce, 1989) and leads to the observation that k_x is the same in both fluids. One distinguishes two possibilities: the trace velocity is higher or lower than the sound speed c_2.

For the first possibility, one has the inequality

$$c_2<c_1/\sin\theta_{\mathrm{I}}, \tag{240}$$

and a propagating plane wave (transmitted wave) is excited in the second fluid, with complex pressure amplitude

$$\hat{p}_{\mathrm{trans}}=\mathscr{T}(\omega,\theta_{\mathrm{I}})\,\hat{f}\, e^{ik_x x}e^{ik_2 y\cos\theta_{\mathrm{II}}}, \tag{241}$$

where $k_2=\omega/c_2$ is the wave number in the second fluid and θ_{II} (angle of refraction) is the angle at which the transmitted wave is propagating. The trace velocity matching principle leads to Snell's law,

$$\sin\theta_{\mathrm{I}}/c_1=\sin\theta_{\mathrm{II}}/c_2. \tag{242}$$

The change in propagation direction from θ_{I} to θ_{II} is the phenomenon of refraction.

The requirement that the pressure be continuous across the interface yields the relation

$$1+\mathscr{R}=\mathscr{T}, \tag{243}$$

while the continuity of the normal component of the fluid velocity yields

$$\frac{\cos\theta_{\mathrm{I}}}{\rho_1 c_1}(1-\mathscr{R})=\frac{\cos\theta_{\mathrm{II}}}{\rho_2 c_2}\,\mathscr{T}. \tag{244}$$

From these one derives the reflection coefficient

$$\mathscr{R}=(Z_{\mathrm{II}}-Z_{\mathrm{I}})/(Z_{\mathrm{II}}+Z_{\mathrm{I}}), \tag{245}$$

which involves the two impedances defined by

$$Z_{\mathrm{I}}=\rho_1 c_1/\cos\theta_{\mathrm{I}}, \tag{246}$$

$$Z_{\mathrm{II}}=\rho_2 c_2/\cos\theta_{\mathrm{II}}. \tag{247}$$

The other possibility, which is the opposite of that in Eq. (240), can only occur when $c_2>c_1$ and, moreover, only if θ_{I} is greater than the critical angle

$$\theta_{\mathrm{cr}}=\arcsin(c_1/c_2). \tag{248}$$

In this circumstance, an inhomogeneous plane wave, propagating in the x direction, but dying out exponentially in the $+y$ direction, is excited in the second medium. Instead of Eq. (241), one has the transmitted pressure given by

$$\hat{p}_{\mathrm{trans}}=\mathscr{T}(\omega,\theta_{\mathrm{I}})\,\hat{f}\,e^{ik_x x}e^{-\beta k_2 y} \tag{249}$$

with

$$\beta=[(c_2/c_1)^2\sin^2\theta_{\mathrm{I}}-1]^{1/2}. \tag{250}$$

The previously stated equations governing the reflection and transmission coefficients are still applicable, provided one replaces $\cos\theta_{\mathrm{II}}$ by $i\beta$. This causes the magnitude of the reflection coefficient $\mathscr{R}$ to become unity, so the time-averaged incident energy is totally reflected. Acoustic energy is present in the second fluid, but its time average over a wave period stays constant once the steady state is reached.

12.3 Theory of the Impedance Tube

Impedance tubes are commonly used in the measurement of specific acoustic impedances; the underlying theory (Paris, 1927; Hall, 1939) is based for the most part on Eqs. (237)–(239). The incident and the reflected waves propagate along the axis of a cylindrical tube with the sample surface at one end. A loudspeaker at the other end creates a sinusoidal pressure disturbance which propagates down the tube. Reflections from the end covered with the test material create an incomplete standing wave pattern inside the tube. The wavelength of the sound emitted by the source can be adjusted, but it should be kept substantially larger than the pipe diameter, so that the plane-wave assumption holds. With k_x identified as being 0, the complex amplitude that corresponds to the sum of the incident and reflected waves has an absolute magnitude given by

$$|\hat{p}|=|\hat{f}|\,|1+\mathscr{R}e^{2iky}|, \tag{251}$$

where y is now the distance in front of the sample. The second factor varies with y and repeats at intervals of a half-wavelength, and varies from a minimum value of $1-|\mathscr{R}|$ to a maximum value of $1+|\mathscr{R}|$. Consequently, the ratio of the peak acoustic pressure amplitude $|\hat{p}|_{\max}$ (which occurs at one y position) to the minimum acoustic pressure amplitude $|\hat{p}|_{\min}$ (which occurs at a position a quarter-wavelength away) determines the magnitude of the reflection coefficient via the relation

$$\frac{|\hat{p}|_{\min}}{|\hat{p}|_{\max}}=\frac{1-|\mathscr{R}|}{1+|\mathscr{R}|}. \tag{252}$$

The phase δ of the reflection coefficient can be determined with use of the observation that the peak amplitudes occur at y values where $\delta+2ky$ is an integer multiple of 2π, while the minimum amplitudes occur where it is π plus an integer multiple of 2π. Once the magnitude and phase of the reflection coefficient are determined, the specific acoustic impedance can be found from Eqs. (130) and (131).

12.4 Transmission through Walls and Slabs

The analysis of transmission of sound through a wall or a partition (Cremer, 1942) is often based on the idealization that the wall is of unlimited extent. If the incoming plane wave has an angle of incidence θ_{I} and if the fluid on the opposite side of the wall has the same sound speed, then the trace velocity matching principle requires that the transmitted wave be propagating in the same direction. A common assumption when the fluid is air is that the compression in the wall is negligible, so the wall is treated as a slab which has a uniform velocity v_{sl} throughout its thickness. The slab moves under the influence of the incident, reflected, and transmitted sound fields according to the relation (corresponding to Newton's second law) given by

$$m_{\mathrm{sl}}\frac{\partial v_{\mathrm{sl}}}{\partial t}=p_{\mathrm{front}}-p_{\mathrm{back}}+\text{bending term}, \tag{253}$$

where m_{sl} is the mass per unit surface area of the slab. The front side is taken as the side facing the incident wave; the transmitted wave propagates away from the back side.

The "bending term" (discussed further below) accounts for any tendency of the slab to resist bending. If the slab is regarded as nonporous then the normal component of the fluid velocity at both the front and the back is regarded the same as the slab velocity itself. If it is taken as porous (Beranek, 1947, 1971) then these continuity equations are replaced by the relations

$$v_{\text{front}} - v_{\text{sl}} = v_{\text{back}} - v_{\text{sl}} = (1/R_f)(p_{\text{front}} - p_{\text{back}}), \tag{254}$$

where R_f is the specific flow resistance. The latter can be measured in steady flow for specific materials. For a homogeneous material, it is given by the product of the slab thickness h and the flow resistivity, the latter being a commonly tabulated property of porous materials.

In general, when one considers the reflection at and transmission through a slab, one can define a slab specific impedance Z_{sl} such that, with regard to complex amplitudes,

$$\hat{p}_{\text{front}} - \hat{p}_{\text{back}} = Z_{\text{sl}}\,\hat{v}_{\text{front}} = Z_{\text{sl}}\,\hat{v}_{\text{back}}, \tag{255}$$

where Z_{sl} depends on the angular frequency ω and the trace velocity $v_{\text{tr}} = c/\sin\theta_{\text{I}}$ of the incident wave over the surface of the slab. The value of the slab specific impedance can be derived using considerations such as those corresponding to Eqs. (254) and (255). In terms of the slab specific impedance, the transmission coefficient $\mathscr{T}$ is

$$\mathscr{T} = [1 + \tfrac{1}{2}(Z_{\text{sl}}/\rho c)\cos\theta_{\text{I}}]^{-1}. \tag{256}$$

The fraction τ of incident power that is transmitted is $|\mathscr{T}|^2$.

12.4.1 Transmission through Limp Plates. If the slab can be idealized as a limp plate (no resistance to bending) and not porous, the slab specific impedance Z_{sl} is $-i\omega m_{\text{sl}}$ and one obtains

$$\tau = \left[1 + \left(\frac{\omega m_{\text{sl}}}{2\rho c}\right)^2 \cos^2\theta_{\text{I}}\right]^{-1} \approx \left(\frac{2\rho c}{\omega m_{\text{sl}} \cos\theta_{\text{I}}}\right)^2 \tag{257}$$

for the fraction of incident power that is transmitted. The latter version, which typically holds at moderate to high audible frequencies, predicts that τ decreases by a factor of 4 when the slab mass m_{sl} per unit area is increased by a factor of 2. In the noise-control literature, this behavior is sometimes referred to as the mass law.

12.4.2 Transmission through Porous Blankets. For a porous blanket that has a specific flow resistance R_f, the specific slab impedance becomes

$$Z_{\text{sl}} = (1/R_f - 1/i\omega m_{\text{sl}})^{-1}, \tag{258}$$

and the resulting fraction of incident power that is transmitted can be found with substitution into Eq. (256), with τ equated to $|\mathscr{T}|^2$.

12.4.3 Transmission through Elastic Plates. If the slab is idealized as a Bernoulli–Euler plate with elastic modulus E, Poisson's ratio ν, and thickness h, the bending term in Eq. (253) has a complex amplitude given by

$$\text{bending term} = -B_{\text{pl}} k_x^4 \hat{v}_{\text{sl}}/(-i\omega), \tag{259}$$

where

$$B_{\text{pl}} = Eh^3/12(1-\nu^2) \tag{260}$$

is the plate bending modulus. The slab specific impedance is consequently given by

$$Z_{\text{sl}} = -i\omega m_{\text{sl}}[1 - (f/f_c)^2 \sin^4\theta_{\text{I}}], \tag{261}$$

where

$$f_c = (c^2/2\pi)(m_{\text{sl}}/B_{\text{pl}})^{1/2} \tag{262}$$

gives the coincidence frequency, the frequency at which the phase velocity of freely propagating bending waves in the plate equals the speed of sound in the fluid.

Although the simple result of Eq. (261) predicts that the fraction of incident power transmitted is unity at a frequency of $f_c/\sin^2\theta_{\text{I}}$, the presence of damping processes in the plate causes the fraction of incident power transmitted to be always less than unity. A simple way of taking this into account makes use of a loss factor η (assumed much less than unity) for the plate, which corresponds to the fraction of stored elastic energy that is dissipated through damping processes, during 1 rad (cycle period divided by 2π). The loss factor can be formally introduced into the mathematical model by the replacement of the real elastic modulus by the complex number $(1-i\eta)E$. When this is done one finds

$$Z_{\text{sl}} = \omega\eta m_{\text{pl}}(f/f_c)^2 \sin^4\theta_{\text{I}} - i\omega m_{\text{sl}}[1 - (f/f_c)^2 \sin^4\theta_{\text{I}}] \tag{263}$$

for the slab impedance that is to be inserted into Eq. (256). The extra term ordinarily has very little effect on the fraction of incident power that is transmitted except when the (normally dominant) imaginary term is close to zero. When the frequency f is $f_c/\sin^2\theta_I$, one finds the value of τ to be

$$\tau=[1+\tfrac{1}{2}(\omega\eta m_{\mathrm{pl}}/\rho c)\cos\theta_I]^{-2} \tag{264}$$

rather than identically unity.

13. WAVEGUIDES, DUCTS, AND RESONATORS

13.1 Guided Modes in a Duct

Pipes or ducts act as guides of acoustic waves, and the net flow of energy, other than that associated with wall dissipation, is along the direction of the duct. The general theory of guided waves applies and leads to a representation in terms of guided modes.

If the duct axis is the x axis and the duct cross section is independent of x, the guided mode series (Rayleigh, 1878; Hartig and Swanson, 1938) has the form

$$\hat{p}=\sum_n X_n(x)\Psi_n(y,z), \tag{265}$$

where the $\Psi_n(y,z)$ are eigenfunctions of the equation

$$\left(\frac{\partial^2}{\partial y^2}+\frac{\partial^2}{\partial z^2}\right)\Psi_n+\alpha_n^2\Psi_n=0 \tag{266}$$

with the α_n^2 being the corresponding eigenvalues. The appropriate boundary condition, if the duct walls are idealized as being perfectly rigid, is that the normal component of the gradient of Ψ_n vanishes at the walls. Typically, the Ψ_n are required to conform to some normalization condition, such as

$$\int \Psi_n^2 dA=A, \tag{267}$$

where A is the duct cross-sectional area.

The general theory leads to the conclusion that one can always find a complete set of Ψ_n which, with the rigid-wall boundary condition imposed, are such that the cross-sectional eigenfunctions are orthogonal, so that

$$\int \Psi_n\Psi_m dA=0 \tag{268}$$

if n and m correspond to different guided modes. The eigenvalues α_n^2, moreover, are all real and non-negative. However, for cross sections that have some type of symmetry, it may be that more than one linearly independent eigenfunction Ψ_n (modes characterized by different values of the index n) correspond to the same numerical value of α_n^2. In such cases the eigenvalue is said to be degenerate.

The variation of guided-mode amplitudes with source excitation is ordinarily incorporated into the axial wave functions $X_n(x)$, which satisfy the one-dimensional Helmholtz equation

$$\frac{d^2X_n}{dx^2}+(k^2-\alpha_n^2)X_n=0. \tag{269}$$

Here $k=\omega/c$ is the free-space wave number. The form of the solution depends on whether α_n^2 is greater or less than k^2. If $\alpha_n^2 < k^2$, the mode is said to be a propagating mode and the solution for X_n is given by

$$X_n=A_ne^{ik_nx}+B_ne^{-ik_nx}, \tag{270}$$

where k_n, defined by

$$k_n=(k^2-\alpha_n^2)^{1/2}, \tag{271}$$

are the modal wave numbers. If, on the other hand, the value of α_n^2 is greater than k^2, the mode is evanescent (not propagating), and one has

$$X_n=A_ne^{-\beta_nx}+B_ne^{\beta_nx}, \tag{272}$$

where β_n is given by

$$\beta_n=(\alpha_n^2-k^2)^{1/2}. \tag{273}$$

Unless the termination of the duct is relatively close to the source, waves that grow exponentially with distance from the source are not meaningful, so only the term that corresponds to exponentially dying waves is ordinarily kept in the description of sound fields in ducts.

13.2 Cylindrical Ducts

For the frequently encountered case of a duct with circular cross section and radius a, the index n is replaced by an index set (q,m,s), and the eigenfunctions Ψ_n are described by

$$\Psi_n = K_{qm} J_m\left(\frac{\eta_{qm} r}{a}\right)\left\{\begin{matrix}\cos\phi \\ \sin\phi\end{matrix}\right\}. \tag{274}$$

Here either the cosine ($s=1$) or the sine ($s=-1$) corresponds to an eigenfunction. The quantities K_{qm} are normalization constants, and the J_m are Bessel functions of order m. The corresponding eigenvalues are given by

$$\alpha_n = \eta_{qm}/a, \tag{275}$$

where the η_{qm} are the zeros of $\eta J_m'(\eta)$, arranged in ascending order with the index q ranging upwards from 1. The smaller roots (Abramowitz and Stegun, 1965) for the axisymmetric modes are $\eta_{1,0}=0.00$, $\eta_{2,0}=3.831\ 71$, and $\eta_{3,0}=7.015\ 59$, while those corresponding to $m=1$ are $\eta_{1,1}=1.841\ 18$, $\eta_{2,1}=5.331\ 44$, and $\eta_{3,1}=8.536\ 32$.

13.3 Low-Frequency Model for Duct Propagation

In many situations of interest (Stewart, 1922; Mason, 1927), the frequency of the acoustic disturbance is so low that only one guided mode can propagate, and all of the other modes are evanescent. Given that the walls can be idealized as rigid, there is always one mode which can propagate, this being the plane-wave mode for which the eigenvalue α_0 is identically zero. The other modes will all be evanescent if the value of k is less than the corresponding α_n for each such mode. This would be so if the frequency is less than the lowest cutoff frequency for any of the nonplanar modes. For the circular duct case discussed above, for example, this would require that the inequality

$$f < \frac{1.841}{2\pi}\frac{c}{a} \tag{276}$$

be satisfied.

When the single guided mode assumption is valid, and even if the duct cross-sectional area should vary with distance along the duct, the acoustic field equations can be replaced to a good approximation by the acoustic transmission-line equations,

$$\frac{\partial p}{\partial t} + \frac{\rho c^2}{A}\frac{\partial U}{\partial x} = 0, \tag{277}$$

$$\rho\frac{\partial U}{\partial t} = -A\frac{\partial p}{\partial x}. \tag{278}$$

Here U, equal to Av_x, is the volume velocity, the volume of fluid passing through the duct per unit time.

One of the implications of the low-frequency model described by Eqs. (277) and (278) is that the volume velocity and the pressure are both continuous even when the duct has a sudden change in cross-section area. The pressure continuity assumption is not necessarily a good approximation, but becomes better with decreasing frequency. An improved model sets the difference of the complex amplitudes of the upstream and downstream pressures just ahead of and after the junction equal to

$$\hat{p}_{\text{ahead}} - \hat{p}_{\text{after}} = Z_J \hat{U}_{\text{junction}}, \tag{279}$$

where the junctions's acoustic impedance Z_J is taken in the simplest approximation as $-i\omega M_{A,J}$, and where $M_{A,J}$ is a real number independent of frequency that is called the acoustic inertance of the junction. Approximate expressions for this acoustic inertance can be found in the literature cited in the text by Pierce (1989); a simple rule is that it is ordinarily less than $8\rho/3A_{\min}$, where $A_{\min}$ is the smaller of the two cross-sectional areas. One may note, moreover, that Z_J goes to zero when the frequency goes to zero.

When an incident wave is incident at a junction, reflected and transmitted waves are created in the two ducts. The pressure-amplitude reflection and transmission coefficients are given by

$$\mathscr{R} = \frac{Z_J + \rho c/A_2 - \rho c/A_1}{Z_J + \rho c/A_2 + \rho c/A_1}, \tag{280}$$

$$\mathscr{T} = \frac{2\rho c/A_2}{Z_J + \rho c/A_2 + \rho c/A_1}. \tag{281}$$

13.4 Sound Attenuation in Ducts

The presence of the duct walls affects the attenuation of sound and causes the attenuation coefficient ordinarily to be much higher than for plane waves in open space. A simple theory for predicting this attenuation uses the concepts of acoustic, entropy, and vorticity modes described in Sec. 2.6. The entropy- and vorticity-mode fields exist in an acoustic boundary layer near the duct walls and are such that they combine with the acoustic-mode field to satisfy the appropriate boundary conditions at the walls. With viscosity and thermal conduction thus taken into account in the acoustic boundary layer, and with the assumption that the duct walls are much better heat conductors than the fluid itself, the approximate attenuation coefficient for the plane-wave guided mode is given by (Mason, 1928)

$$\alpha=\alpha_{\text{walls}}$$
$$=\left(\frac{\omega}{8\rho c^2}\right)^{1/2}\left[\mu^{1/2}+(\gamma-1)\left(\frac{\kappa}{c_p}\right)^{1/2}\right]\frac{L_P}{A}, \tag{282}$$

where L_P is the length of the perimeter of the duct cross section.

A related effect is that sound travels slightly slower in ducts than in an open environment. The phase velocity (Henry, 1931) is given by

$$v_{\text{ph}}=c-(c^2\alpha_{\text{walls}}/\omega), \tag{283}$$

so the group velocity is midway between the phase velocity and the free-space sound velocity c (still less than c).

13.5 Mufflers and Acoustic Filters

The analysis of mufflers (Davies, 1964; Embleton, 1971; Bender and Bremmer, 1975) is often based on the idealization that their acoustic transmission characteristics are independent of sound amplitudes, so that they act as linear devices. The muffler is regarded as an insertion into a duct, which reflects waves back toward the source and which alters the transmission of sound beyond the muffler. The properties of the muffler vary with frequency, so the theory analyzes the muffler's effects on individual frequency components. The frequency is assumed to be sufficiently low that only the plane-wave mode propagates in the inlet and outlet ducts. Because of the assumed linear behavior of the muffler, and the single-mode assumption, the muffler conforms to the model of a linear two-port, the ports being the inlet and outlet. The model leads to the prediction that one may characterize the muffler at any given frequency by a matrix, such that

$$\begin{pmatrix}\hat{p}_{\text{in}}\\ \hat{p}_{\text{out}}\end{pmatrix}=\begin{pmatrix}K_{11} & K_{12}\\ K_{21} & K_{22}\end{pmatrix}\begin{pmatrix}\hat{U}_{\text{in}}\\ \hat{U}_{\text{out}}\end{pmatrix}, \tag{284}$$

where the coefficients K_{ij} represent the acoustical properties of the muffler. Reciprocity requires that the determinant of the matrix be unity. Also, for a symmetric muffler, K_{12} and K_{21} must be identical.

It is ordinarily a good approximation that the waves reflected at the entrance of the muffler back to the source are significantly attenuated, so that they have negligible amplitude when they return to the muffler. Similarly, the assumption is ordinarily valid that the waves transmitted beyond the muffler do not return to the muffler (anechoic termination). With these assumptions, the insertion of the muffler causes the mean squared pressure downstream of the muffler to drop by a factor

$$\tau=\left(\frac{1}{4}\left|K_{11}+K_{22}+\frac{\rho c}{A}K_{21}+\frac{A}{\rho c}K_{12}\right|^2\right)^{-1}, \tag{285}$$

where A is the cross section of the duct ahead of and behind the muffler.

Acoustic mufflers can be divided into two broad categories: reactive mufflers and dissipative mufflers. In a reactive muffler, the basic property of the muffler is that it reflects a substantial fraction of the incident acoustic energy back toward the source. The dissipation of energy within the muffler itself plays a minor role; the reflection is caused primarily by the geometrical characteristics of the muffler. In a dissipative muffler, however, a low transmission of sound is achieved by internal dissipation of acoustic energy within the muffler. Absorbing material along the walls is ordinarily used to achieve this dissipation.

13.5.1 Nonreflecting Dissipative Muffler. When a segment of pipe of cross section A and length L is covered with a duct-lining material that attenuates the amplitude of traveling plane waves by a factor of $e^{-\alpha L}$, the muffler's K matrix is given by

$$[K]=\begin{pmatrix}\cos(kL+i\alpha L) & -\frac{i\rho c}{A}\sin(kL+i\alpha L)\\ -\frac{iA}{\rho c}\sin(kL+i\alpha L) & \cos(kL+i\alpha L)\end{pmatrix}, \tag{286}$$

so the fractional drop in mean squared pressure reduces to

$$\tau=e^{-2\alpha L}. \tag{287}$$

13.5.2 Expansion Chamber Muffler. The simplest reactive muffler is the expansion chamber which consists of a duct of length L

and cross section A_M connected at both ends to a pipe of smaller cross section A_p. The K matrix for such a muffler is found directly from Eq. (286) by setting α equal to zero (no dissipation in the chamber), but replacing A by A_M. The corresponding result for the fractional drop in mean squared pressure is

$$\tau=[\cos^2 kL+\tfrac{1}{4}(m+m^{-1})^2\sin^2 kL]^{-1}, \qquad (288)$$

where m is the expansion ratio A_M/A_P. The relative reduction in mean square pressure is thus periodic with frequency. A maximum reduction occurs when the length L is an odd multiple of quarter wavelengths. The greatest reduction in mean squared pressure is when τ has its minimum value, which is that given by

$$\tau=4/(m+m^{-1})^2. \qquad (289)$$

13.6 Helmholtz Resonators

An idealized acoustic system (Helmholtz, 1860; Rayleigh, 1870) which is the prototype of commonly encountered resonance phenomena consists of a cavity of volume V with a neck of length l and cross section S. In the limit where the acoustic frequency is sufficiently low that the wavelength is much larger than any dimension of the resonator, the compressible fluid in the resonator acts as a spring with spring constant given by

$$k_{\text{sp}}=\rho c^2 S^2/V \qquad (290)$$

and the fluid in the neck behaves as a lumped mass of magnitude

$$m=\rho S l'. \qquad (291)$$

Here l' is l plus end corrections for the two ends of the neck. If l is somewhat larger than the neck radius a, and if both ends are terminated by flanges, then the two end corrections are each $0.82a$. The resonance frequency ω_r, in radians per second, of the resonator is given by

$$\omega_r=2\pi f_r=(k_{\text{sp}}/m)^{1/2}=(M_A C_A)^{-1/2}, \qquad (292)$$

where

$$M_A=\rho l'/S \qquad (293)$$

gives the acoustic inertance of the neck and

$$C_A=V/\rho c^2 \qquad (294)$$

gives the acoustic compliance of the cavity. The ratio of the complex pressure amplitude just outside the mouth of the neck to the complex volume velocity amplitude of flow into the neck is the acoustic impedance Z_{HR} of the Helmholtz resonator and given, with the neglect of damping, by

$$Z_{\text{HR}}=-i\omega M_A+1/(-i\omega C_A) \qquad (295)$$

and this vanishes at the resonance frequency.

If a Helmholtz resonator is inserted as a side branch into the wall of a duct, it acts as a reactive muffler that has a high insertion loss near the resonance frequency of the resonator. The analysis assumes that the acoustic pressures in the duct just before and just after the resonator are the same as the pressure at the mouth of the resonator. Also, the acoustical analog of Kirchhoff's circuit law for currents applies, so that the volume velocity flowing in the duct ahead of the resonator equals the sum of the volume velocities flowing into the resonator and through the duct just after the resonator. These relations, with Eq. (295), allow one to work out expressions for the amplitude reflection and transmission coefficients at the resonator, the latter being given by

$$\mathscr{T}=\frac{2Z_{\text{HR}}}{2Z_{\text{HR}}+\rho c/A_D}. \qquad (296)$$

The fraction of incident power that is transmitted is consequently given by

$$\tau=\left(1+\frac{1}{4\beta^2(f/f_r-f_r/f)^2}\right)^{-1}, \qquad (297)$$

where β is determined by

$$\beta^2=(M_A/C_A)(A_D/\rho c)^3. \qquad (298)$$

The fraction transmitted is formally zero at the resonance frequency, but if β is large compared with unity, the bandwidth over which the drop in transmitted power is small is narrow compared with f_r.

14. RAY ACOUSTICS

14.1 Wave-Front Propagation

The theory of plane-wave propagation predicts that wave fronts move with speed c when viewed in a coordinate system in which the ambient medium appears at rest. If the ambient medium is moving with velocity $\mathbf{v}$, the wave velocity $c\mathbf{n}$ seen by an observer moving with the fluid becomes $\mathbf{v}+c\mathbf{n}$ in a coordinate system at rest. Here $\mathbf{n}$ is the unit vector normal to the wave front; it coincides with the direction of propagation if the coordinate system is moving with the local ambient fluid velocity $\mathbf{v}$. A ray can be defined (Milne, 1921) as the time trajectory of a point that is always on the same wave front, and for which the velocity is

$$\mathbf{v}_{\text{ray}}=\mathbf{v}+\mathbf{n}c. \tag{299}$$

To determine ray paths without explicit knowledge of wave fronts, it is appropriate to consider a function $\tau(\mathbf{x})$, which gives the time at which the wave front of interest passes the point $\mathbf{x}$. Its gradient $\mathbf{s}$ is termed the wave slowness vector and is related to the local wave-front normal by the equations

$$\mathbf{s}=\mathbf{n}/(c+\mathbf{v}\cdot\mathbf{n}), \tag{300}$$

$$\mathbf{n}=c\mathbf{s}/\Omega, \tag{301}$$

where the quantity Ω is defined by

$$\Omega=1-\mathbf{v}\cdot\mathbf{s}. \tag{302}$$

Given the concepts of ray position and the slowness vector, a purely kinematical derivation leads to the ray-tracing equations

$$\frac{d\mathbf{x}}{dt}=\frac{c^2\mathbf{s}}{\Omega}+\mathbf{v}, \tag{303}$$

$$\frac{d\mathbf{s}}{dt}=-\frac{\Omega}{c}\nabla c-(\mathbf{s}\cdot\nabla)\mathbf{v}-\mathbf{s}\times(\nabla\times\mathbf{v}). \tag{304}$$

Simpler versions result when there is no ambient flow, or when the ambient variables vary with only one coordinate. If the ambient variables are independent of position, then the rays paths are straight lines.

The above equations are often used for analysis of propagation through inhomogeneous media (moving or nonmoving) when the ambient variables do not vary significantly over distances of the order of a wavelength, even though they may do so over the total propagation distance. The rays which connect the source and listener locations are termed the eigenrays for that situation. If there is more than one eigenray, one has multipath reception. If there is no eigenray, then the listener is in a shadow zone.

14.2 Reflected, Transmitted, and Diffracted Rays

The theory is readily extended to take into account solid boundaries and interfaces. When an incident ray strikes a solid boundary, a reflected ray is generated whose direction is determined by the trace velocity matching principle, such that the angle of incident equals the angle of reflection. At an interface a transmitted ray is also generated, whose direction is predicted by Snell's law.

An extension of the theory, known as the geometrical theory of diffraction and due primarily to J. B. Keller (1958), allows for the possibility that diffracting edges can be a source of diffracted rays which have a multiplicity of directions. The allowable diffracted rays must have the same trace velocity along the diffracting edge as does the incident ray.

The ray paths connecting source and listener satisfy Fermat's principle (Ugincius, 1972), that the travel time along an actual eigenray is stationary relative to other geometrically admissible paths. Keller's geometrical theory of diffraction (Keller, 1958) extends this principle to include paths which have discontinuous directions and which may have portions that lie on solid surfaces.

14.3 Wave Equation for Inhomogeneous Moving Media

The determination of the amplitude variation along ray paths requires a more explicit use of the equations of linear acoustics. If there is no ambient fluid velocity then an appropriate wave equation is that of Eq. (54). When there is also an ambient flow present, an appropriate generalization (Blokhintzev, 1946; Pierce, 1990) for the acoustic mode is

$$\frac{1}{\rho}\nabla\cdot(\rho\nabla\Phi)-D_t\left(\frac{1}{c^2}D_t\Phi\right)=0. \tag{305}$$

Here D_t, defined by

$$D_t=\frac{\partial}{\partial t}+\mathbf{v}\cdot\nabla, \tag{306}$$

is the time derivative following the ambient flow. The dependent variable Φ is related to the acoustic pressure perturbation by

$$p=-\rho D_t\Phi. \tag{307}$$

The above wave equation is derived from the linear-acoustics equations for circumstances when the ambient variables vary slowly with position and time, and neglects terms of second order in $1/\omega T$ and $c/\omega L$, where ω is a characteristic frequency of the disturbance, T is a characteristic time scale for temporal variations of the ambient quantities, and L is a characteristic length scale for spatial variations of these approximations. The nature of the entailed approximations is consistent with the notion that geometrical acoustics is a high-frequency approximation and yield results that are the same in the high-frequency limit as would be derived from the complete set of linear acoustic equations.

14.4 The Eikonal Approximation

The equations of geometrical acoustics follow (Sommerfeld and Runge, 1911) from Eq. (305), if one sets the potential function Φ equal to the expression

$$\Phi(\mathbf{x},t)=\Psi(\mathbf{x})F(t-\tau). \tag{308}$$

Here the function F is assumed to be a rapidly varying function of its argument. The quantities Ψ and τ vary only with position. (It is assumed here that the ambient variables do not vary with time.)

When such a substitution is made, one obtains terms that involve the second, first, and zeroth derivatives of the function F. The geometrical-acoustics or eikonal approximation results when one requires that the coefficients of F'' and F' both vanish identically, and thus assumes that the terms involving undifferentiated F are of lesser importance in the high-frequency limit. The setting equal to zero of the coefficient of the second derivative yields

$$(1-\mathbf{v}\cdot\nabla\tau)^2=c^2(\nabla\tau)^2, \tag{309}$$

which is termed the eikonal equation (Heller, 1953; Keller, 1954). The setting equal to zero of the coefficient of the first derivative yields

$$\nabla\cdot\left(\frac{\rho\Psi^2}{c^2}[c^2\nabla\tau+(1-\mathbf{v}\cdot\nabla\tau)\mathbf{v}]\right)=0, \tag{310}$$

which is termed the transport equation. The convenient property of these equations is that they are independent of the nature of the wave-form function F.

The eikonal equation, which is a nonlinear first-order partial differential equation for the eikonal $\tau(\mathbf{x})$, can be solved by Cauchy's method of characteristics. What results are the ray-tracing equations of Eqs. (303) and (304). However, the time variable t is replaced by the eikonal τ. The manner in which these equations solve the eikonal equation is such that if τ and its gradient $\mathbf{s}$ are known at any given point, then the ray-tracing equations determine these same quantities at all other points on the ray that passes through this initial point. The initial value of $\mathbf{s}$ must conform to the eikonal equation itself, as is stated in Eq. (309). If this is so, then the ray-tracing equations ensure that it conforms to the same equation, with the appropriate ambient variables, all along the ray.

Solution of the transport equation, given by Eq. (310), is facilitated by the concept of a ray tube. One conceives of a family of adjacent rays which comprise a narrow tube of cross-sectional area A, this area varying with distance l along the path of the central ray of the tube. Then the transport equation reduces to

$$\frac{d}{dl}\left(A\frac{\rho\Psi^2}{c^2}\Omega v_{\mathrm{ray}}\right)=0, \tag{311}$$

so the quantity within parentheses is constant along the ray tube.

Alternatively, the relation of Eq. (307) implies that the acoustic pressure is locally given to an equivalent approximation by

$$p=P(\mathbf{x})f(t-\tau), \tag{312}$$

where f is the derivative of F, and P is related to Ψ by

$$P=-\rho\Omega\Psi. \tag{313}$$

Then Eq. (311) requires that

$$B=AP^2v_{\mathrm{ray}}/\rho c^2\Omega \tag{314}$$

be constant along a ray tube, so that

$$\frac{dB}{dl}=0. \tag{315}$$

This quantity B is often referred to as the Blokhintzev invariant.

If there is no ambient flow then the constancy of B along a ray tube can be regarded as a statement that the average acoustic power flowing along the ray tube is constant, for a constant-frequency disturbance, or in general that the power appears constant along a trajectory moving with the ray velocity. The interpretation when there is an ambient flow is that the wave action is conserved (Hayes, 1968).

Geometrical acoustics, insofar as amplitude prediction is concerned, breaks down at caustics, which are surfaces along which the ray-tube areas vanish. Modified versions (Buchal and Keller, 1960; Ludwig, 1966), involving Airy functions and higher transcendental functions, of the geometrical acoustics theory have been derived which overcome this limitation.

14.5 Amplitude Variation in Rectilinear Propagation

A simple but important limiting case of geometrical acoustics is for propagation in homogeneous nonmoving media. The rays are then straight lines and perpendicular to wave fronts. A given wave front has two principal radii of curvature R_{I} and R_{II}. With the convention that these are positive when the wave front is concave in the corresponding direction of principal curvature, and negative when it is convex, the curvature radii increase by a distance l when the wave propagates through that distance. The ray-tube area is proportional to the product of the two curvature radii, so the acoustic pressure varies with distance l along the ray as

$$p=\left(\frac{R_{\mathrm{I}}R_{\mathrm{II}}}{(R_{\mathrm{I}}+l)(R_{\mathrm{II}}+l)}\right)^{1/2} f(t-[l/c]). \qquad (316)$$

Here R_{I} and R_{II} are the two principal radii of curvature when l is zero. The relations of Eqs. (176) and (188), for spherical and cylindrical spreading, are both limiting cases of this expression.

15. PARABOLIC-EQUATION APPROXIMATIONS

It is often useful in propagation analyses to replace the Helmholtz equation or its counterpart for inhomogeneous media by a partial differential equation that is first order, rather than second order, in the coordinate which corresponds to the primary direction of propagation. Approximations that achieve this are known generally as parabolic-equation approximations and stem from early work by Fock (1965) and Tappert (1977). Their chief advantage is that the resulting equation is no longer elliptic, but parabolic, so it is no longer necessary to check whether a radiation condition is satisfied at large propagation distances. This is especially convenient for numerical computation, for the resulting algorithms march out systematically in propagation distance, without having to "look far ahead" for the determination of the field at a subsequent point.

A simple example of a parabolic-equation approximation is that of two-dimensional propagation in a medium where the sound speed and density vary primarily with the coordinate y, but weakly with x. A wave of constant angular frequency ω is propagating primarily in the x direction but is affected by the y variations of the ambient medium, and by the presence of interfaces that are nearly parallel to the x direction. The propagation is consequently governed by the two-dimensional reduced wave equation,

$$\frac{\partial}{\partial x}\left(\frac{1}{\rho}\frac{\partial \hat{p}}{\partial x}\right)+\frac{\partial}{\partial y}\left(\frac{1}{\rho}\frac{\partial \hat{p}}{\partial y}\right)+\frac{\omega^2}{\rho c^2}\hat{p}=0, \qquad (317)$$

which can be obtained from Eq. (54) by use of the complex amplitude convention.

In the parabolic approximation, the exact solution $\hat{p}$ of Eq. (317), with a radiation condition imposed, is represented by

$$\hat{p}\,(x,y)=e^{i\chi(x)}F(x,y), \qquad (318)$$

where

$$\chi(x)=\int_0^x k_0\,dx. \qquad (319)$$

Here $k_0(x)$ is a judiciously chosen reference wave number (possibly dependent on the primary coordinate x). The crux of the method is that the function $F(x,y)$ is taken to satisfy an approximate partial differential equation (parabolic equation) that differs from what would result were Eq. (318) inserted in Eq. (317) with no discard of terms.

The underlying assumption is that the x dependence of the complex pressure amplitude is accounted for in a major part by the exponential factor, so the characteristic scale for variation of the amplitude factor F with the coordinate x is much greater than the reciprocal of k_0. Consequently, second derivatives of F with respect to x can be neglected in the derived differential equation. The y derivatives of the ambient variables are also neglected. The resulting approximate equation is given by

$$\frac{\partial}{\partial x}\left(\frac{k_0}{\rho}F\right)+\frac{k_0}{\rho}\frac{\partial F}{\partial x}=i\frac{\partial}{\partial y}\left(\frac{1}{\rho}\frac{\partial F}{\partial y}\right)+i\frac{k_0^2}{\rho}(n^2-1)F, \tag{320}$$

where n, the apparent index of refraction, abbreviates $k_0^{-1}\omega/c$. If the reference wave number k_0 is selected to be independent of x, then Eq. (320) reduces to

$$2k_0\frac{\partial F}{\partial x}=i\rho\frac{\partial}{\partial y}\left(\frac{1}{\rho}\frac{\partial F}{\partial y}\right)+ik_0^2(n^2-1)F. \tag{321}$$

Although the computational results must depend on the selection of the reference wave number k_0, results for various specific cases tend to indicate that the sensitivity to such a selection is not great.

GLOSSARY

Absorption: Process whereby some or all of the energy of a sound wave is transferred to the medium through which it is passing or to an object or surface on which it impinges.

Acoustic Boundary-Layer Theory: Theory which accounts for the typically rather abrupt changes in the nature of an acoustic field that take place near solid surfaces, so that the field outside the boundary layer more nearly conforms to idealizations appropriate to an unbounded medium.

Acoustic Compliance: Acoustic lumped parameter element analogous to capacitance in electric circuit theory. The volume velocity difference across a compliance element equals acoustic compliance times the time rate of change of pressure within the element.

Acoustic Fluid Velocity: Portion of the fluid velocity that is associated with the acoustic field.

Acoustic Impedance: Complex number pertaining to acoustic fields of constant frequency, equal to the ratio of a complex pressure amplitude to the complex amplitude of the volume velocity.

Acoustic Inertance: Acoustic lumped parameter element analogous to inductance in electric circuit theory. The pressure difference across an inertance element equals acoustic inertance times the time rate of change of volume velocity through the element.

Acoustic Intensity: Vector that describes the acoustic energy flowing per unit area and per unit time. The projection of this vector on any given direction gives the energy flow rate per unit area of surface normal to that direction.

Acoustic Mode: Acoustic part of a disturbance governed by the linearized equations of fluid mechanics. The three portions (acoustic mode, vorticity mode, and entropy mode) collectively superimpose to yield the overall perturbation disturbance.

Acoustic Pressure: The portion of the overall pressure that is associated with the acoustic field.

Acoustically Compact: An object or region of space that has dimensions that are small compared with a representative acoustic wavelength.

Acoustics: Science of sound, including its production, transmission, and effects, with sound defined as organized disturbances of a primarily mechanical nature that can propagate as waves or be regarded as a superposition of waves.

Affinity: Generic term for thermodynamic variables that appear as coefficients when the equation of state is written in differential form.

Ambient: Generic adjective referring to the medium and to its properties in the absence of an acoustic disturbance.

Ambient State: State of the medium or thermodynamic state in the absence of an acoustic disturbance.

Anechoic: Adjective used to imply that the subject does not reflect sound (without echos).

Angle of Incidence: Angle between the normal direction into a surface or interface and the direction of propagation of an incident acoustic wave.

Angle of Refraction: Angle between the normal direction into an interface and the direction of propagation of a transmitted acoustical wave. The phenomenon whereby the angle of refraction is not the same as the angle of incidence is referred to as refraction.

Angular Frequency: Frequency of a disturbance expressed in radians per second.

Associated Legendre Functions: Functions that are solutions of the associated Legendre equation (a second-order ordinary differential equation, which emerges when one solves the wave equation by separation of variables in spherical coordinates).

Asymptotic Limit: Simplified value or expression for a given function which holds to an increasingly higher accuracy when the independent variable becomes increasingly large.

Attenuation: Exponential decay in amplitude of a sound wave with increasing propagation distance as it passes through a medium.

Attenuation Coefficient: Exponential rate of decay with propagation distance of the amplitude of a sound wave, typically measured in nepers per meter.

Audible Frequencies: Those frequencies of acoustic disturbances that are ordinarily audible to the human ear, the range typically being taken as between 20 and 20 000 Hz.

Axial Wave Function: Factor describing the variation with distance along the waveguide axis when the wave function for a guided wave is expressed by the method of separation of variables.

Baffle: A relatively rigid extended surface surrounding an acoustic source.

Bending Modulus: Parameter describing the resistance (stiffness) of a beam or plate to bending. For a plate temporarily bent into a cylindrical shape, the bending modulus is the ratio of the curvature (reciprocal of the radius of curvature) to the bending torque per unit length.

Bernoulli–Euler Plate: Plate whose static and dynamic behavior adheres to the generalization of that model appropriate to a Bernoulli–Euler beam, including the assumption that points on any line normal to the central surface remain on a straight line, and that such lines are always normal to the surface throughout the motion.

Blokhintzev Invariant: Quantity proportional to the square of the magnitude of the wave amplitude which has the same value at every point along a geometrical acoustics ray path in inhomogeneous moving media.

Boundary Layer: Layer adjacent to a surface in which effects of viscosity or thermal conductivity are important.

Bulk Viscosity: The second viscosity coefficient, defined such that the nonequilibrium part of the average normal stress is bulk viscosity times the divergence of the fluid velocity.

Cauchy's Equation of Motion: The continuum generalization of Newton's second law which involves the distributed forces associated with stress gradient.

Caustic: Lines or surfaces along which adjacent rays intersect each other and along which the ray-tube area goes to zero.

Characteristic Frequency: Equivalent to representative frequency; whatever value of frequency is sufficient for making order-of-magnitude estimations and in assessing whether certain approximations are appropriate and whether certain terms in the governing equations are negligible. Equivalent to the reciprocal of characteristic time.

Characteristic Time: A value for a time interval that is representative of the source excitation or of the boundary conditions inherent to the determination of a wave disturbance; used in making order-of-magnitude estimations and in assessing whether certain approximations are appropriate and whether certain terms in the governing equations are negligible.

Classical Dissipation: The dissipation that is associated with viscosity and thermal conduction, in contrast to the dissipation associated with relaxation effects.

Compact: Within the context of acoustics, compact refers to an object or region that is small compared to a representative wavelength.

Compliance: Often used as an abbreviation for acoustic compliance.

Conduction Heat Transfer: The type of heat transfer that is governed by Fourier's law of heat conduction, as contrasted to heat transfer by convection or radiation.

Conservation of Mass Equation: Partial differential equation of fluid mechanics that accounts for the increase of density in a region in terms of the net flow of matter into that region.

d'Alembertian Operator: Operator equal to Laplacian minus product of square of reciprocal of sound speed with second time derivative.

Degenerate: Adjective used to characterize eigenvalues which are associated with more than one eigenfunction.

Diffusion Equation: Linear partial differential equation that accounts for diffusion of a concentrate, equating the time derivative of the concentrate to a constant times the Laplacian of the concentrate.

Dilatational: Having to do with the enlargement of the volume occupied by a definite amount of mass; opposite of compressional.

Dipole: Type of source formed by two closely spaced monopoles with equal and opposite source strengths.

Dispersion: Phenomenon whereby different frequencies propagate with different phase velocities.

Dispersion Relation: Any mathematical relation that involves angular frequency and wave number, such that one could, in principle, determine all of the possible values of angular frequency that correspond to a given wave number.

Dissipative Wave Equation: Any wave equation that accounts for dissipation of energy during wave propagation.

Eigenfunction: Nonzero solution of a homogeneous boundary-value problem with one adjustable parameter, when for almost all such values of that parameter the only solutions are identically zero; the values when a nonzero solution is possible are called the eigenvalues.

Eigenray: Ray connecting two specified points which satisfies the ordinary differential equations of geometrical acoustics.

Eikonal Equation: Nonlinear first-order partial differential equation arising in the theory of geometrical acoustics. Its solution is typically given parametrically in terms of ray paths.

Euler Equation: Counterpart of Newton's second law for an ideal fluid without viscosity, in which acceleration is caused by pressure gradients.

Eulerian Description: Scheme for a mathematical description of material motion in a continuum in which field quantities are expressed as functions of actual position coordinates rather than of the coordinates of initial positions of material particles.

Evanescent: Adjective referring to wave phenomenon that does not propagate but which dies out exponentially with distance, without necessarily being accompanied by any dissipation of energy.

Fermat's Principle: Actual path followed by an eigenray must be such that the travel time along that path is stationary (does not change to first order) to all small virtual changes along that path, originally stated (with less universality) as a principle of least time and sometimes stated as the principle that the travel time must be an extremal (maximum or minimum).

Flow Resistance: A counterpart of Ohm's law for flow through a porous slab is that the pressure difference across the slab is a constant (the flow resistance) times the apparent velocity of flow through the slab. The latter is the mass flowing through the slab per unit area and per unit time, divided by the ambient density of the fluid external to the slab.

Flow Resistivity: Flow resistance per unit thickness of the slab.

Fourier's Law of Heat Conduction: The heat flux vector is taken to be opposite in direction and proportional to the gradient of the temperature.

Geometrical Acoustics: Approximate theory of acoustics based on the premise that disturbances which locally resemble plane traveling waves propagate locally according to the relations appropriate to such waves; the theory leads to the concept of rays or ray paths which are, in general, curved and along which the dominant features in the disturbance travel.

Geometrical Theory of Diffraction: Generalization of geometrical optics or geometrical acoustics based on rigorous asymptotic analysis of wave theory, which includes as a basic tenet that waves diffracted by edges and curved objects propagate away from such edges or objects along rays, which are completely analogous to the rays along which direct and reflected waves propagate.

Group Velocity: Velocity at which energy is transported by a wave of nearly constant frequency.

Helmholtz Corollary: Alternatively known as the Helmholtz–Kirchhoff corollary to the wave equation, this applies to a constant-frequency disturbance and expresses the acoustic pressure (or an analogous field variable) at a point off the surface as an integral over the surface involving the field and its normal derivative, as well as a Green's function. The integral is often referred to as the Helmholtz integral.

Helmholtz Equation: Form of the wave equation which holds for disturbances of constant frequency, with the dependent variable being the spatially dependent complex amplitude of a field quantity such as acoustic pressure.

Impedance Tube: A device consisting of a long cylindrical tube with a sound source at one end and a sample at the other end, which is used to measure the surface impedance of the sample.

Inertance: A lumped parameter quantity which plays a role analogous to mass in the equations describing a system's dynamics.

Intensity: The energy flux vector of a wave disturbance, not to be confused with the amplitude or the energy density of the disturbance. The dot product of a given unit vector with the intensity vector yields the energy flow per unit area and time across a surface normal to that unit vector.

Kirchhoff Corollary: A corollary of the linear acoustic equations which expresses the acoustic pressure field off of a surface as an integral over the surface involving the field, its time derivative, and its normal derivative, as well as a Green's function, usually referred to as the Helmholtz–Kirchhoff corollary.

Lamé Constants: Coefficients in the linear relations between the stress and strain tensor components, which appear in theory of elasticity of isotropic materials.

Law of Mirrors: The rule that for reflection of waves at a smooth surface, the angle of incidence equals the angle of reflection.

Mass Law: Approximate rule that the fraction of incident energy transmitted through a wall or panel is inversely proportional to the square of the mass per unit area in the wall.

Medium: Abstract term referring to whatever a wave is propagating through, characterized by the nature and coordinate dependences of the coefficients in those equations that govern the propagation.

Momentum Balance Equation: Equation related to Newton's second law for a continuum which accounts for changes in momentum in terms of forces.

Monopole: Source of sound whose radiation characteristics are the same as those of an omnidirectional point source.

Monopole Strength: Descriptor of a constant-frequency source's ability to produce monopole radiation, equal to the coefficient of $r^{-1}e^{ikr}$ in the expression for the complex amplitude of the radiated pressure.

Muffler: Device for abating the noise accompanying the flow of gas through a pipe.

Multipath: Phenomena whereby more than one ray path can reach a given reception point.

Multipole: Adjective referring to a type of mathematical expansion of radiated sound fields from localized sources, the various terms being monopole, dipole, quadrupole, etc., terms.

Navier–Stokes Equation: Generalization of Newton's second law for a viscous fluid.

Navier–Stokes–Fourier Equations: Set of fluid dynamic equations that govern a compressible fluid with viscosity and thermal conductivity.

Newtonian Fluid: A fluid within which the stress tensor components are linearly dependent on the rate of strain tensor components.

Parseval's Theorem: The version for a Fourier series expresses the time average of the square of the function in terms of a sum over the squares of its Fourier coefficients; that for transients expresses the time integral of the square of the function in terms of the frequency integral of the square of the Fourier transform.

Phase Velocity: The velocity with which position would have to change such that the phase remains constant; if $\phi(x,t)$ is the phase, then the phase velocity is found by setting $x=x[t]$ and then setting the total derivative with respect to time of the phase equal to zero.

Plane Wave: Wave which depends on distance in only one direction, so that the field variables are constant along planes perpendicular to that direction.

Poisson's Ratio: Constant in the theory of elasticity which corresponds to the negative of the ratio of transverse strain to axial strain when a thin elastic rod undergoes axial stretching, with a simultaneous shrinking in cross-sectional area.

Pressure Release Surface: Surface on which the acoustic pressure vanishes.

Quadrupole: Source of sound whose radiation properties are similar to those of four closely spaced point sources with source strengths such that (i) their sum is identically zero, and (ii) their net dipole moment is identically zero.

Radiation Condition: A condition which a constant-frequency solution of a wave equation must satisfy at large distances from the source in order that the radiated field be the aftermath of the source having been turned on at some time in the past.

Radiation Impedance: Specific radiation impedance is the ratio of the complex amplitude of the acoustic pressure to the complex amplitude of the fluid velocity in the outward normal direction on the surface of a vibrating body.

Rate-of-Shear Tensor: Rate-of-strain tensor minus a multiple of the unit tensor, with the coefficient chosen such that the trace is identically zero; the tensor vanishes for rates of strain occurring during uniform compression or dilatation.

Rate-of-Strain Tensor: In the linear approximation, this is the same as the time derivative of the strain tensor.

Ray: Path in space, or a trajectory in space-time, along which characteristic features of an acoustic field propagate.

Ray Tube: Hypothetical surface enclosing a bundle of ray paths, such that if any given ray paths touches the surface at one point, then it lies entirely in the surface.

Reactive Muffler: Muffler whose primary mechanism for attenuating sound involves the frequency-dependent reflection of sound back toward the source.

Reciprocity: Principle in wave theory which asserts, with various conditions, that the amplitude detected by a given receiver due to a disturbance generated by a given source will be the same if the positions of the source and receiver are interchanged.

Reference Wave Number: Parameter that enters into the formulation of the parabolic equation approximation.

Reflection Coefficient: A complex number that describes the ratio of the complex amplitude of a reflected wave to the complex amplitude of the corresponding incident wave.

Relaxation Processes: Processes whereby a thermodynamic system evolves toward thermodynamic equilibrium.

Salinity: Measure of the total salt content of sea water, expressed as parts per thousand, or grams of dissolved salts per kilogram of water.

Spherical Spreading: The characteristic decay of wave amplitudes as $1/r$ when propagating out from a localized source in an unbounded medium.

Stokes's Time Derivative Operator: The time derivative that would be measured by someone moving with the fluid.

Strain Tensor: Tensor which describes the state of deformation within a continuum material. The diagonal elements correspond to stretching strains (elongation per unit length) and the off-diagonal elements correspond to shear strains.

Stress Tensor: Tensor which describes the distributed internal forces within a continuum material. The tensor product of the stress tensor with a given unit vector yields the force vector per unit area exerted by adjacent material on an internal surface with unit normal in that direction.

Thermal Conductivity: Material constant that appears in Fourier's law of heat conduction: heat flux vector is the negative product of the thermal conductivity with the temperature gradient.

Thermodynamic Coefficient: Thermodynamic quantity described by an expression involving one or more partial derivatives of one thermodynamic state variable with respect to another, with the evaluation being at the ambient thermodynamic state. In linear acoustics, the thermodynamic coefficients are independent of field amplitudes, but may vary with position.

Thermodynamic Field Quantity: Quantities such as pressure, density, specific entropy, and temperature which are associated with the thermodynamic state of the material, but which are perturbed during an acoustic disturbance, with the perturbations varying with position and time.

Trace Velocity: The apparent speed at which an acoustic disturbance moves along a specified line that is not necessarily aligned with the direction of propagation. If the disturbance is associated with a plane wave, then the trace velocity is the sound speed divided by the cosine of the angle between the direction of propagation and the direction of the line.

Trace Velocity Matching Principle: If a primary portion of a disturbance has a single fixed trace velocity along a surface or interface, then all of the other portions of the overall wave disturbance that can be regarded as caused by the primary disturbance must have the same trace velocity.

Unit Area Acoustic Impedance: Same as specific acoustic impedance, equal to the ratio of the complex amplitude of the acoustic pressure to the complex amplitude of the acoustic particle velocity component pointing into the surface.

Volume Acceleration: Time derivative of the volume velocity.

Volume Expansion Coefficient: Thermal expansion coefficient, equal to the change in volume per unit volume per unit change in temperature at constant pressure.

Volume Velocity: Apparent volume of fluid which crosses a specified surface per unit time, equal to the rate of mass flow across the surface divided by the ambient density of the fluid.

Vorticity: Curl of the fluid velocity.

Vorticity Mode: That part of a disturbance governed by the linearized equations of fluid mechanics which is characterized by a nonzero vorticity. The three portions (acoustic mode, vorticity mode, and entropy mode) collectively superimpose to yield the overall perturbation disturbance.

Wave: Disturbance moving through a medium, typically yielding little or no net transport of mass, but carrying energy.

Wave Action: For an oscillating one-degree-of-freedom system undergoing adiabatic changes that affect its oscillation frequency, induced by gradual changes of the environment or of the applied external forces, it is often true that the quantity which most nearly remains constant is the energy divided by the oscillation frequency, rather than the energy itself. Because this is equivalent to an integral of energy over a time period, which in turn is analogous to the integral of a Lagrangian over time in the principle of stationary action, this conserved quantity is called the system action. For a propagating wave, the wave action density is the energy density divided by the local frequency that would be perceived by someone moving with the ambient flow.

Wave Equation: In the narrow sense this is the ordinary wave equation that holds for the most idealized case and whose one-dimensional version appears in the elementary theory of the vibrating string; the term is also often used to refer to any equation that governs wave phenomena.

Wave Front: Moving surface associated with a propagating wave; the surface is one along which the wave's phase is everywhere the same or one along which a distinct waveform feature is being simultaneously received.

Waveguide: Device or circumstance that causes acoustic propagation to be confined to a restricted range of propagation directions.

Wave Number: Rate of change of phase with propagation distance, equal to 2π divided by the wavelength, and having units of radians per meter.

Wave Slowness: Reciprocal of phase velocity, equal to wave number divided by angular frequency.

Wave Slowness Vector: Wave-number vector divided by angular frequency.

INTRODUCTION

Nonlinear acoustics is the analysis of mechanical waves and vibrations in a medium where the governing differential equations cannot be assumed to be linear. It is a rather backward definition of a field, defining it only in the negative, but this is a fact of historical experience.

Since the approximation of linearity extends to the entire field of acoustics, it follows that every branch has its nonlinear supplement. In addition, however, there are phenomena that are inherently nonlinear and form branches of acoustics in their own right (for example, shock waves and radiation pressure).

Ordinary linear acoustics presumes that the variations of local pressure, density, and temperature produced by a sound wave are negligible in comparison with the equilibrium values of these same quantities. In that sense, linear acoustics is said to be an infinitesimal theory. In the case of the displacement velocity of a particle in a continuous medium, subject to the passage of a sound wave, we cannot make the same comparison, since the basic treatment presupposes a con-

tinuous medium that is at rest in equilibrium. However, we can compare the particle velocity with the velocity of propagation of sound in the medium.

This ratio is called the acoustic Mach number M. If the amplitude of the displacement velocity is u_0 and the sound velocity is c_0, then $M=u_0/c_0$. Also, since the excess pressure amplitude p_a is related to the displacement velocity amplitude by the relation $p_a=\rho_0 c_0 u_0$, where ρ_0 is the mean density of the medium, then $M=p_a/\rho_0 c_0^2$. This Mach number must be negligible in value if linear acoustics is to prevail. As an example, we consider the sound level of a rock concert, which, in decibel notation, is 120 dB *re*: 20 μm Pa. That is, $120=20\log[p_a/(20\times 10^{-6})]$; hence $p_a=20$ Pa. Hence $M=20/(1.4)(343)^2=1.2\times 10^{-4}$ (density of air $\rho_0=1.4$ kg/m^3, c_0 for air$=343$ m/s).

However, as a sound wave passes through such a medium, the nonlinear effects are cumulative. Thus it is meaningful to consider that the linear approximation will fail when the product of the number N of wavelengths traversed by the beam and the acoustic Mach number M becomes an appreciable fraction of unity. In the example considered, the wavelength of the sound will, at a frequency of 10 kHz, be equal to $(343\ \mathrm{m\ s^{-1}})/(10\times 10^3\ \mathrm{s^{-1}})=0.0343$ m. For $MN=0.1$, we obtain a value of $N=0.1/M=0.1/1.2\times 10^{-4}=830$. This corresponds to a distance of $830\times 0.0343=28.5$ m. If the frequency were 100 kHz, the wavelength would decrease by a factor of 10, and the distance required would shrink to 2.85 m. Such a distance would be even smaller in the case of liquids, so that the nonlinearity is almost always present in sound propagation to some degree.

Historical references to what we would now call nonlinear acoustics abound. In the Aeolian harp, an instrument that goes back to Biblical times, a flow of wind past a string or wire can set that string into oscillation. Today, we know these oscillations to be due to the growth and shedding of vortices of air downwind, with the creation of an alternating force on the string. A similar shedding of vortices in the flow of air past a narrow wedge is the source of so-called edge tones and is responsible for the operation of some musical instruments. In the nineteenth century, it was observed that there is a one-way flow of air near a sound source. Such acoustic streaming is another nonlinear sound effect. Cavitation, or the creation of holes (or gas bubbles) in a liquid due to the passage of intense sound waves, is another example of the nonlinear behavior of acoustic media. And finally, the creation of turbulent flow by jet engines, for example, is responsible for the emission of the strong sound waves that are created in the wake of jet aircraft.

1. THE EQUATION OF MOTION

Ordinary sound and vibration are treated by the use of linear differential equations (see ACOUSTICS, LINEAR). For example, for a one-dimensional vibrating string, and with neglect of dissipation, the equation is

$$c^2\frac{\partial^2 y}{\partial x^2}=\frac{\partial^2 y}{\partial t^2}, \tag{1}$$

where y is the transverse displacement of the string at the position x, and c is the speed of propagation of the wave along the string.

With such an equation, the general solution is of the form

$$y=A\cos(\omega t-kx)+B\sin(\omega t-kx), \tag{2}$$

where A and B are arbitrary constants. Such an equation and its solutions have the property of superposition; i.e., the linear combination of any two solutions of Eq. (1) is also a solution of that equation. Thus, if we analyze any initial disturbance into its Fourier components, the amplitude of every frequency component initially present in the wave will remain constant in time. The presence of dissipation can be taken into account by the addition of a term $R(\partial y/\partial t)$ on the left-hand side of Eq. (1). If, in addition, a forcing term $F(x,t)$ is introduced, the resultant equation takes the form

$$c^2\frac{\partial^2 y}{\partial x^2}+R\frac{\partial y}{\partial t}-\frac{\partial^2 y}{\partial t^2}=F(x,t). \tag{3}$$

If the forcing term is decomposed by Fourier analysis into its harmonic components, each harmonic term can be treated separately, and the complete solution will be the sum of all the solutions of the individual forcing terms.

We look first at the one-dimensional equation governing the propagation of plane waves in a nondissipative ideal gas:

$$\frac{\partial^2\xi}{\partial t^2}=\frac{c_0^2}{(1+\partial\xi/\partial x)^{\gamma+1}}\frac{\partial^2\xi}{\partial x^2}. \tag{4}$$

Here ξ is the displacement of a point on the wave that was initially at coordinate x (the Lagrangian coordinate), γ is the ratio of specific heats, and c_0 is the smallest-amplitude (small ξ) speed of sound.

The normal procedure of linear acoustics is to neglect the contribution of $\partial\xi/\partial x$. This makes the differential equation a linear one. In fact, it becomes the one-dimensional wave equation [Eq. (1)] with propagation velocity c_0.

If a solution of this linear equation is

$$\xi=-\xi_0\cos(\omega t-kx), \tag{5}$$

so that $\xi=\omega\xi_0\sin(\omega t-kx)$ is the displacement velocity, then

$$\left(\frac{\partial\xi}{\partial x}\right)_{\max}=k\xi_0=\frac{\xi_0\omega}{c_0}=\frac{u_0}{u}=M,$$

which is the acoustic Mach number of the displacement velocity. As noted in the Introduction, this quantity is extremely small in air for even the loudest of sounds, and for that reason it has traditionally been neglected.

The principle of superposition does not hold for the nonlinear equation of motion, and entirely different methods are necessary for its solution.

2. NONLINEAR PROPAGATION IN FLUIDS

2.1 Solution of Basic Equation

As far back as 1808, Poisson derived a form for the displacement velocity of the so-called acoustical particle which is

$$u=f(x-(c_0+u)t), \tag{6}$$

in the case of a plane wave traveling along the x axis, where u is the particle velocity and c_0 is the small-amplitude speed of sound. That is, points in the wave with a particle velocity u travel with the enhanced speed c_0+u. Physically, this means that the points with greater particle velocity move forward in the wave relative to those points with lesser particle velocities, thus building up an increasingly steep wave front. This behavior is similar to that of the particles in a water wave, where the crests overtake the troughs and finally break into surf.

There are two historic methods for dealing with such motions. In one, the Eulerian coordinates, one deals with the motions occurring at a fixed point in the medium. In such a case, for a nondissipative medium, the equation of motion becomes

$$\dot{\mathbf{u}}+(\mathbf{u}\cdot\nabla)\mathbf{u}=-\nabla p/\rho, \tag{7}$$

where $\mathbf{u}$ is the particle velocity at the point x. In one dimension this equations becomes

$$\ddot{\xi}+\dot{\xi}\,\frac{\partial\dot{\xi}}{\partial x}=-\frac{1}{\rho}\frac{\partial p}{\partial x}, \tag{8}$$

where $\dot{\xi}$ is the particle velocity in the x direction at the point x.

In the second system (the Lagrangian coordinates), one follows the behavior of a point of the fluid that was initially at rest at the point x. The one-dimensional equation governing the propagation of a plane wave in a nondissipative ideal gas in Lagrangian coordinates becomes

$$\frac{\partial^2\xi}{\partial t^2}=\frac{c_0^2}{(1+\partial\xi/\partial x)^{\gamma+1}}\frac{\partial^2\xi}{\partial x^2}, \tag{9}$$

where ξ is the displacement of the acoustical particle that was at rest at the point x and γ is the ratio of specific heats. If the displacement of a point of the fluid from its rest position is negligible (which is the basic assumption of linear acoustics), then the two sets of coordinates become identical.

It was shown by Earnshaw in 1858 that the implicit solution of Eq. (8) is of the form

$$\dot{\xi}=f(\omega(t\pm x/v)), \tag{10}$$

where

$$v=c_0\left(1+\frac{\gamma-1}{2}\frac{u}{c_0}\right)^{2/(\gamma-1)+1}$$

and $f(\omega t\pm\omega x/c_0)$ is the solution of the corresponding linear equation. More specifically, in the case of an initially sinusoidal wave,

$$\begin{aligned}\dot{\xi}&=u\\&=u_0\sin\left[\omega t-\frac{\omega x}{c_0}\left(1+\frac{\gamma-1}{2}\frac{u}{c_0}\right)^{-2/(\gamma-1)-1}\right],\end{aligned} \tag{11}$$

where u_0 is the initial amplitude of the particle velocity.

In 1935, Fubini-Ghiron solved this equation explicitly for the case of low acoustic Mach numbers (i.e., low values of u_0/c_0). He first recast in Eq. (10) in the form

$$u(x,t)=u_0 \sin\left[\omega t-\frac{\omega x}{c_0}\left(1-\beta \frac{u}{c_0}\right)\right], \tag{12}$$

or

$$\frac{u}{u_0}=\sin\left(\omega t-kx+\frac{x}{l}\frac{u}{u_0}\right). \tag{13}$$

This equation holds for small values of the Mach number. Here $1/l=\beta Mk$, $\beta=(\gamma+1)/2$, and $k=\omega/c_0$.

The quantity l is known as the *discontinuity distance,* being the distance from the source at which the steepness of the wave front in Eq. (13) becomes negatively infinite at the point where u is equal to zero.

The quantity β is known as the *nonlinearity coefficient.* To evaluate it for a liquid, we begin by expanding the pressure in the medium in a Taylor series in the density:

$$p=p_0+\left(\frac{\partial p}{\partial \rho}\right)_{S,\rho=\rho_0}(\rho-\rho_0) + \frac{1}{2}\left(\frac{\partial^2 p}{\partial \rho^2}\right)_{S,\rho=\rho_0}(\rho-\rho_0)^2+\cdots, \tag{14}$$

or

$$p=p_0+As+(B/2)s^2, \tag{15}$$

where s is the condensation, $s=(\rho-\rho_0)/\rho_0$,

$$A=\rho_0\left(\frac{\partial p}{\partial \rho}\right)_{S,\rho=\rho_0}=\rho_0 c_0^2, \tag{16}$$

$$B=\rho_0^2\left(\frac{\partial^2 p}{\partial \rho^2}\right)_{S,\rho=\rho_0},$$

and where we have cut off the series after the quadratic term. It can easily be shown that Eqs. (12) and (13) above remain valid if γ is replaced by $1+B/A$. Hence

$$\gamma=1+B/A,$$

$$\beta=\tfrac{1}{2}(\gamma+1)=1+B/2A. \tag{17}$$

The ratio B/A is known as the parameter of nonlinearity. Its determination has been the subject of considerable study. By thermodynamic analysis (Beyer, 1974), B/A can be expressed as

$$\frac{B}{A}=2\rho_0 c_0\left(\frac{\partial c}{\partial p}\right)+\frac{2\beta_T c_0}{c_p}\left(\frac{\partial c}{\partial T}\right). \tag{18}$$

Here β_T is the volume coefficient of thermal expansion, $\beta_T=(1/V)(\partial V/\partial T)$, and c_p is the specific heat at constant pressure. The ratio can also be determined from analysis of the harmonic content of a finite-amplitude wave as it progresses through the medium. A number of values of B/A are shown in Table 1.

An empirical formula, known as *Ballou's rule,* connects the values of B/A with the sound velocity c_0:

$$B/A=(1.2\times 10^4\ \mathrm{m/s})/c_0-0.5. \tag{19}$$

This formula is moderately successful for liquid metals and a number of other liquids, but it is not uniformly successful, and fails to predict the temperature dependence of the ratio. Some theoretical justification of this rule has been provided by Hartman (1979), who connected the behavior of B/A with the intermolecular potentials of the molecules.

The solution of Eq. (12) is given by (Fubini-Ghiron, 1935)

$$\frac{u}{u_0}=2\sum_{n=1}^{\infty}\frac{J_n(nx/l)}{nx/l}\sin n(\omega t-kx), \tag{20}$$

where $J_n(x)$ is a Bessel function of the first kind of order n. It is clear from Eq. (20) that the fundamental component falls off with distance, while each harmonic increases from zero to a maximum and then falls off. Examples of this behavior are shown in Fig. 1. The solution (20) is valid only as long as $x \ll l$ and as long as damping can be neglected. It is useful, over short ranges, in indicating the harmonic content of an intense sound wave, but is not very effective in realistic situations.

2.2 Burgers' Equation

A method that does take absorption into account is one proposed by Burgers (1948). In this case, Eq. (9) is replaced by an equation in a coordinate system that travels with the crest of the wave. That is, we replace t by $\tau=t-x/c$. Such a change in coordinates enables one to eliminate a number of small terms, so that a new differential equation is obtained—Burgers' equation:

Table 1. Values of B/A. Except where indicated, all values are at atmospheric pressure.

Substance	T (°C)	B/A	Substance	T (°C)	B/A

$$c_0^3 u_z - \beta c_0 u u_\tau = \frac{1}{2}\frac{b\eta}{\rho_0} u_{\tau\tau} = \frac{c_0^3 \alpha}{\omega^2} u_{\tau\tau}. \tag{21}$$

Here a single subscript denotes differentiation by that variable, α=absorption coefficient, $b=\frac{4}{3}+\eta'/\eta$ is the viscosity number, $z=x$, $\tau=t-x/c_0$.

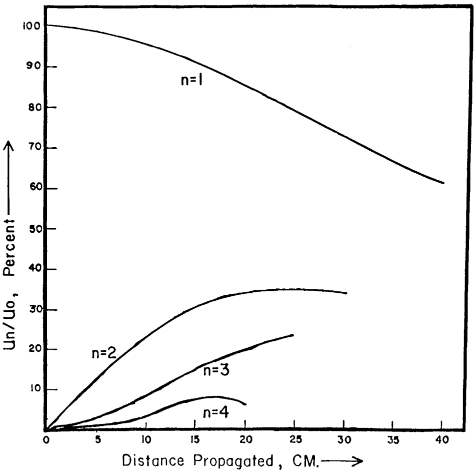

FIG. 1. Fundamental and several harmonics as a function of distance traveled in water. Frequency=2.5 MHz; pressure amplitude, 3.0 atm (Ryan, 1963).

Equation (21) can be put in dimensionless form by setting

$$W=u/u_0,\quad \sigma=z/l,\quad y=\omega\tau,$$

and

$$\Gamma=\beta(u_0/c_0\alpha)(2\pi/\lambda)=1/\alpha l:$$

$$W_\sigma - W W_y = (1/\Gamma) W_{yy}. \tag{22}$$

The quantity Γ is sometimes called the Goldberg number. It is widely used as a scaling parameter. Physically, its reciprocal measures the effective absorption coefficient over the discontinuity distance.

A further substitution, $W = (2/\Gamma\zeta)\zeta_y = (2/\Gamma)\partial \ln\xi/\partial y$, in Eq. (18) reduces that equation to the (linear) diffusion equation

$$\xi_\tau = (1/\Gamma)\xi_{yy}. \tag{23}$$

This equation can be solved exactly (see Beyer, 1974, and Rudenko and Soluyan, 1977).

Table 2. Notation in generalized Burger's equation.

Type of wave	a	W	f	E
Plane	0	u/u_0	σ	Γ^{-1}
Cylindrical	$\frac{1}{2}$	$\left(\frac{\sigma}{\sigma_0}\right)^{1/2}\frac{u}{u_0}$	$2[(\sigma\sigma_0)^{1/2}-\sigma_0]$	$\left(1+\frac{f}{2\sigma_0}\right)^{\Gamma-1}$
Spherical	1	$\left(\frac{\sigma}{\sigma_0}\right)\frac{u}{u_0}$	$\sigma_0 \ln\frac{\sigma}{\sigma_0}$	$\exp\left(\frac{f}{\sigma_0}\right)^{\Gamma-1}$

2.3 Spherical and Cylindrical Coordinates

A generalized form of Burgers' equation, good for the three standard coordinate forms, can be written as

$$W_f - WW_z = EW_z, \tag{24}$$

where

$$W = (\sigma/\sigma_0)^a u/u_0, \quad z = \omega(1 - x/c_0), \quad \sigma = x/l,$$

$\sigma_0 = x_0/l$, x_0 is the source radius (for spheres and cylinders), x is the field position, and the definitions of a, f, and E are given in Table 2. These lead to rather complicated calculations and also suffer from limits on their generality.

In all the analysis thus far, it has been assumed that one is dealing with unbounded waves. A technique for handling bounded beams in a nondissipative medium was developed by Zabolotskaya and Khokhlov (1969). This procedure led to the equation

$$\frac{\alpha}{2}\frac{\partial^2\rho}{\partial\tau^2} - \frac{\partial^2\rho}{\partial\tau\,\partial x} + \frac{c_0}{2}\left(\frac{\partial^2\rho}{\partial y^2} + \frac{\partial^2\rho}{\partial x^2}\right) = 0. \tag{25}$$

Here $\alpha = (\gamma+1)/2\rho_0 c_0$, $\tau = t - x/c$, and ρ is the density of the medium.

The dissipative case was considered by Kuznetsov (1970), leading to the equation

$$\frac{\alpha}{z}\frac{\partial^2\rho}{\partial\tau^2} - \frac{\partial^2\rho}{\partial\tau\,\partial x} + \frac{c_0}{2}\left(\frac{\partial^2\rho}{\partial y^2} + \frac{\partial^2\rho}{\partial z^2}\right) + K\frac{\partial^3\rho}{\partial\tau^3} = 0, \tag{26}$$

where $K = b\eta/2\rho_0 c_0^3$ and b is the combination of viscosity and thermal conductivity terms

$$b = \frac{\eta'}{\eta} + \frac{4}{3} + \kappa\left(\frac{1}{c_v} - \frac{1}{c_p}\right). \tag{27}$$

Here η' is the bulk viscosity, η is the shear viscosity, κ is the thermal conductivity, and c_v and c_p are the specific heats at constant volume and pressure, respectively. Equation (26) is referred to in the literature as the KZK equation. Numerous examples of solutions of this equation and Eq. (25) can be found in Bakhvalov *et al.* (1987) and Novikov *et al.* (1987). The analysis presented above has been confirmed experimentally in many instances. Studies of the harmonic content of an originally sinusoidal wave have produced results closely following those of the Fubini-Ghiron solution of Eq. (17). Examination of the distorted wave form has also been carried out. Analysis of the phenomenon of optical diffraction produced by a sound beam (the Debye–Sears effect) at high sound intensities indicates that the distortion of the wave form due to the production of higher harmonics follows closely the values calculated theoretically.

3. SHOCK WAVES AND AEROACOUSTICS

3.1 Rankine–Hugoniot Equation

The steepening of the wave front due to nonlinearities, discussed in Sec. 1, leads, in the absence of dissipation, to the formation of a front of infinite steepness, which is characteristic of a shock front. The development of this steepness is shown in Fig. 2. One could therefore consider finite-amplitude waves as a form of weak shocks.

The field of shock waves is an enormous one and will not be discussed in detail here (see SHOCK WAVES). The fundamental equation governing the fluid motion, relating the properties of the fluid ahead of the shock (denoted by the subscript a) and those behind

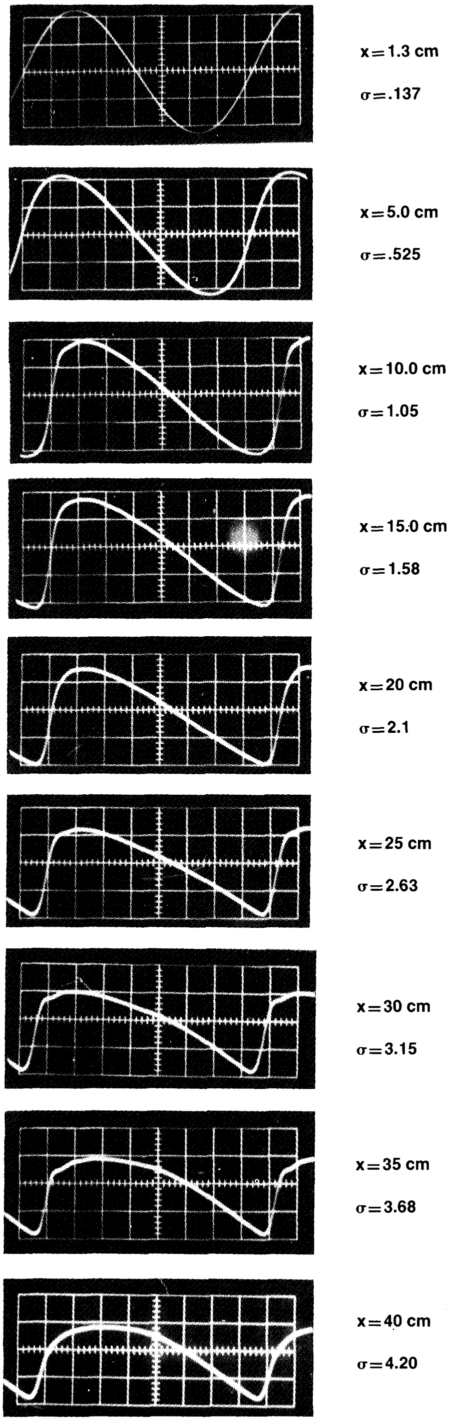

FIG. 2. Progressive distortion of a wave form in an originally sinusoidal signal. Frequency $\nu=2.58$ MHz; initial acoustic pressure, 6.0 atm. The medium was water at 22°C, x=distance from source, and σ=reduced length=x/l. Since the pictures are oscilloscope traces of the signal, the leading edge of the wave is at the left (Ryan, 1963).

the shock (subscript b) is the Rankine–Hugoniot equation (see Beyer, 1974):

$$\frac{\rho_b}{\rho_a}=\frac{p_b(\gamma+1)+p_a(\gamma-1)}{p_a(\gamma+1)+p_b(\gamma-1)}, \tag{28}$$

or using the coefficient of nonlinearity, $\beta=(\gamma+1)/2$,

$$\frac{\rho_b}{\rho_a}=\frac{p_b\beta+p_a(\beta-\frac{1}{2})}{p_a\beta+p_b(\beta-\frac{1}{2})}. \tag{29}$$

In the weak-shock approximation ($u_0<0.1c_0$), the speed of propagation of the shock front v, derived from Eq. (29), takes the form (Blackstock, 1966)

$$v=c_0+(\beta/2)(u_a+u_b). \tag{30}$$

If a shock begins to form at a point $\bar{x}$ and a time $\bar{t}$, then it will arrive at a point x at a time t given by

$$t=\bar{t}+\int_{\bar{x}}^{x}\frac{dy}{\bar{v}},$$

where y is a dummy variable. If we substitute the speed of propagation of the shock, Eq. (30), then we have, approximately,

$$\frac{1}{\bar{v}}=\frac{1}{c_0}-\frac{1}{2}\frac{\beta}{c_0^2}(u_a+u_b), \tag{31}$$

from which we can write down the derivative

$$\frac{d\tau_s}{dz}=-\frac{\beta}{2c_0^2}(u_a+u_b). \tag{32}$$

A plot of the successive distortions of the wave form is shown in Fig. 3.

3.2 Shock-Wave Thickness

The properties of the medium ahead of and behind the shock front must change continuously from one set into the other. The distance over which this change takes place is measured by the shock-wave thickness. The variation of the pressure through the front is usually approximated by the expression

$$p=\frac{1}{2}(p_a+p_b)+\frac{1}{2}(p_b-p_a)\tanh\frac{2x}{\delta}, \tag{33}$$

and the wave thickness δ is defined by the relation

$$\delta=\frac{p_2-p_1}{(dp/dx)_{\max}}, \tag{34}$$

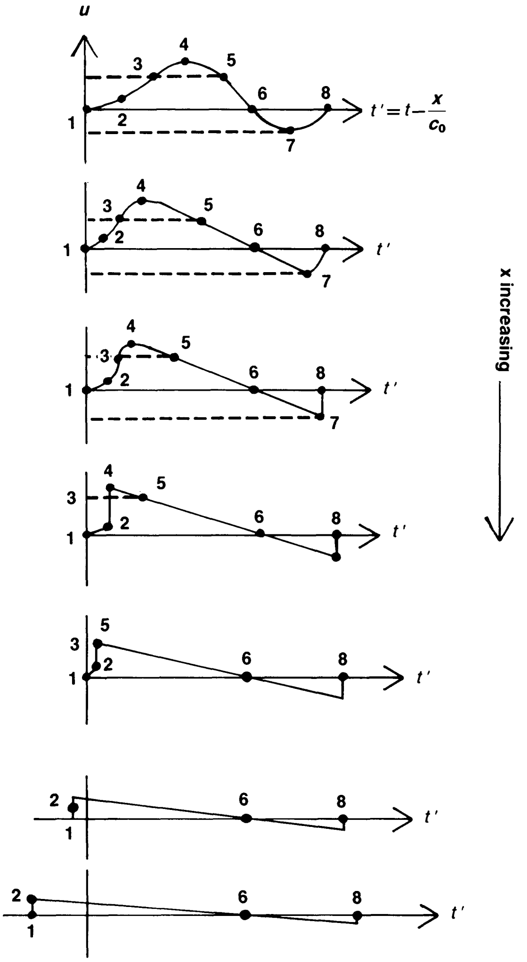

FIG. 3. Steepening of an originally sinusoidal pulse as a function of the reduced time $t' = t - xc_0$. The numbers refer to corresponding points on the wave. As in the case of Fig. 2, the leading edge of the wave (in space) is at the left (Blackstock, 1966).

which can be calculated from thermodynamic properties. It is in fact given by

$$\delta = \frac{[16b\eta + \kappa(1/c_v - 1/c_p)]}{\beta}\,\frac{c_0}{\Delta p}. \tag{35}$$

These results have been confirmed experimentally (see Eisenmenger, 1984).

3.3 N Waves

The buildup of a shock in the neighborhood of a speeding projectile in air (or the formation of the analogous wave in the case of a fast-moving boat on the surface of water) is a direct consequence of the medium's inability to move the wave out of the way of the oncoming source fast enough, so that there is a substantial compression of the medium just ahead of the projectile. The form of the wave front in this case can be obtained from a consideration of Fig. 4.

In the figure, a source of sound is moving to the right with velocity $v = 1.6c_0$. The points A, B, C, D, and E are the positions of the source as observed after each of a series of equal time intervals Δt.

The spherical waves set up by the source when it was located at each of these points are shown at corresponding later times. Thus, when the source reaches B, the sound from point A will lie along the curve B', of radius $c_0\Delta t$. When the source reaches C, the sound from A lies along the curve C' [radius $c_0(2\Delta t)$], while the sound from B lies along C'' (radius $c_0\Delta t$). The other curves are similarly drawn when the source is at D,E.

The trace of the resulting wave front is then given by the tangent curve shown. The angle made by the front with the direction of motion of the source is then

$$\sin\phi = c/u_0 = 1/M, \tag{36}$$

where M is the Mach number. The front of the wave therefore moves out over a conical surface. In the air, this is what is known as

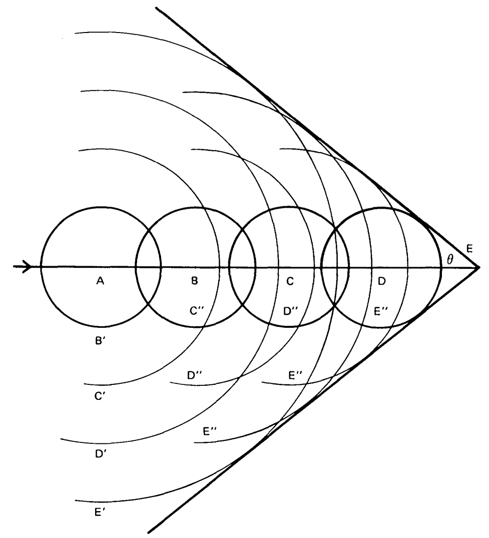

FIG. 4. Generation of a sonic boom (or bow wave). The source of the sound is moving at constant speed along the path *ABCD*, and the crests of the sound waves emitted from the four points *A*, *B*, *C*, and *D* are shown.

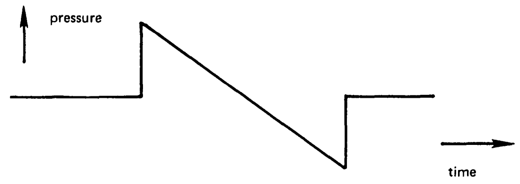

FIG. 5. N wave.

the sonic boom. The corresponding wave in water is called the bow wave.

In addition to this disturbance in front of the projectile, where the pressure undergoes a sudden rise, there is also a similar disturbance at the rear of the projectile, where the pressure returns to normal. The entire pressure cycle is shown in Fig. 5 and has been given the name of the N wave (after Dumond *et al.*, 1946).

The N wave differs from the ordinary shock wave in that the pressure is not constant behind the shock front. Therefore, some of the formulas applying to that case require modification. In the most elementary treatment, one starts with the Earnshaw relation [Eq. (11)] in terms of $\gamma=(B/A)+1$, in the form

$$u-u_0=\frac{2c_0}{\gamma-1}\left(\frac{p}{p_0}\right)^{(\gamma-1)/2\gamma} . \tag{37}$$

After numerous transformations, and with the approximation $p=p_0(1+\phi)$, where $\phi\ll 1$, Dumond *et al.* (1946) were able to derive the relation

$$-\frac{\gamma+1}{\gamma}c\phi\frac{\partial p}{\partial x}=\frac{\partial p}{\partial t} , \tag{38}$$

where terms of order ϕ and higher are neglected. The speed with which a particular pressure propagates can be found from the relation

$$\left.\frac{\partial x}{\partial t}\right|_{p=\text{const}}=-\frac{\partial p/\partial t}{\partial p/\partial x}=\frac{\gamma+1}{2\gamma}c_0\phi. \tag{39}$$

This is the speed with which the pressure p moves relative to the center of the N wave (where $p=0$ and $u=c_0$). Hence two points with pressures corresponding to the values φ and $-\varphi$ will separate at a rate that is twice the value given by Eq. (39) or $[(\gamma+1)/\gamma]c_0\phi$.

Figure 6 shows the behavior of the N wave in spatial coordinates. The discontinuity moves to the right with a speed $[(\gamma+1)/x\gamma]c_0\phi A$ relative to the forward motion of the point. In some small time interval δt, it therefore moves to the x position C''. Now the excess pressure $p_0\phi A$ moves to the right at twice this velocity, reaching the line AC'; i.e., the peak pressure in the shock has fallen to the value $p_0\,\phi''_A$. Since the reverse holds at the tail of the wave, the rate at which the entering wave increases its length is given by

$$\frac{dL}{dt}=\frac{\gamma+1}{2\gamma}c_0\phi . \tag{40}$$

Thus the N wave gets weaker in strength and longer in its duration as it propagates.

3.4 The Lighthill Equations

The starting point for the development of the Lighthill equations (Lighthill, 1954, 1978) is the study by Lord Rayleigh of the scattering of sound from small-scale inhomogeneities. In his development, Rayleigh (1945, Vol. II, p. 150) wrote down the expression for the D'Alembertian of the pressure

$$\Box^2 p\equiv\nabla^2 p-\frac{1}{c_0^2}\frac{\partial p}{\partial t^2} . \tag{41}$$

He then collected all other terms on the right-hand side of the equation. These included terms dependent on the relative inhomogeneities in the sound velocity $\Delta c/c_0$ and the density $\Delta\rho/\rho_0$ of the medium, as well as other nonlinear terms in the pressure and its derivatives. Since he was interested in the effectiveness of the inhomogeneities in scattering an incident sound beam, he neglected the higher-order terms not associated with the inhomogeneities, so that his equation took the form

$$\Box^2 p=-\frac{2\Delta c}{c_0}\frac{\partial^2 p_s}{\partial t^2}-\frac{\partial}{\partial y}\left(\frac{\Delta\rho}{\rho_0}\right)\frac{\partial p_s}{\partial y} , \tag{42}$$

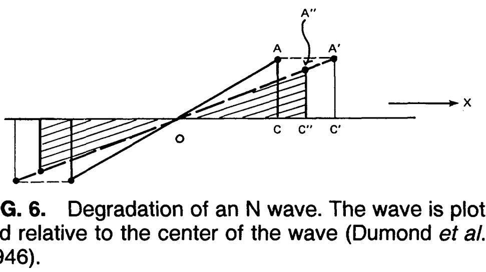

FIG. 6. Degradation of an N wave. The wave is plotted relative to the center of the wave (Dumond *et al.*, 1946).

where p_s is the pressure in the incident beam.

Lighthill's study began at this point. Since he was interested in the production of sound by turbulence, he started with the absence of an extended source (so that $p_s=0$); the terms kept by Rayleigh on the right-hand side of Eq. (42) disappear, while the terms that he neglected must now be considered.

In this analysis, Lighthill considered a fluctuating fluid flow that occupied a limited part of a large volume of fluid, the rest of which was at rest (Fig. 7). He then made a comparison between that system [Fig. 7(a)] and a similar one [Fig. 7(b)] whose density values were those appropriate to a uniform acoustic medium at rest. Outside the zone of low fluctuations, the two systems were therefore identical. Lighthill then stated that the difference between the systems was to be "considered as if it were the effect of a fluctuating external force field, known if the flow is known, acting in the said uniform acoustic medium at rest and hence radiating sound in it according to the ordinary laws of acoustics" (Lighthill, 1954, p. 564).

The momentum in a fixed region of space changes as a result of the combined effect of the stresses on its boundary and the momentum flow across that boundary. The boundary stresses are expressed by the Reynolds stresses $\rho v_i v_j$, while p_{ij} gives the real stress. Hence the contribution to the rate of momentum change in the shaded areas of Fig. 7(a) is of the form

$$T'_{ij}=p_{ij}+\rho v_i v_j. \tag{43}$$

A uniform acoustic medium at rest [Fig. 7(b)] would have stresses only in the form

$$T''_{ij}=\rho c_0^2 \delta_{ij}, \tag{44}$$

where δ_{ij} is the Kronecker delta; that is, only simple hydrostatic pressure would be present. The difference between these two terms then is the equivalent external stress acting on the uniform acoustic medium of Fig. 7(b):

$$T_{ij}=T'_{ij}-T''_{ij}=\rho v_i v_j+p_{ij}-\rho c_0^2 \delta_{ij}. \tag{45}$$

Under these conditions, the equation of motion then takes the form

$$\square^2 p=-\frac{\partial^2 T_{ij}}{\partial y_i \partial y_j}=c_0^2 \square^2 \rho=c_0^2 \nabla^2 \rho-\frac{\partial^2 \rho}{\partial t^2}. \tag{46}$$

This equation can also be written in terms of the density:

$$\nabla^2 \rho=-\frac{1}{c_0^2}\frac{\partial^2 \rho}{\partial t^2}=\frac{1}{c_0^2}\square^2 \rho=\frac{\partial^2 T_{ij}}{\partial x_i\, \partial x_j}. \tag{47}$$

The effect of viscosity on the processes involved here may be taken into account in the stress tensor p_{ij}. For a Stokesian gas (for which the bulk viscosity $\zeta=0$),

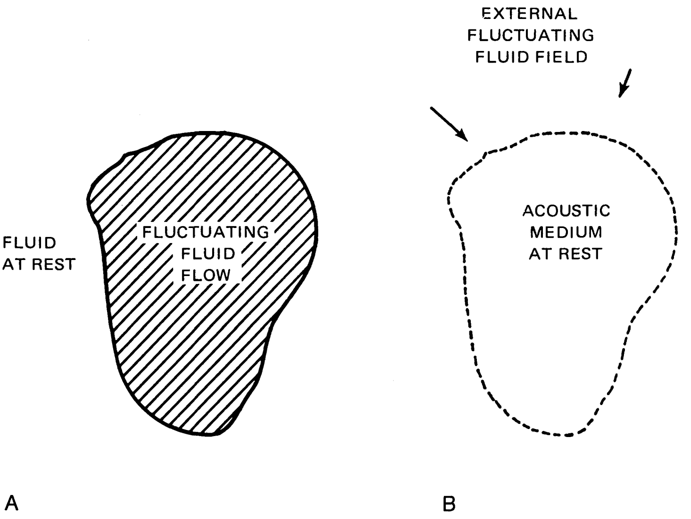

FIG. 7. (a) Lighthill concept of fluctuating fluid flow and (b) equivalent acoustic system.

$$p_{ij}=p_0\delta_{ij}+\eta\left[-\frac{\partial v_i}{\partial x_j}-\frac{\partial v_j}{\partial x_i}+\frac{2}{3}\left(\frac{\partial v_k}{\partial x_k}\right)\delta_{ij}\right], \qquad (48)$$

where η is the shear viscosity coefficient and p_0 is the equilibrium pressure.

Equation (46) together with Eq. (45) constitute the Lighthill equations. Equation (46) is a rather complicated one, but it can be reduced for the problems at hand. First, the stresses T_{ij} can be neglected outside the flow region. In such space, $v_i=0$, and one has only the motions of the medium due to the sound waves. Next, the viscous stresses in p_{ij} constitute small-scale absorption effects which can be neglected except for large-scale phenomena. And, finally, for low Mach numbers, T_{ij} can be approximated by $\rho_0 v_i v_j$.

The Lighthill equations have had great significance in the study of aerodynamic noise produced by turbulence (see Lighthill, 1978). Their application to nonlinear acoustics will be treated in Sec. 5.

3.5 Monopole, Dipole, and Quadrupole Sources

The following is a brief discussion of the mathematics of acoustic sources. The simplest possible sound is a small pulsating sphere whose radius varies sinusoidally with time ($u_s=u_0e^{i\omega t}$). By small is meant $ka\ll 1$, where a is the radius of the sphere and k is the wave number. In such a case the pressure at a distance r will be

$$p=i\omega\rho a^2\frac{u_0e^{i(\omega t-kr)}}{r}. \qquad (49)$$

We now define S as the *simple* or *point source strength.* It is equal to the amplitude of the volume rate of expansion the sphere, i.e., $S=4\pi a^2u_0$. Hence the pressure can be written as

$$p=\frac{i\omega\rho Se^{i(\omega t-kr)}}{4\pi r}. \qquad (50)$$

The variations of the density can be found from Eq. (50), since the excess pressure $p=c_0^2\Delta\rho$ or

$$\rho-\rho_0=\frac{i\omega\rho Se^{i(\omega t-kr)}}{4\pi c_0^2r}. \qquad (51)$$

Such a simple source is an example of a *monopole source.* Monopole sources usually involve the introduction of a new fluid into the source region (explosions or gas combustions), but they can also originate from the introduction of heat into a localized region (laser-induced sound) or from the presence of turbulence (pulsed jets).

If the source emits more generalized radiation than sinsuoidal, we may descreibe the density fluctuations, say, by the expression

$$\rho-\rho_0=\frac{1}{4\pi c_0^2}\frac{q'(t-r/c_0)}{r}. \qquad (52)$$

where q is the rate at which a point source adds mass to the medium, and $q'(z)=\partial q(x)/\partial z$.

In comparison with Eq. (51), $q[(t-r/c_0)]^{\cdot}$ has replaced $Se^{i(ut-kr)}$. For an extended distribution of sources of matter, we need to replace the point equation (46) by a volume integral, i.e., rewrite Eq. (46) as

$$\rho-\rho_0=\frac{1}{4\pi c_0^2}\int\frac{\partial}{\partial t}Q\left(\mathbf{R},t-\frac{|\mathbf{r}-\mathbf{R}|}{c_0}\right)\times\frac{dV_R}{|\mathbf{r}-\mathbf{R}|}, \qquad (53)$$

where $q\,dV_R$ is the time rate of mass production in the volume element dV_R marked out by the vector $\mathbf{R}$ (Fig. 8). The integration in Eq. (53) is over all space, but in practice is carried out only over the region in which there are sources. The quantity $q'(t)$ is called the *instantaneous strength* of the point source, and $\partial Q/\partial t$ is the (mass) *source strength per unit volume* or more briefly the (monopole) *source density.*

All the expressions for the density can be converted to pressure expressions by the linear relationship between pressure and density given in Sec. 1, i.e., $\Delta p=c_0^2\Delta\rho$.

While there are many monopole acoustic sources, in most physical situations the monopole strength vanishes, and attention

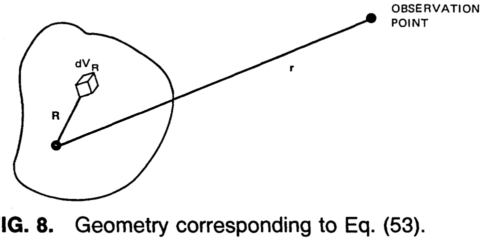

FIG. 8. Geometry corresponding to Eq. (53).

must be focused on the next higher level of sources: dipoles. If there are no matter sources, the sound is generated by a fluctuating force field F_i per unit volume in some part of the medium ($i=1,2,3$, corresponding to the vector components x,y,z). Such a force would appear as $-(\partial F_i/\partial x_i)$ on the right-hand side of Eq. (41). This force field would be equivalent to a source distribution with strength per unit volume equal to $-(\partial F_i/\partial x_i)$.

Paralleling the derivation of the monopole source, the density from such dipole sources can be obtained as

$$\rho-\rho_0=-\frac{1}{4\pi c_0^2}\frac{\partial}{\partial x_i}\int F_i\left(\mathbf{R},t-\frac{|\mathbf{r}-\mathbf{R}|}{c_0}\right)\times\frac{dV_R}{|\mathbf{r}-\mathbf{R}|}, \tag{54}$$

which, in the far field, takes the form

$$\rho-\rho_0\simeq\frac{1}{4\pi c_0^2}\int\frac{r_iR_i}{|\mathbf{r}-\mathbf{R}|^2}\frac{1}{c_0}\times\frac{\partial}{\partial t}F_i\left(\mathbf{R},\mathrm{t}-\frac{|\mathbf{r}-\mathbf{R}|}{c_0}\right)dV_R\,. \tag{55}$$

Thus the density changes at the point of interest depend on the time rate of change of the dipole strength F_i and are not due to simultaneous time changes in the local density, but depend on their time of arrival at the distant point.

While the fluctuating stresses T_{ij} in Eq. (41) produce a force per unit volume equal to their inward flux $-(\partial T_{ij}/\partial x_j)$, so that they generate like a dipole field of strength $-(\partial T_{ij}/\partial x_j)$ per unit volume, the sound radiated is not to be computed from the total dipole strength per unit volume, since this is, in fact, zero at any instant of time. Rather, the sound will come from the next higher order of terms; i.e., it will be the equivalent quadrupole field, a field that is the limiting case of four simple sources which obey the inverse square law of radiation. At large distances from the quadrupole producing the radiation, arguments similar to those above justify the approximation

$$\rho-\rho_0\cong\frac{1}{4\pi c_0^2}\int\frac{(R_i-r_i)(R_j-r_j)}{|\mathbf{R}-\mathbf{r}|^3}\times\frac{1}{c_0^2}\frac{\partial^2}{\partial t^2}T_{ij}\left(\mathbf{R},t-\frac{|\mathbf{r}-\mathbf{R}|}{c_0}\right)dV_R\,. \tag{56}$$

When the coordinate origin is within the flow region and the latter's dimensions are small compared with $\mathbf{r}$ (Fig. 8), we can disregard $\mathbf{R}$ and R_l in the difference terms of the integrand of Eq. (56), obtaining

$$\rho-\rho_0\cong\frac{1}{4\pi c_0^2}\frac{r_ir_j}{r^3}\times\int\frac{1}{c_0^2}\frac{\partial^2}{\partial t^2}T_{ij}\left(\mathbf{R},t-\frac{|\mathbf{r}-\mathbf{R}|t}{c_0}\right)dV_R. \tag{57}$$

Equation (57) has served as the starting point for the study of the interaction of two sound beams that will be described in Sec. 5.

4. RADIATION PRESSURE, STREAMING, AND CAVITATION

4.1 Radiation Pressure

In linear acoustics, the average pressure at a point due to a sound wave (which must be of infinitesimal amplitude in order that linearity prevail) must be equal to zero. The fact that there is a steady force associated with the passage of sound waves is evidence of finiteness of the waves and hence nonlinearity.

The situation is complicated by the fact that it becomes necessary to distinguish between the acoustic behavior of a fixed point in space (Eulerian coordinates) and the behavior of a point in the fluid that was originally at rest at some reference point (Lagrangian coordinates). Since the radiation pressure is the pressure measured at a surface which must be moving with the particles of the medium as they undergo oscillations, the Lagrangian representation is the more useful in calculating this pressure.

In addition, the literature discriminates between two definitions: the *Rayleigh radiation pressure*, defined as the difference between average pressure at a surface moving with the particle (i.e., the mean Lagrangian pressure), and the pressure that would have existed in the fluid of the same mean density at rest. For a gas, this quantity has the value $[(\gamma+1)/4]\langle E\rangle$, where $\langle E\rangle$ is the mean energy density in the sound wave. In the case of a liquid, the Rayleigh pressure is equal to $[(1+B/2A)/2]\langle E\rangle$.

The second definition is the *Langevin radiation pressure,* defined as the difference between the mean pressure (the Lagrangian pressure) at an absorbing or reflecting wall and in the same acoustic medium, at rest, behind the wall. This value is equal to $\langle E\rangle$.

The usual experimental setup leads to a radiation pressure of the Langevin type. While these pressures are relatively small, they are sufficient to produce instances of acoustic levitation of small particles and can also lead to the phenomenon of an acoustical fountain. Radiation pressure can be used as a measure of the intensity of a sound beam, since the mean intensity $\langle I\rangle$ is given by $\langle I\rangle = c\langle E\rangle$, where c is the speed of sound, and a sound-intensity meter has been developed on the basis of this principle. The measurement of the sound intensity can also be used for the determination of the sound absorption coefficient (Piercy and Lamb, 1954).

4.2 Acoustic Streaming

The flow of air in a strong sound beam was first observed by Faraday (1831), but the phenomenon came under more regular study only many years later. The eddies of air flow in a Kundt's tube, for example, were shown by Rayleigh (1883) to be due to this phenomenon. Analysis of streaming is carried out by expressing such variables as density, velocity, and temperature as series of zero-, first-, and second-order terms. Under such circumstances, the second-order vorticity $\mathbf{R}_2$ ($\mathbf{R}_2 = \nabla\times\mathbf{u}_2$, where $\mathbf{u}_2$ is the second-order displacement velocity) is given by (Medwin and Rudnick, 1953)

$$\Delta^2\mathbf{R}_2 = \frac{1}{\rho_0}\, b\, \Delta\rho_1 \times \Delta\, \frac{\partial\rho_1}{\partial\tau} - \frac{\rho_0}{\eta}\, \nabla\times(\mathbf{u}_1\times\mathbf{R}_1) - \frac{1}{\rho_0}\, \nabla\times(\rho_1\nabla\times\mathbf{R}_1). \qquad (58)$$

The first term on the right-hand side is due to Eckart (1948), the second to Rayleigh (1945, Vol. II, p. 333).

Solutions of this equation exist for special cases. In the case of a cylinder of liquid, the flow is similar to that shown schematically in Fig. 9. Figure 10 shows an experimental example of this streaming.

Since the Eckart streaming term depends on the quantity b [Eq. (27)], which is the basic constituent of the acoustic absorption coefficient, the amount of streaming depends directly on the acoustic absorption coefficient and can be used to measure this quantity.

4.3 Acoustically Induced Cavitation

The name cavitation applies to the phenomenon of the appearance of holes in liquids. This appearance is usually due to the stress of tensile forces of some kind. These latter may, in turn, be due to high-speed flow, the rapid motion of a solid (such as a propeller blade) through the liquid, or high-intensity sound. It is this last phenomenon that is of concern here.

Acoustical cavitation can be divided into two types. The first of these, called by various names such as gaseous cavitation or pseudocavitation, results from the growth of gaseous bubbles in the liquid during the pas-

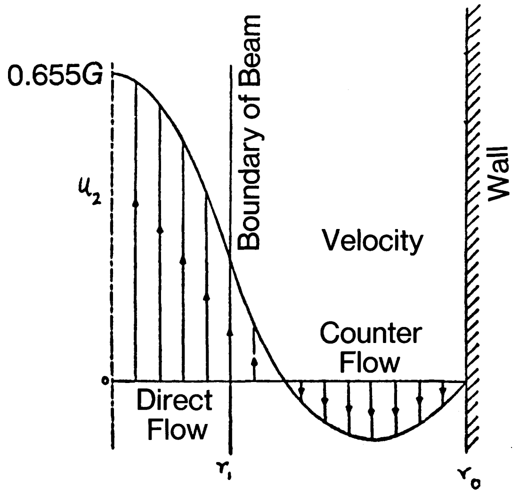

FIG. 9. Plot of theoretical value of streaming velocity as a function of radius r in a cylinder. (r_1 = radius of beam, r_0 = radius of cylinder. $r_1/r_0 = 1/3$, G is a parameter of the medium.) (Eckart, 1948.)

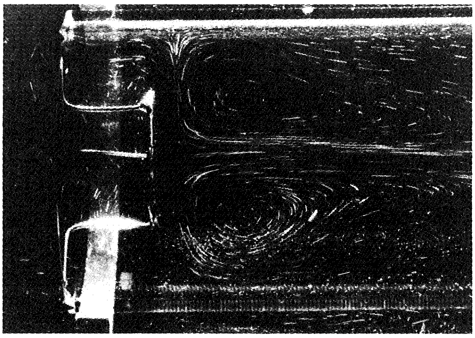

FIG. 10. Acoustic streaming from a sound source in water. The sound source is at the left center. The motion is made visible by a means of a suspension of finely divided aluminum particles (Liebermann, 1949).

sage of a sound wave, while the second, vapor cavitation, describes the appearance and growth of holes in a degassed liquid, where the only gaseous content is the vapor of the host liquid. Flynn (1965) has described these, respectively, as the stable bubble field and the transient bubble (or cavitation) field.

In the cavitation process, one sees a very small bubble that grows very rapidly and then collapses with a distinctive sound. What is not seen is how the tiny bubble came to be. Much of cavitation theory presumes the bubble was already there, clinging to some bit of impurity in the medium or created by the passage of some external radiation. Such analyses have led to an understanding of conditions under which a bubble will be stable in a liquid. A bubble of radius R will be stable if the pressure in the liquid p_0 is related to the pressure inside the bubble, p_i, by the equation

$$p_0=p_i-(2\sigma/R), \tag{59}$$

where σ is the surface tension of the liquid. In the case of vapor cavitation, $p_i=p_v$, the vapor pressure of the host liquid. Equation (59) indicates that the cavitation bubble will be stable only if the pressure in the liquid is lower than the vapor pressure by $2\sigma/r$, so that a very minute bubble would require enormous negative pressures to keep it stable. Such a bubble would dissolve itself rapidly if it were small and rise rapidly to the surface if it were large, being unstable in either case. Another possibility is the existence of a thin organic skin in the bubble, preventing solution of the entrapped gas in the surrounding liquid, and therefore giving greater stability to the minute bubble.

The dynamic behavior of bubbles has been studied extensively, and several equations have been developed to describe their behavior. In the Noltingk–Neppiras (1950, 1951) equation, the liquid is assumed to be incompressible, so that the analysis does not hold up in the stage of bubble collapse. The governing equation here is

$$\frac{dU}{dt}+\frac{3}{2}\frac{U^2}{R}=\frac{1}{\rho_{l_0}R}\left[\left(p_0+\frac{2\sigma}{R_0}\right)\left(\frac{R_0}{R}\right)^{3\Gamma}+p_v-\frac{2\sigma}{R}\right.$$
$$\left.-p_{l_0}+p_m\sin\omega t\right]. \tag{60}$$

In the Herring–Flynn (1941,1965) equation, compressibility of the liquid is taken roughly into account, but the results are not accurate if the rate of growth of the bubble $(U-dR/dt)$ is comparable with or large than the speed of sound. The Herring–Flynn equation is

$$\left(1-\frac{2U}{c_0}\right)\frac{dU}{dt}+\frac{3}{2}\left(1-\frac{4}{3}\frac{U}{c_0}\right)\frac{U^2}{R}$$
$$=\frac{1}{\rho_{l_0}R}\left[p_l(t)-p_\infty(t)+\frac{R}{c_0}\left(1-\frac{1}{c_0}U\right)\frac{dp_l}{dt}\right]. \tag{61}$$

Finally, there is the Kirkwood–Bethe equation (1942), developed for underwater explosions. This takes the form

$$\left(1-\frac{u}{c}\right)\frac{dU}{dt}+\frac{3}{2}\left(1-\frac{U}{3c}\right)\frac{U^2}{R}$$
$$=\left(1+\frac{U}{c}\right)H+\frac{U}{c}\left(1-\frac{U}{c}\right)\frac{dH}{dR}=0. \tag{62}$$

Here

$$H=\int_{p_\infty}^{p(R)}\frac{dp}{\rho}.$$

In the above equations, Γ is the effective specific-heat ratio, $p_\infty=p_{l_0}-p_m\sin\omega t$, R is the radius of the bubble, R_0 is the initial radius of the bubble, p_{l_0} and p_l are the pressure in the liquid at $R=R_0$ and $R=R_l$, p_v is the vapor pressure, $U=dR/dt$, σ is the surface tension, and p_m is the pressure amplitude of the sound wave of angular frequency.

The similarity of results from these various equations are indicated in the theoretical results shown in Fig. 11. The solid curve expresses in each case the behavior at 10 kH,

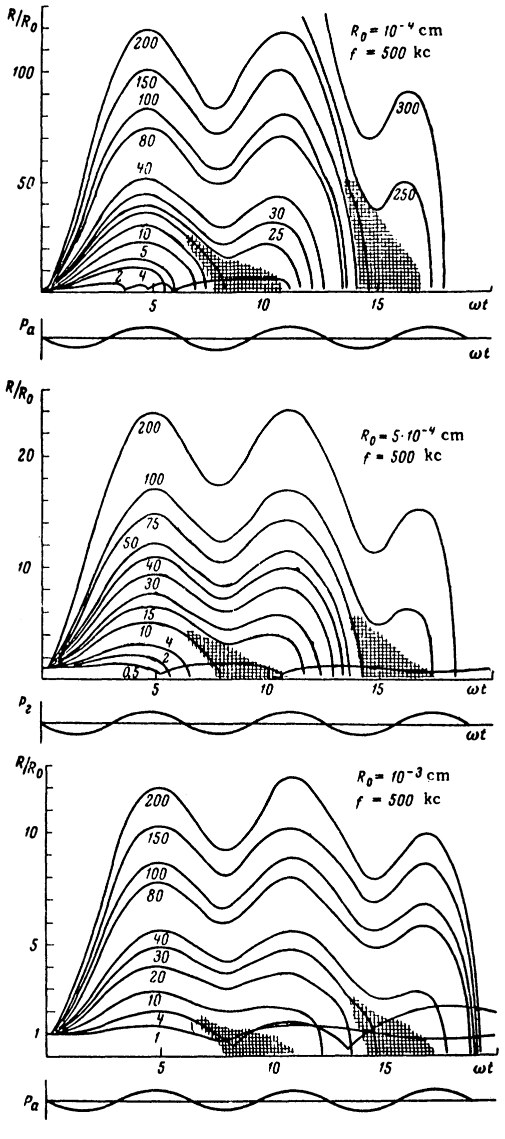

FIG. 11. Pulsation of cavitation bubble at 500 kHz for R_0 (initial bubble radius)$=10^{-4}$ cm. The numbers on the curves indicate the original sound-pressure amplitude in atmospheres. The sine wave at the bottom of the drawing indicates the sound signal (Akulichev, 1971).

while the broken curve indicates 500 kHz. The numbers on the individual curves indicate the value of the sound pressure p_m in atmospheres, while the sine wave at the bottom is the applied acoustic signal.

The threshold of vapor cavitation has been studied in a number of liquids. Galloway (1954) obtained the result that it takes a negative pressure of at least 200 atm to produce cavitation in degassed liquid, and this figure may still be low, for the existence of perfectly pure, degassed water is probably a fiction. To quote a worker in the field (Sirotyuk, 1971), "The production of absolutely pure water is impossible. One of the strongest of existing solvents, it dissolves the walls of the container, and on coming into contact with any gas, dissolves that gas."

Cavitation is also accompanied by the emission of visible radiation, which is called *sonoluminescence* (Kuttruff, 1962). It has been suggested that this light is due to the appearance of nonspherical bubbles in the cavitation which then develop positive and negative charges. These charges could then lead to an electrical microdischarge.

Such an explanation applies only to vapor cavitation, but the phenomenon has been observed in the case of gaseous cavitation also. Here the effect has been attributed to microshocks that develop in the process of bubble collapse. This would be the same phenomenon that produces luminescence in the case of cavitation bubbles produced by a continuous gas flow.

5. NONLINEAR INTERACTION OF SOUND WAVES

5.1 Two Intersecting Sound Beams in a Fluid

In a linear system, there can be no interaction of two intersecting sound beams. In line with the principle of superposition, the solution of two waves passing separately through a region will be equal to the solution of two waves passing simultaneously through the same region. No new terms will appear, and the interaction is therefore zero.

There is considerable evidence in support of the nonlinear interaction of two sound waves, but there still remains much disagreement on the basic governing relations. This stems from the fact that approximations or simplifications occur in every theory, and these may be sufficient to give erroneous results. Experimentally, the impossibility of obtaining two perfectly collimated beams, or of plane waves, raises the possibility that any interactions that are measured experimentally may be taking place on the face of the detecting instrument rather than in the "interaction region."

Ingard and Pridmore-Brown (1956) applied Lighthill's theory (Sec. 3) to the interaction of two perfectly collimated beams (Fig. 12) (frequencies ν_1, ν_2) and, neglecting viscous losses, obtained the following relation for the sum-frequency signal at a point outside the interaction region in the far field, defined by the radius r and angle θ:

$$p_+(r)=\frac{4\pi a^3}{\rho c_0^4}(\nu_1+\nu_2)^2\,\frac{p_1^{(I)}p_2^{(I)}}{r}$$

$$\times\left(\sin 2\theta+2\frac{B}{A}\right)\frac{\sin\alpha}{\alpha}\,\frac{\sin\beta}{\beta}. \tag{63}$$

B/A is the nonlinear parameter defined in Sec. 2, a is the radius of each source, and the angles α and β are defined by

$$\alpha=\frac{2\pi a}{c_0}[\nu_1-(\nu_1+\nu_2)\cos\theta],$$

$$\beta=-\frac{2\pi a}{c}[(\nu_1+\nu_2)\sin\theta-\nu_2].$$

These researchers performed experiments supporting these results, but their work has been criticized on the ground that the theory assumed perfect collimation of the beams, but the signals used in their experiments were relatively low, 10 and 100 kHz, so that there could be interaction of the two signals on the face of the microphone, wherever it was placed.

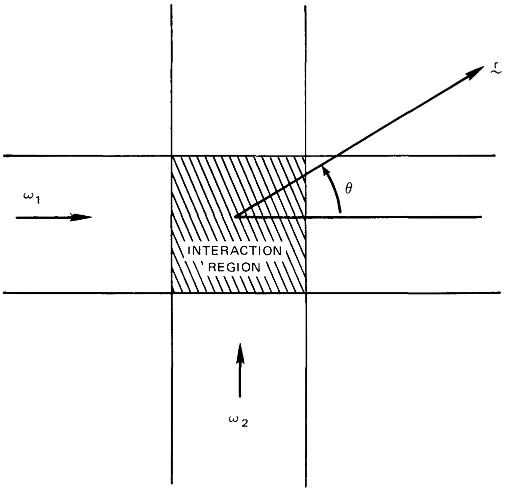

FIG. 12. Geometry for interaction of two crossed beams.

Westervelt (1957) used Lighthill's equation and deduced a relation for the lowest order in the scattering process:

$$\Box^2\rho_s=-\frac{1}{c_0^2}\frac{\partial^2}{\partial x_i\,\partial x_j}\left[\rho_0 u_i u_j+\frac{1}{2}\left(\frac{\partial^2 p}{\partial\rho^2}\right)_{\rho=\rho_0}\rho^2\delta_{ij}\right]. \tag{64}$$

Here $\Box^2$ is the D'Alembertian [Eq. (14)], and ρ_s is the density in scattered wave. Westervelt then recast Eq. (64) in the form for harmonic dependence of the initial waves:

$$\Box^2\rho_s=c_0^{-2}\Box^2E_{12}-\nabla^2(2T_{12}+qV_{12}), \tag{65}$$

where

$$T_{12}=\rho_0\mathbf{u}_1\cdot\mathbf{u}_2,\quad W_{12}=\left(\frac{c_0^2}{\rho_0\omega_1\omega_2}\right)\frac{\partial\rho_1}{\partial t}\,\frac{\partial\rho_2}{\partial t},$$

$$V_{12}=c_0^3\,\frac{\rho_1\rho_2}{\rho_0},\quad q=\frac{\rho_0}{c_0^2}\left(\frac{\partial^2 p}{\partial\rho^2}\right)_{\rho=\rho_0}, \tag{66}$$

$$E_{12}=T_{12}+V_{12},$$

$$\nabla^2V_{12}=\frac{1}{2}\,\frac{\omega_1^2+\omega_2^2}{\omega_1^2\omega_2^2}\,\Box^2W_{12}+\frac{1}{c_0^2}\,\frac{\partial^2T_{12}}{\partial t^2}.$$

In these relations ρ_1 and ρ_2 refer to the excess density in each of the primary beams, while T_{12}, V_{12}, and E_{12} are, respectively, the kinetic, potential, and total interaction energies.

For the case of two mutually perpendicular beams, considerable reduction takes place, and Eq. (65) becomes

$$\Box^2\rho_s=\Box^2\psi, \tag{67}$$

where

$$\psi=\frac{1}{c_0^2}\left[E_{12}-\frac{\rho_0}{2\omega_1\omega_2c_0^2}\left(\frac{\partial^2 p}{\partial\rho^2}\right)_{\rho=\rho_0}\nabla^2W_{12}\right]. \tag{68}$$

Westervelt concluded that $\rho_s = \psi$ is the complete solution of Eq. (61). Thus, if the two beams are perfectly collimated, W_{12} and E_{12} will vanish everywhere outside of the interaction region.

Westervelt's conclusions were challenged by Berktay (1969) who argued that the more general solution of Eq. (67) is

$$\rho_0=\psi+A, \tag{69}$$

where A is a homogeneous function satisfying the equation

$$\square^2 A=0. \tag{70}$$

On this basis, he obtained the following for the scattered pressure for the sum frequency $p_+(r)$ at distances that are large when compared with the interaction region:

$$p_+(r)=4\pi a^3 \frac{(\nu_1+\nu_2)^2}{\rho_0 c_0^4}\left(\frac{p_1(I)p_2(I)}{r}\right)\frac{B}{A} \times\frac{\sin\alpha}{\alpha}\,\frac{\sin\beta e^{-\alpha_+ r}}{\beta}, \tag{71}$$

which differs but slightly from the results of Ingard and Pridmore-Brown. A similar result was obtained by Zverev and Kalachev (1970).

5.1.1 Nondispersive and Dispersive Media. The disagreements regarding the interaction of two sound beams referred to above may be due to a failure to distinguish between two cases, nondispersive and dispersive media. In the first case, where there is no dependence of the sound velocity on frequency, the interaction of two noncollinear beams would appear to be impossible. But in the second case, there is substantial evidence that such interaction is possible at oblique angles between the beams. In particular, the use of bubbly media, where dispersion effects are very strong, makes possible a much larger interaction between two primary beams.

5.2 Two Collinear Sound Beams

In subsequent papers, Westervelt (1960, 1963) derived an expression for the interaction that would result if the two beams were collinear and perfectly collimated. He deduced an equation for the D'Alembertian of the scattered pressure for two such beams:

$$\square^2 p=-\rho_0\frac{\partial q}{\partial t}, \tag{72}$$

where

$$q=\frac{1}{\rho_0^2 c_0^4}\left(1+\frac{B}{2A}\right)\frac{\partial}{\partial t}p_i^2. \tag{73}$$

The quantity q is the simple source strength density resulting from the primary waves ρ. The solution to Eqs. (72) and (73) involves the appearance of two new components in the scattered signal, with frequencies equal to the sum and difference, respectively, of the two original frequencies.

For the case of two primary waves of the same pressure amplitude but different frequencies, Westervelt obtained the following expression for the scattered intensity in the far field (the geometry is shown in Fig. 13):

$$I_s=\frac{\omega_s^4\,P_0^4\,S_0^4(1+B/2A)^2}{2(8\pi)^2\rho_0^3\,c_0^9\,R_0^2}\,\frac{1}{\alpha^2+k_s^2\sin^4\theta/2}. \tag{74}$$

These latter results have been well confirmed experimentally (Bellin and Beyer, 1962).

One of the distinguishing characteristics of this interaction is the almost complete absence of sidelobes. The width of the main beam can be determined by Eq. (68).

5.3 Parametric Arrays

The success of the Westervelt collinear beam analysis, to which experimental arrangement he gave the name of "parametric array," has led to a large amount of research on the application of the array to the problems of transmission and reception of acoustic signals, especially in underwater sound. Of greatest interest has been work in the far field.

5.3.1 Far-Field Transmission. The following expression, due to Berktay (1965), describes the far field of a rectangular transducer radiating two beams of initial pressure amplitudes P_1 and P_2 (Fig. 14):

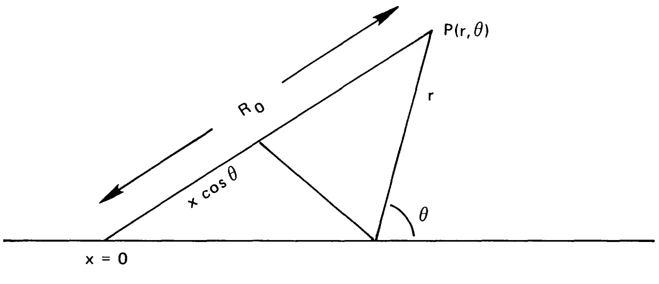

FIG. 13. Geometry for parametric array source.

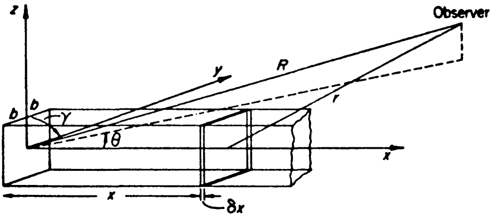

FIG. 14. Geometry for two collinear interacting sound beams traveling in the *x* direction (Berktay, 1965).

$$P_s=\frac{\beta P_1P_2S\omega_s^2\exp(-\alpha_s R)\psi(\gamma,0)}{4\pi\rho_0c_0^4R_0[A^2+4k_s^2\sin^2(\theta/2)]^{1/2}},\tag{75}$$

where

$$S=(2b)(2d),$$

$$A=\alpha_1+\alpha_2-\alpha_s\cos\theta,$$

$$\psi(\gamma,\theta)=\frac{\sin(dk_s\cos\gamma)}{dk_s\cos\gamma}\,\frac{\sin(bk_s\sin\gamma\sin\theta)}{bk_s\sin\theta\sin\gamma}.\tag{76}$$

A somewhat similar form can also be developed for the circular transducer. Experimental results indicate good agreement with the theory. Some typical experimental examples are shown in Fig. 15.

An important characteristic of the parametric array is the absence (or great reduction) of sidelobes. It is therefore useful as a search tool in situations where sidelobes on the beam can prevent accurate detection. This is especially the case in subbottom investigations in the shallow ocean (see Sec. 7).

5.3.2 Far-Field Reception. The parametric array can also be used as a receiving array in which an incoming wave interacts nonlinearly with a local sound source (the pump) and the scattered sum or difference frequency is detected. One such system is shown in Fig. 16 (Barnard *et al.*, 1972). The first-order field consisted of a spherical-wave source of angular frequency ω_1 and a plane-wave source of a lower frequency ω_2 ($\omega_1>\omega_2$). The spherical wave emanated from a baffled circular piston, and both sources were assumed to have harmonic time dependences. It is further assumed that (i) linear-field effects are disregarded; (ii) while absorption of the spherical wave is taken into account, the absorption in the plane wave is neglected; and (iii) the amplitudes of the primary waves are such that losses in the primary beams due to finite-amplitude effects can be neglected. The analysis began with the Westervelt equation for the scattered wave:

$$p_s(R_0,t)=-\frac{\rho_0}{4\pi}\int\frac{\partial q}{\partial t}\frac{\exp[i(k_s+i\alpha_s)]}{|\mathbf{R}_0-\mathbf{r}|}\times|\mathbf{R}_0-\mathbf{r}|\,dV,\tag{77}$$

where q is the source strength and the subscript s refers to quantities in the scattered wave. (The absorption factor was added to the Westervelt formula to take approximate account of the absorption of the secondary radiation.)

With $q=(\beta/\rho_0^2c_0^2)(\partial p_f^2/\partial t)$, where p_f is the first-order sound field p_f, the pressure p is given by

$$p_f=p_1\frac{r_0}{r}\left(\frac{2J_1(k_1a\sin\phi)}{k_1a\sin\phi}\right)e^{-\alpha_1 r}\cos(\omega_1t-k_1r)+p_2\cos(\omega_2t-k_2k),\tag{78}$$

and the scattered field becomes

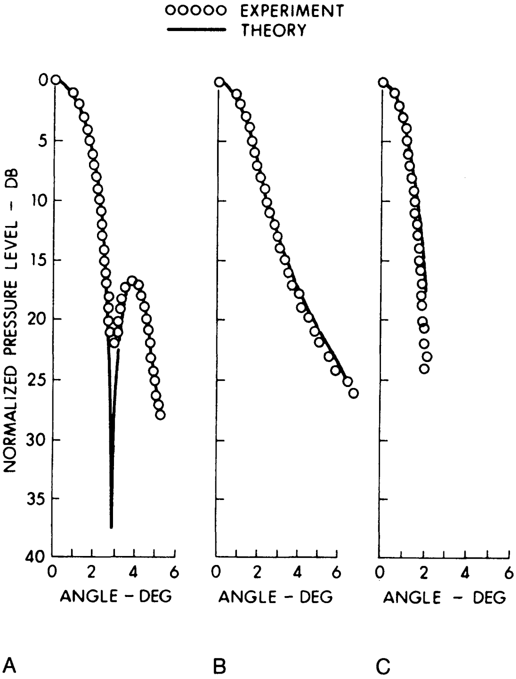

FIG. 15. Beam patterns for carrier and sum- and difference-frequency components in a transmitting array. (a) 482-kHz carrier; (b) 64-kHz difference-frequency radiation, and (c) 900-kHz sum-frequency radiation (Muir and Willette, 1972).

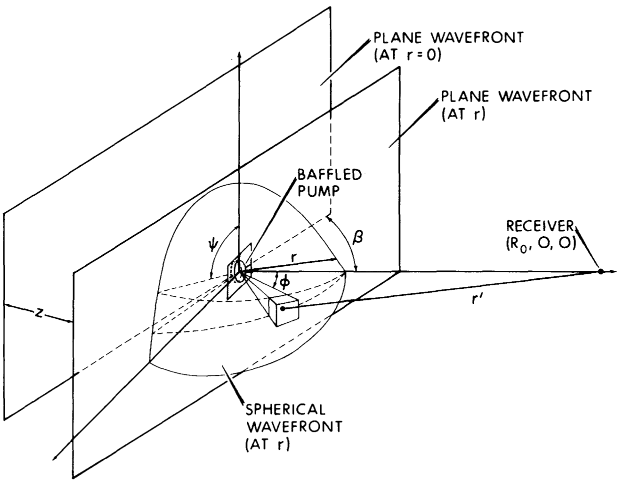

FIG. 16. Orientation of the plane- and spherical-wave primaries in the spherical coordinate system (r, ψ, φ) (Barnard *et al.*, 1972).

$$p_s \simeq \frac{\beta\omega_0^2 p_1 p_2 r_0}{2\rho_0 c_0^4 a k_1} \int_0^{R_0} \int_0^{\phi_{\text{eff}}} J(k_1 a \sin\theta) \times J_0(k_2 r \sin\theta \cos\gamma) \times \exp[i(k_1 \pm k_2 \sin\gamma \cos\theta + i\alpha_1) r] \times \frac{\exp[i(k_s + i\alpha_s) r]}{r'} \, r \, d\phi \, dr, \tag{79}$$

where $\omega = \omega_1 + \omega_2$ and the upper limit on the q integration, ϕ_{eff}, is the angle from the axis of the acoustic beam to the first zero of the pump far-field radiation pattern. Equation (79) has been solved numerically and the results tested experimentally for the sum frequency. Some results are shown in Fig. 17, while Fig. 18 shows a typical detection system.

6. NONLINEAR EFFECTS IN SOLIDS

6.1 The Scope of Nonlinear Behavior

In an ideally elastic medium, propagating waves are represented by functions that are solutions of the linear wave equation and therefore obey the principle of superposition. Even a very small-amplitude wave in a real solid, however, will only approximate this linear behavior. Fundamental nonlinearities are assumed to be negligible in order to derive the linear wave equation. It is a common occurrence, however, that elastic waves in solid do in fact interact with one another. Quantum mechanically, one can speak of phonon-phonon interactions. Such familiar phenomena as lattice thermal resistivity, thermal expansion, and the maintenance of an equilibrium distribution of thermal phonons are all possible only if the lattice waves behave in a nonlinear way. Thus much of nonlinear acoustical effects in solids is studied as a part of solid-state physics. Such subjects will not be treated here.

6.2 Third-Order Elastic Constants

The fundamental relations for strains in a solid are given by the strain tensor u_{ij}, whose components are

$$u_{ij} = \frac{1}{2}\left(\frac{\partial \xi_i}{\partial x_j} + \frac{\partial \xi_j}{\partial x_i} + \frac{\partial \xi_l}{\partial x_i}\frac{\partial \xi_l}{\partial x_j}\right). \tag{80}$$

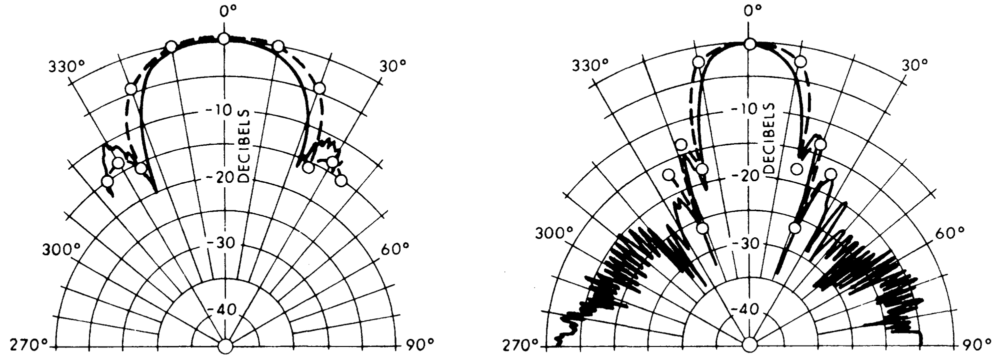
If one deals with small deformations only, the linear Hooke's law of elasticity applies; this can be written in tensor form as (summation convention is used)

$$T_{ij} = c_{ijkl} u_{kl}. \tag{81}$$

When the direction of propagation is a pure-mode direction, one longitudinal and two transverse polarizations exist. The particle displacements are either parallel or perpendicular to the propagation direction. In other, nonpure-mode directions, the branch with the greatest phase velocity is usually identified as the longitudinal branch.

The elastic potential energy of a solid is given by

$$V = \tfrac{1}{2} c_{ijkl} \epsilon_{ij} \, \epsilon_{kl}. \tag{82}$$



f_s = 91 kHz

EXPERIMENT: θ_{HP} = 10.5°
THEORY: θ_{HP} = 11.0°
SIGNAL FREQUENCY: 10 kHz

FIG. 17. Sum-frequency patterns for a pump-receiver separation of 48 ft. Theoretical values, broken lines with circles; experimental values, solid lines; F=90 kHz. P_1=101 dB *re*:1 μbar at 1 yd, and P_2=85 dB *re*:1 Mbar at input to parametric receiving array (Barnard *et al.*, 1972).

The quantities c_{ijkl} are commonly called the second-order elastic constants, for the reason that they appear in an expression that is second order in the strains. Nevertheless, they represent linear elastic phenomena. If we expand the internal energy $U(S,\xi)$ about the point of zero strain $\epsilon=0$ in the isentropic case, we obtain

$$\rho_0 U(S,\xi) - \rho_0 U(S,0) = \frac{1}{2!} c_{ijkl}\epsilon_{ij}\,\epsilon_{kl} + \frac{1}{3!} c_{ijklmn}\epsilon_{ij}\,\epsilon_{jk}\,\epsilon_{mn} + \cdots, \qquad (83)$$

where the third-order elastic constants are defined by

$$c^S_{ikl;\cdots} = \rho_0 \left(\frac{\partial^n U}{\partial\epsilon_{ij}\,\partial\epsilon_{kl}\cdots}\right)_S. \qquad (84)$$

[In the case in which Hooke's law is valid, only the first term on the right-hand side of Eq. (83) differs from zero, and the left-hand side becomes the elastic potential energy.] Because of inherent symmetries in crystal systems, it is possible to simplify the subscripts of the elastic constants. In particular, the six subscripts of the third-order constants can be

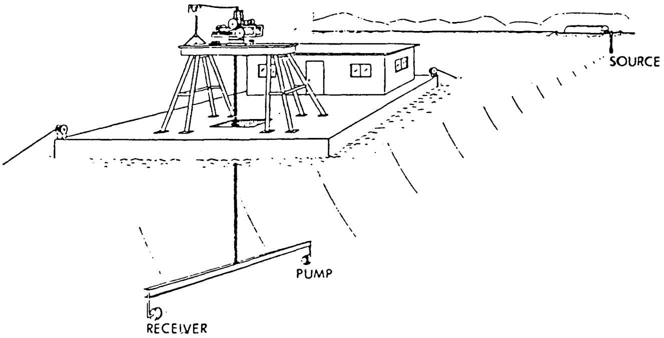

FIG. 18. Configuration for parametric reception. The source is located at some great distance, while the pump and receiver can be rotated for best reception (Barnard *et al.*, 1972).

reduced to three. In the case of a cubic crystal, there are three independent second-order constants and six independent third-order constants. If one is dealing with an isotropic solid, the representation is the same as for a cubic crystal, but with additional relationships that reduce the number of independent constants to two in the second-order constants and three in third order. Equation (83) then becomes

$$\begin{aligned}\rho_0 U(S,\xi)-\rho_0 U(S,0)\\ &=\tfrac{1}{2}c_{12}\epsilon_{ii}\,\epsilon_{jj}+c_{44}\epsilon_{ij}\,\epsilon_{ij}+\tfrac{1}{6}C_{123}\epsilon_{jj}\,\epsilon_{kk}\\ &\quad+C_{144}\epsilon_{jj}\,\epsilon_{ik}\,\epsilon_{ik}+\tfrac{4}{3}C_{456}\epsilon_{ik}\,\epsilon_{ij}\,\epsilon_{kj}\\ &\quad+\text{higher-order terms.} \qquad (85)\end{aligned}$$

Considerable attention has been paid to these third-order constants, and they have been evaluated for a large number of solids through the equation of motion

$$\frac{\partial^2 u}{\partial t^2}=\frac{1}{\rho_0}\frac{\partial^2 u}{\partial x^2}\left(K_2+(K_3+3K_2)\frac{\partial u}{\partial x}\right.$$
$$\left.+\ \text{higher-order terms}\right), \qquad (86)$$

where K_2 and K_3 are given in Table 3 for various crystalline directions.

Acoustic nonlinearities in solids are due mainly to two sources. First is the anharmonicity due to a departure of the medium from the simple linear behavior of Hooke's law, and the second is that of dislocation displacements. The first of these leads primarily to a small shift in the sound propagation velocity. The accurate measurement of this velocity therefore provides for the measurement of the third-order elastic constants.

The effect of dislocation displacements is associated with the point defects present in any crystal. A dislocation is a linear imperfection in a crystal. Such dislocations move under stress within a crystal, facilitating the propagation of lattice vibrations that are sound waves. The motion of the dislocation is hindered by the presence of point defects and by other dislocations. Internal stresses surrounding dislocations and point defects are both relieved by their interactions so that they tend to attract one another, causing the dislocations to be pinned at certain points.

In passing through a real crystal, a sound wave will be attenuated by interaction with the dislocations. The theory for such dislocation damping is based on the concept of the motion of dislocations between the two pin-

Table 3. Values of K_2 and K_3 for the [100], [110], and [111] directions.

Direction	K_2	K_3
[100]	C_{11}	C_{111}
[110]	$\dfrac{C_{11}+C_{12}+C_{14}}{2}$	$\dfrac{C_{111}+3C_{112}+12C_{166}}{4}$
[111]	$\dfrac{C_{11}+2C_{12}+4C_{44}}{3}$	$\dfrac{C_{111}+6C_{112}+12C_{144}+24C_{166}+2C_{123}+16C_{456}}{9}$

ning points as analogous to the motion of a vibrating string equal in length to the distance between the pinning points. The small-amplitude oscillations of such dislocation loops lead to an attenuation that has been well confirmed by experiment (see the work of Granato and Lücke, 1956).

As the amplitude of the oscillations becomes larger (Fig. 19), the dislocation loop will break away from many of the points, producing the bowing shown in the latter stages of the drawing. The results of the analysis of this phenomenon indicate that dislocation displacements can produce second harmonics that are comparable to those resulting from lattice inharmonicity, while the corresponding contribution to the third harmonic is enormously greater. Experimental investigation of the nonlinear behavior of dislocations is therefore most conveniently carried out by use of the third harmonic (Hikata and Elbaum, 1966).

6.3 Interaction of Sound with Sound

The phenomenon of the interaction of sound with sound also takes place in solids. A summary of possible interaction cases is shown in Table 4 (after Jones and Kobett, 1963). Many of these combinations have been confirmed experimentally.

6.4 Nonlinear Surface Waves

Surface waves on solids have been widely studied in acoustics. A typical transducer arrangement is shown in Fig. 20 (Kino and Matthew, 1971a; see also de Klerk, 1972). Detailed studies reveal that whenever the amplitudes of the surface waves become appreciable, nonlinear effects appear, paralleling those described for bulk waves. The nonlinear mixing of two waves of different frequency leads to combination waves (Luukala and Kino, 1971), while the correlation function of two signals can also be obtained (Quate and Thompson, 1970). Some applications are discussed in Sec. 7.

7. RECENT APPLICATIONS

7.1 General View

There are numerous applications of nonlinear acoustics to practical problems. Indeed, to some, the entire field of nonlinear acoustics is one of applied physics, and we have already mentioned a number of applications—for example, the use of the radiation pressure to measure the intensity of a sound. Below are given several more recent applications.

7.2 Radiation Pressure

The acoustic radiation pressure described in Sec. 4, though relatively small in comparison with the pressure amplitudes of intense sound waves, is sufficient to levitate small objects such as glass spheres and coins (Allen and Rudnick, 1947). An example of such levitation, using a high-intensity siren, is shown in Fig. 21 (Barmatz, 1982).

In an orbiting spacecraft, it is not possible to obtain a zero-gravity environment, but the acoustic radiation pressure can be used to establish and maintain such a situation. A three-dimensional, piezoelectrically controlled mechanism is shown in Fig. 22 (Wang *et al.*, 1974; Wang, 1986). The chamber is cubic. If the x-axis transducer excites the fundamental

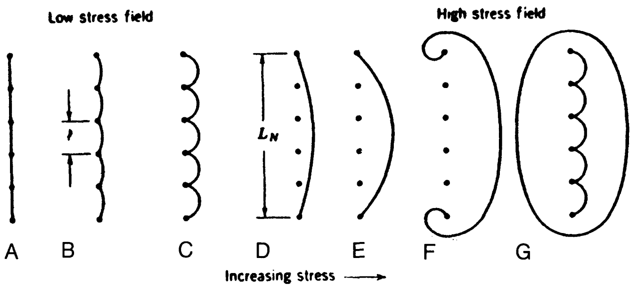

FIG. 19. Bowing out of a pinned dislocation line by an increasing applied stress. The loop length, determined by the impurity pinning, is l and the network length is L_N. At (d) the stress is large enough to cause the dislocation to break away from the impurity pinning sites (Granato and Lücke, 1956).

Table 4. Interaction cases which produce a scattered wave.[a]

Primary waves	Resonant wave type and frequency	Direction of scattered wave	$\cos\phi$ [b]	Frequency limits[c]
Two transverse	Longitudinal $(\omega_1+\omega_2)$	$\mathbf{k}_1+\mathbf{k}_2$	$c^2+\frac{(c^2-1)(a^2+1)}{2a}$	$\frac{1-c}{1+c}<a<\frac{1+c}{1-c}$
Two longitudinal	Transverse $(\omega_1-\omega_2)$	$\frac{\mathbf{k}_1-\mathbf{k}_2}{\omega_1-\omega_2}$	$\frac{c^2}{1}+\frac{(c^2-1)(a^2+1)}{2ac^2}$	$\frac{1-c}{1+c}<a<\frac{1+c}{1-c}$
One longitudinal and one transverse[d]	Longitudinal $(\omega_1+\omega_2)$	$\mathbf{k}_1+\mathbf{k}_2$	$c+\frac{a(c^2-1)}{2c}$	$0<a<\frac{2c}{(1-c)}$
One longitudinal and one transverse[d]	Longitudinal $(\omega_1-\omega_2)$	$\frac{\mathbf{k}_1-\mathbf{k}_2}{\omega_1-\omega_2}$	$c+\frac{a(1-c^2)}{2c}$	$0<a<\frac{2c}{(1+c)}$
One longitudinal and one transverse[d]	Transverse $(\omega_1-\omega_2)$	$\frac{\mathbf{k}_1-\mathbf{k}_2}{\omega_1-\omega_2}$	$\frac{1}{c}+\frac{(c^2-1)}{2ac}$	$\frac{1-c}{2}<a<\frac{1+c}{2}$

[a] From Jones and Kobett (1963).

[b] ϕ is the angle between $\mathbf{k}_1$ and $\mathbf{k}_2$ at resonance, a is the frequency ratio ω_2/ω_2, and c is the velocity ratio c_{tr}/c_{long}.

[c] When a is within the limits shown, it is possible to choose an angle ϕ that will give a scattered wave.

[d] The frequency of the longitudinal primary wave is ω_1.

acoustic resonance in the x direction, there would be a minimum radiation force in the x direction along the midplane. If the y-axis transducer excites the corresponding resonance in the y direction, the force minimum would be along the line of intersection of the two midplanes. By exciting the z-axis transducer, the particle could be constrained to the central point of the cube.

Such manipulations of the acoustic field make it possible to maintain a sample in the center of the cube without its being in contact with any support structure, so that containerless processing of materials becomes possible (Barmatz, 1982).

7.3 Parametric Array

The techniques described in Sec. 5 for parametric arrays have been applied in a number of ways in searching the bottom and

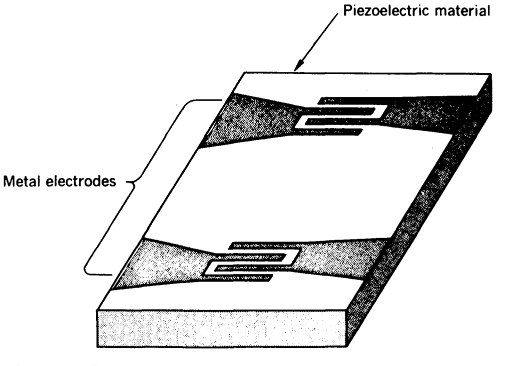

FIG. 20. Schematic representation of a typical piezoelectric surface-wave device with interdigital electrodes (Kino and Matthews, 1971).

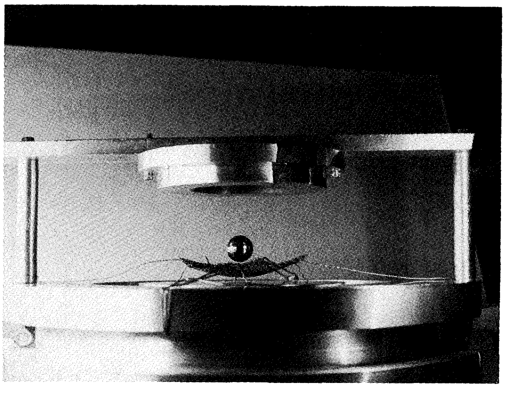

FIG. 21. Levitation of a steel ball in a ground-based siren. The diameter of the ball is 1.9 cm (Barmatz, 1982).

subbottom layers of relatively shallow waters. Detailed descriptions of a number of systems appear in Novikov *et al.* (1987). Figure 23 shows the use of a difference-frequency beam (with no sidelobes) observing the bottom of a portion of the Gulf of Riga (Novikov *et al.*, 1987). Figure 24 shows an object buried in the mud sludge on the bottom of the Semevskii Lake, as well as a stone falling in that sludge, while Fig. 25 shows the detection of fish schools swimming in shallow waters. In all these cases, the parametric array beam has the advantage of a narrow, single lobe and a low frequency, so that its absorption is not a serious problem. In the several applications described above, the operating difference frequency ranged from 10 to 50 kHz, with half-angle beamwidths of 3°–4°.

7.4. Lithotripsy

An important recent application of shock waves (Sec. 3) has been in the field of lithotripsy, i.e., the use of focused shock waves to break up kidney and other stones embedded in body organs. The procedure for breaking up gallstones is shown in Fig. 26 (Sauerbrach *et al.*, 1986). Spark-produced shock pulses are focused by an ellipsoidal system into a patient in a water bath. The conditions within the gallbladder are monitored by acoustic imaging or, alternatively, by means of x rays. Similar systems have been used for kidney stones (Coleman *et al.*, 1987). In more refined systems, the shock pulses are generated electromechanically and focused by means of an

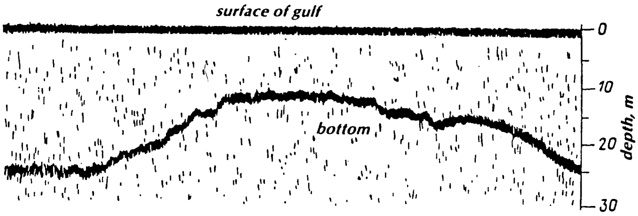

FIG. 23. Echogram of the bottom profile of a region of the Gulf of Riga, obtained by use of a parametric array system (Novikov *et al.*, 1987).

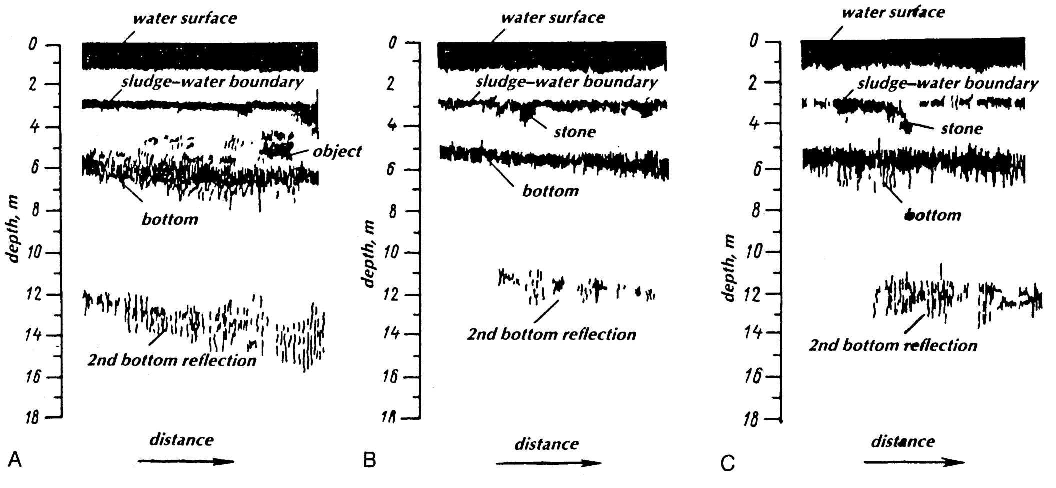

FIG. 24. Echograms of the bottom of Semevskii Lake, showing reflections from (a) a buried object, and (b), (c) a stone in different stages of sinking. The echograms were obtained with a parametric array system (Novikov *et al.*, 1987).

acoustic lens. Piezoelectric elements on a concave spherical shell have also been used and the need for a water bath eliminated (Crum *et al.*, 1989).

In these systems, the pressure signal that impinges on the stone consists of a positive pulse of about 1 μs in length, followed by a longer, negative trough (5–10 μs duration). The amplitude of a pulse may be as high as 100 MPa for the positive section, while the negative section reaches up to no more than 5 MPa. In a typical procedure, 1500 pulses will be directed on the stone.

7.5 *B/A* in Biological Tissues

Another biological application can be found in recent detailed studies of the nonlinear parameter *B/A* (Sec. 2) in biological tissues. Recently, Zhang and Dunn (1987) have measured *B/A in vitro* and *in vivo* for cat livers by measurement of the second-harmonic production, as suggested in Sec. 2. A typical setup is shown in Fig. 27. Their preliminary results suggest that there exists no significant difference in the two sets of measurements, which should open up the future for studies of tissue characterization by measurement of *B/A in vitro.*

Extensive measurements have been made on a variety of human tissues *in vitro*, using the thermodynamic method described in Sec. 2 (Errabolu *et al.*, 1988). A small but definite difference was noted by this same group (Seghal *et al.*, 1984) in the nonlinear parameter *B/A* in cancerous human liver tissues, so that evaluation of *B/A* in tissue samples may prove to be of diagnostic value, although the evidence so far is rather slight.

7.6 Surface Acoustic Waves (SAW)

The principal application of nonlinear SAWs (Sec. 6) is in its use as a convolver of two signals. The principle is illustrated in Fig.

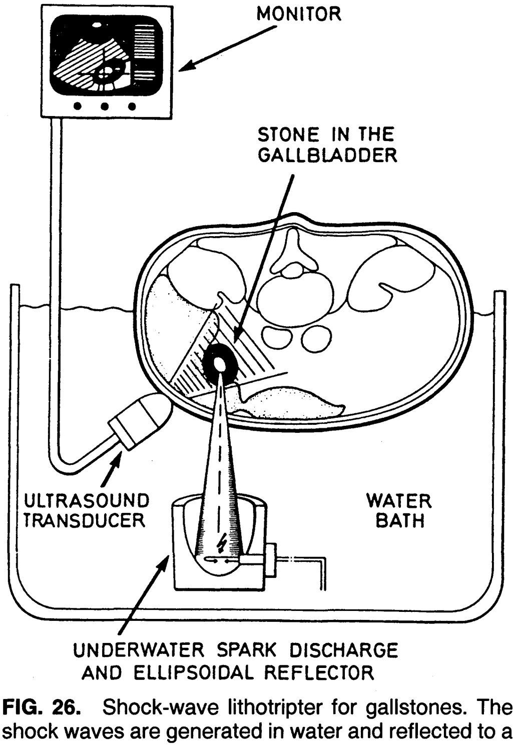

FIG. 26. Shock-wave lithotripter for gallstones. The shock waves are generated in water and reflected to a focal point where the stone has been positioned (Sauerbruch *et al.*, 1986).

28 (Grassl *et al.*, 1987). Two SAWs are introduced onto a piezoelectric substrate by means of two interdigital transducers: the signal $s(t)$ and the reference $r(t)$. The two waves interact as described in Sec. 6, and the resultant signal $c(t)$ is detected by a third transducer. Analysis shows that the linear signals and the quadratic terms from each of the two original signals make a negligible contribution to the detecting transducer, but that the cross term remains. This term can be written in the form

$$c(t/2+T_d/2)=C_{\mathrm{NL}} + \int_{(t-T_i)/2}^{(t+T_i)/2} s(t-\tau)r(\tau)d\tau, \qquad (87)$$

where T_d, T_i, L, and L_i are defined in the figure, v is the velocity of the surface wave, and C_{NL} is a constant of integration. The integral is recognized as the convolution of the two signals.

The nonlinearity can be produced by interaction of the wave fields with free charge carriers in semiconductor substrates, in which case the system is called an acoustoelectric convolver. The nonlinearity can also be produced by taking advantage of the nonlinearity of the piezoelectric substrate. This is the so-called elastic convolver. The operation of an elastic convolver is shown in Fig. 29. The two parallel paths are used to suppress reflections at the transducers: The transducers are connected acoustically in phase at one end and with opposite phase at the other, so that the electrical responses in the connected transducers cancel. More recently, small-aperture, focusing chirp transducers have been employed. These have enough degrees of freedom so that the transfer function can be shaped to compensate for various distortions in the system. A sample of such transducers is shown in Fig. 30.

GLOSSARY

Acoustic Cavitation: The creation of holes (or gas bubbles) in a liquid, produced by the passage of intensesound waves.

Acoustic Mach Number: The ratio of the particle displacement velocity in a sound wave to the local sound velocity.

Acoustic Particle: A hypothetic small volume in a fluid, considered as a homogeneous medium, and subject to the forces that give rise to sound waves.

Acoustic Streaming (also called Quartz Wind and Hydrodynamic Flow): The one-directional flow of a fluid produced by the passage of a sound wave in it.

Aeolian Harp: An ancient musical instrument involving loose strings that can be driven by the flow of air past them.

Ballou's Rule: Empirical formula [Eq. (23)] connecting values of B/A with the sound velocity.

Burgers' Equation: An approximate equation [Eq. (18)] describing wave motions in a coordinate system that travels with the speed of sound.

Collimated Beam: A beam in which none of the radiation escapes from a limited, axial and near-axial region.

Convolution Integral: The integral of the product of two functions varying in the manner prescribed by Eq. (87).

Dipole Source: Source in which the monopole sources vanish, but positive and negative fluctuations within the system lead to sound radiation. Force field is equivalent to a distribution of dipole sources.

Discontinuity Distance: The distance from the source at which the steepness of the wave front becomes negatively infinite at the point at which the displacement velocity is zero.

Displacement Velocity: The time rate of change of the position of an acoustic particle in a sound wave.

Eulerian Coordinates: The system of coordinates in which one follows the behavior of the medium at a fixed point in the medium.

Far Field: Points in the sound field whose distance from the source is greater than the square of the size of the source divided by the wavelength. It is equivalent to the region where Fraunhofer diffraction prevails.

Fubini Solution: Explicit solution of the Earnshaw equation for propagation of finite-amplitude waves in a nondissipative medium.

Goldberg Number: Ratio of the extinction distance (reciprocal of the absorption coefficient) to the discontinuity distance in a finite-amplitude wave.

Herring–Flynn Equation: Equation describing bubble oscillations in an acoustic field in which the compressibility of the liquid is taken roughly into account.

In Vitro: Measurements on biological materials made outside the living organism.

In Vivo: Measurements on biological materials under natural conditions in the living organism.

Khokhlov–Zabolotskaya (KZ) Equation: Modification of Burgers' equation, taking diffraction effects into account.

Khokhlov–Zabolotskaya–Kuznetsov (KZK) Equation [Eq. (22)]: Modification of Burgers' equation, taking both diffraction and dissipation into account.

Kundt's Tube: A historic piece of apparatus, consisting of a glass tube, plugged at its ends, with an axial centered metal rod. The rod is excited by stroking to produce sound, and dry dust particles placed in the tube will be moved to accumulate at the nodes of the resulting standing waves.

Lagrangian Coordinates: The system of coordinates in which one follows the behavior of the medium at a point in the medium that was initially at rest at the point x.

Lagrangian Radiation Pressure: The difference between the mean pressure at an absorbing or reflecting wall and the pressure in the same acoustic medium at rest, behind the wall.

Levitation: The raising of an object against the pull of gravity.

Lighthill Equations: Equations of motion [Eqs. (39)- (42)] in which the fluctuating fluid flow in a small part of a system is used as the forcing term, determining the wave field throughout the system.

Monopole Source: Source of acoustic radiation that consists of an oscillating spherical surface. System involves matter sources.

N Waves: Finite-amplitude waves in which the wave profile (particle velocity versus time) resembles the letter N.

Near Field: Points in the sound field where the distance from the source is less than the square of the size of the source divided by the wavelength. It is equivalent to the region in which Fresnel diffraction prevails.

Noltingk–Neppiras Equation: Equation describing bubble oscillations in an acoustic field, in which the liquid is assumed to be incompressible.

Nonlinearity Coefficient β: The coefficient of correction terms when nonlinearity is taken into account:

$$\beta=1+\rho_0\left(\frac{\partial^2 p}{\partial\rho^2}\right)\bigg/2\left(\frac{\partial p}{\partial\rho}\right),$$

where the derivatives are taken at constant entropy and infinitesimal amplitude.

Parameter of Nonlinearity, B/A: The ratio of the coefficients of the quadratic to the linear term in the expansion of pressure changes in a power series of the density changes.

Parametric Array, Endfire: The interaction of two collinear finite-amplitude sound beams to produce a beam at the difference position.

Point Defect: A local irregularity in a crystal, viz., a vacancy (missing atom), a foreign atom (impurity), or an atom in an irregular position.

Quadrupole Source: Source in which both monopole and dipole sources vanish, but the fluctuations of pressure within the system can be equivalent to a distribution of quadrupoles.

Radiation Pressure: The time-independent pressure at a point resulting from the passage of a sound wave.

Rankine–Hugoniot Equation [Eq. (24)]: Fundamental equation of fluid motion, connecting the properties of the fluid ahead of a shock with those behind the shock.

Rayleigh Radiation Pressure: The difference between the average pressure at a surface and the pressure that would have existed in the fluid of the same density at rest.

Sonoluminescence: The emission of visible radiation during acoustic cavitation.

Sound-Pressure Level (SPL): Logarithmic scale of measuring sound pressure relative to a specified level:

$$\text{SPL}=20\ \log(p/p_0),$$

where p is the amplitude of the observed pressure, and p_0 is an arbitrarily chosen reference level, usually taken to be equal to 20 μPa.

Viscosity Number b: The ratio of the total viscosity effect in a material to the shear viscosity, as defined in Eq. (21). It is often generalized to include the effects of thermal conduction as in Eq. (27).

Vortex Shedding: When air flows past a solid edge, as in an airfoil or the reed of a musical instrument, small eddies or vortices appear at the edge and detach themselves from it, being carried away by the fluid flow.

INTRODUCTION

The sense of hearing of mammals is a marvelous achievement of biological evolution. Even when considered as merely a physical sensor, the ear's capabilities are tremendous: humans can detect sounds at levels at which air particle displacements are as small as 1 pm, approximately equivalent to 1/100 of the radius of a hydrogen atom. The highest attainment of the sense of hearing arguably consists of carrying out psychoacoustical tasks, such as pitch perception and intensity discrimination, that ultimately permit speech communication among humans. A description of these psychoacoustical tasks is provided in the companion article, ACOUSTICS, PSYCHOLOGICAL.

The present chapter sketches the physiology of the auditory system, the physical basis of the hearing sensation. The auditory system consists fundamentally of three components: (1) the auditory sensory organ, the cochlea or inner ear, which, aided by the external ear and the middle ear, transduces and encodes the acoustic signal into electrical pulse trains in the peripheral terminals of the cochlear nerve; (2) the auditory or cochlear nerve, which conveys the electrical pulse trains to the brain; and (3) the auditory regions of the brain. Whether from a numerical standpoint, or from an assessment of organizational complexity, it is clear that it is in the auditory centers of the brain where "hearing" emerges out of the extremely intricate interactions of many millions of neurons. Because of their complexity, our understanding of central auditory mechanisms lags our knowledge of peripheral auditory physiology. Therefore, the present account of physiological acoustics places greater emphasis on peripheral processes than will likely be the case in future editions of this encyclopedia.

We begin our account of physiological acoustics with an overview of the peripheral auditory system (Sec. 1), before proceeding to more detailed accounts of the auditory nerve (Sec. 2), the external and middle ears (Sec. 3), and the cochlea (Sec. 4). Rather than systematically following the acoustic signal and its transformations from the environment toward the brain, we shall start with a description of the activity of the auditory nerve. This is justified on the grounds that the responses to sound of cochlear neurons are quite well known in comparison with the mechanical, electrical, and chemical processes of the cochlea that give rise to these neural responses. A coherent description of the neural code used by the auditory nerve to transmit acoustic information (Sec. 2) provides a convenient foundation for the subsequent exploration of how the encoding results from acoustical and mechanical transformations in the external and middle ears (Sec. 3), and from mechanoelectrical transduction in the cochlea (Sec. 4). In the final sections of the chapter we discuss what is known about how the brain channels and transforms the acoustic information received from the auditory nerve.

1. OVERVIEW OF THE PERIPHERAL AUDITORY SYSTEM

Figure 1 presents a block diagram of the peripheral auditory system. The arrows indicate the direction of signal transmission. The traditional view of the auditory periphery, current until less than a decade ago, was that the path of signal transmission and transduction proceeded steadily from the periphery

FIG. 1. A block diagram of the organization of the peripheral auditory system. Blocks are arranged from peripheral (i.e., closer to the environment, left) to central (i.e., closer to the brain, right). Arrows indicate the direction of signal transmission. Inner hair cells and outer hair cells are represented by the blocks labeled "IHC" and "OHC," respectively. The two types of cochlear afferent neurons are indicated by the blocks labeled "Type I" and "Type II." As the (initially, acoustic) signal proceeds inward from the periphery, it is successively transformed into mechanical vibrations of the middle ear, pressure fluctuations in the cochlear fluids, and displacements of the basilar membrane. Mechanical-to-electrical transduction takes place in the hair cells, whose deformation generates intracellular voltage analogs of the acoustic stimulus; these in turn cause chemical transmitter release at the hair cell basal surface, leading to the initiation of all-or-none impulses in the peripheral endings of the cochlear afferents. The neural impulses propagate along the axons of the auditory nerve toward the cochlear nucleus.

inward to the auditory central nervous system (with two exceptions, the olivocochlear efferents, which travel in the auditory nerve from the brain to the cochlea, and the efferents to the middle ear muscles). Thus, proceeding from left to right in Fig. 1: sound impinges upon the external ear and the eardrum, setting in motion tiny bones in the middle ear; these, in turn, create pressure fluctuations in the largely fluid-filled cochlea (inner ear), causing a slow displacement wave to propagate along the basilar membrane. The displacement of the basilar membrane stimulates cellular transducers, the inner and outer hair cells (IHCs and OHCs), to generate, much like tiny microphones, electrical receptor potentials that mimic the acoustic stimulus. Finally, these receptor potentials produce chemically mediated excitation in the peripheral terminals of cochlear afferent neurons, generating trains of electrical pulses (action potentials) which travel, via the auditory nerve, to the cochlear nucleus, the first station of the auditory central nervous system.

Note that at several stages of the auditory periphery (Fig. 1) signal transmission proceeds not only inward, in accordance with the traditional view, but also outward toward the environment. At the external ear the arrows signify that not only is sound conveyed from the environment into the middle ear, but also middle ear vibrations can broadcast sound into the environment. The discovery that the ear, in addition to serving as a passive receiver and transducer, can also act as an active generator of sound has contributed to a recent revolution in our understanding of cochlear physiology.

While the external ear and the middle ear are each represented in Fig. 1 as single, undivided boxes, the cochlea, auditory nerve, and cochlear nucleus are represented as being subdivided into segments numbered from 1 through N. These subdivisions represent the property of tonotopicity, i.e., the systematic mapping of frequency into space. Tonotopicity, ubiquitous throughout the auditory central nervous system, has its origin in the inner ear, where the basilar membrane, cochlear fluids, and sensory cells jointly perform a mechanical frequency analysis whereby waves of basilar membrane displacement resulting from low-frequency stimulation travel the length of the cochlea and peak toward its apex, while waves evoked by higher-frequency stimuli reach a peak toward the cochlear base and do not propagate farther. This mechanical frequency analysis causes the longitudinal array of hair cells to be stimulated by a spatial representation of the audible frequency spectrum. Thus, adjacent segments of the basilar membrane and, as a result, the hair cells on each segment and their associated cochlear afferents are tuned to slightly different frequencies. The inner ear may therefore be viewed as analogous to a bank of bandpass filters connected to long-distance signal transmission lines. These, the thousands of cochlear neurons and their axons, encode in their trains of action potentials all the information that, after processing by the many millions of neurons in the auditory central nervous system, make up the auditory experience.

Whenever possible, the ensuing account of peripheral auditory physiology will use the chinchilla as a representative mammalian species. Focusing on a single species makes it simpler to follow the acoustic-signal transformations from one stage of the peripheral auditory apparatus to another. The chinchilla has been chosen here as a counterpoint to reviews that have emphasized data for cats and guinea pigs, the other mammalian species whose ears and auditory nerves have been intensively studied.

2. THE OUTPUT OF THE COCHLEA: AUDITORY NERVE ACTIVITY

The axons of cochlear afferent neurons, whose cell bodies reside in the spiral ganglion of the cochlea, make up the bulk of the auditory (or cochlear) nerve [Figs. 1, 10, 13(a), and 13(b)]. There are two types of cochlear neurons, Type I and Type II, both of which carry signals from hair cells to the cochlear nucleus, where they terminate (Fig. 1; Spoendlin, 1988). Type I neurons, each of which innervates a single inner hair cell, constitute the vast majority of cochlear afferents (90% out of a total of about 30 000 neurons in chinchillas; Bohne *et al.*, 1982, and Ruggero *et al.*, 1982); each Type II neuron, on the other hand, innervates many outer hair cells. While nothing is known about what information Type II neurons transmit or what role they play in hearing, a great deal is known about the responses to sound of Type I neurons (reviewed by Kiang, 1984, and Pickles, 1988).

2.1 Spontaneous Activity

Like most neurons, Type I cochlear afferents transmit information by modulating the instantaneous frequency of occurrence of all-or-none electrical pulses (action potentials or "spikes") that travel nondecrementally along their cablelike axons at speeds of tens of m/s. These action potentials can be recorded by placing a microelectrode (usually a glass pipette with a tip smaller than 1 μm, filled with a conductive fluid) in the trunk of the auditory nerve near its exit from the cochlea, between the modiolus and the cochlear nucleus [Figs. 1, 10, and 13(a)]. Examples of oscillographic records of action potential trains may be seen in Fig. 6. In the absence of sound, cochlear afferents are nevertheless active, generating action potentials at average rates ranging from less than 1/s to 140/s. The distribution of rates of spontaneous activity across the population of cochlear Type I afferents is bimodal, with a substantial proportion of neurons being spontaneously active at rates less than 10/s and the remainder having higher, widely distributed rates, with a second mode around 60/s (Liberman, 1978; Dallos and Harris, 1978). The time of occurrence of each action potential is highly random: the distribution of interspike intervals closely resembles a Poisson distribution, except for the absence of intervals shorter than 0.7 ms (due to the period of inexcitability, the "refractory period," following each action potential).

2.2 Responses to Single Tones

2.2.1 Frequency-Domain Description. When effectively stimulated by sound, cochlear afferents increase their rate of discharge. At low intensities, such rate increases are evoked only by a narrow range of stimulus frequencies. The locus of intensity–frequency combinations for single tones that cause a just-measurable increase in firing above spontaneous rate is known as the frequency-threshold tuning curve, often abbreviated to "tuning curve" (Fig. 2). The tonal frequency at which responses are elicited at the lowest intensity is called the "characteristic frequency" (CF). The CF is a fundamental property of each cochlear afferent which provides accurate information about the cochlear location of the hair cell innervated by that afferent: there is a one-to-one CF-to-space mapping in the cochlea, such that high-CF cochlear afferents (i.e., those preferentially tuned to high frequencies) innervate inner hair cells at the basal end of the cochlea, while low-CF cochlear afferents innervate inner hair cells at the cochlear apex (see dual scale in abscissa of Fig. 8).

Figure 2 shows that the shapes of tuning curves change systematically as a function of CF. The tuning curves of high-CF cochlear afferents have very steep (e.g., 300 dB/octave) high-frequency slopes. The low-frequency sides of these tuning curves have two distinct segments. One segment has a relatively steep slope and extends from the tuning-curve tip to 40–70 dB above the CF threshold; the second, lowest frequency, segment has a relatively shallow slope. Tuning curves of cochlear afferents with lower CFs are broader and more symmetrical. A common measure of frequency tuning, adapted by auditory physiologists from the "quality factor" (Q_3) used by electrical engineers, is the Q_{10}, defined as the CF divided by the bandwidth at 10 dB above CF threshold. In the chinchilla auditory nerve, Q_{10}'s vary from 1 at CFs around 150 Hz to 7 at CFs close to 16 kHz (Dallos and Harris, 1978). Because of the strict CF-to-cochlear location correspondence, the brain could extract frequency information on the basis of the site of origin of excited neurons. This place code would be most precise at low stimulus levels and would become less specific for intense stimuli, which excite a widely distributed population of cochlear afferents.

There is a clear relationship between the rate of spontaneous activity of cochlear afferents and their thresholds at CF. High-spontaneous-rate afferents have the lowest thresholds, which, for a given CF, do not vary by more that 10 dB. The CF thresholds of low-spontaneous-rate afferents are substantially higher and more variable. In chinchillas, the lowest CF thresholds (10–20 dB SPL) are those of high-spontaneous-rate afferents with CF between 500 Hz and 8 kHz. When CF thresholds are plotted as a function of frequency, they describe a function which is roughly parallel to the behavioral audiogram for a particular species (Fig. 2). Afferents innervating inner hair cells at the extremes of

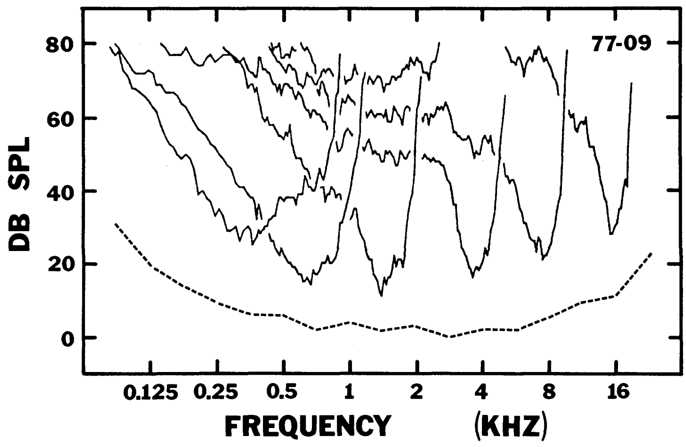

FIG. 2. Representative frequency-threshold tuning curves for cochlear afferents recorded from one chinchilla auditory nerve. Each tuning curve indicates the locus of frequency/intensity stimulus combinations that elicited a discharge rate just exceeding spontaneous activity. (Unpublished neural data of M. A. Ruggero.) Also shown (dashed line) is the behavioral audiogram for normal-hearing chinchillas, according to Miller (1970).

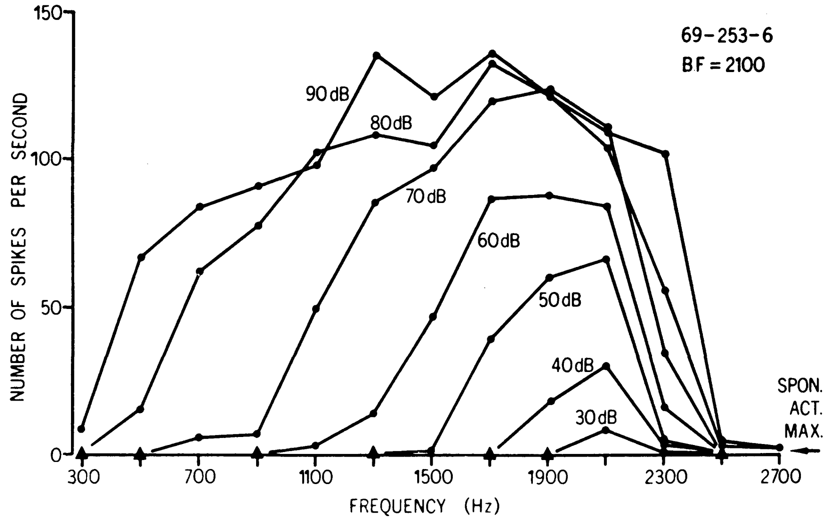

FIG. 3. Responses to tones, as a function of stimulus frequency and intensity, of a cochlear neuron in the squirrel monkey. The abscissa indicates the stimulus fundamental frequency. The ordinate indicates mean discharge rate. Responses to equal-intensity tones are connected, with intensity indicated as the parameter. Reproduced by permission from Rose *et al.* (1971), Fig. 2(b).

the chinchilla cochlea have CFs as low as 150 Hz and as high as 22 kHz; the absence of afferents with CF beyond these extremes probably determines the frequency limits of hearing for the chinchilla.

Because cochlear-nerve responses are nonlinear, to explore their sound-encoding capabilities adequately, it is necessary to use many different types of stimuli at various intensities. For stimulation with single tones, at levels above threshold, the average response rate increases roughly in proportion to the logarithm of sound pressure over a limited intensity range (the dynamic range), eventually reaching a rate plateau. A general description of the complex, intensity-dependent properties of a cochlear neuron's responses to single tones is obtained by plotting response rate as a function of frequency and intensity (Fig. 3). At low stimulus levels, the neuron responds to a narrow range of frequencies; at higher levels, responses extend to higher and lower frequencies. In accordance with the previously noted asymmetry in the slopes of threshold tuning curves of high-CF afferents (Fig. 2), increases in stimulus level incorporate wider response ranges at frequencies below CF than at frequencies above CF. In addition, at higher stimulus levels the highest response rates tend to shift toward lower frequencies. For tones at CF (2100 Hz), increments in response rate occur over a 40-dB range at a rate that is roughly proportional to the logarithm of pressure (i.e., proportional to decibels). At higher-than-CF frequencies the dynamic range is wider, and the maximum response rate lower, than at CF.

2.2.2 Time-Domain Description. Because of the stochastic nature of action potential generation noted above (Sec. 2.1), the spike trains evoked by identical stimuli are highly variable, and responses to sound must be described using statistical averages, such as the mean rate used for the construction of frequency-threshold tuning curves. In the time domain, the most commonly used statistical representation of spike trains is the so-called post-stimulus-time histogram (PSTH), constructed by averaging responses to repeated presentations of identical stimuli, binning spikes according to their latency relative to stimulus onset. Examples of PSTHs are shown in Fig. 4 for responses of a chinchilla cochlear neuron to a high-frequency (9450 Hz) tone burst and to a low-frequency (500 Hz) tone burst, both presented at a moderately intense level (70 dB SPL). The ordinate indicates the average rate of firing in responses to 200 repetitions of 25-ms tone bursts. Spontaneous activity is evident before each response onset and after the end of the

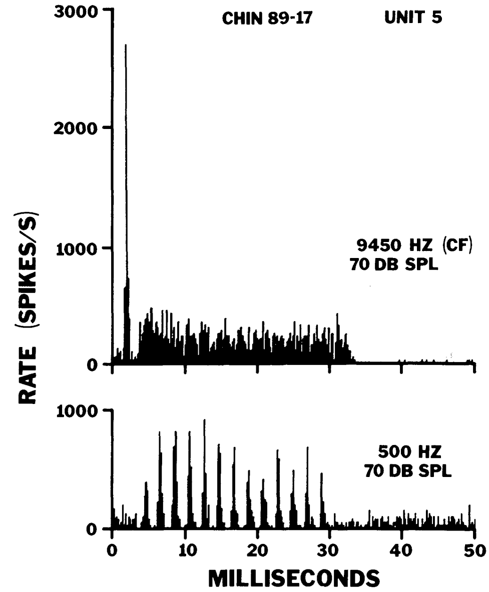

FIG. 4. Poststimulus time histograms for the responses of a single chinchilla cochlear neuron to 9450-Hz (top) and 500-Hz (bottom) tone pips. Stimuli had rise and fall times of 4 ms, lasted 25 ms, and were presented every 150 ms. Histograms are averages of responses to 200 stimulus repetitions. The neuron's CF was 9450 Hz and it had a CF threshold of 3 dB SPL and spontaneous activity of 59 spikes/s. The data for this figure were collected by B. Shivapuja.

500-Hz tone. In the PSTH for responses to the tone burst at 9450 Hz (Fig. 4, top), corresponding to the neurons's CF, activity attains an initially very high discharge peak, which is followed by a brief rate notch; after a few milliseconds, the response settles to a steady rate that is maintained until the end of the stimulus. The rate notch reflects the aforementioned refractory period following the action potential that occurs at the onset, in this case, of the majority of stimulus repetitions. The disparity between the initial discharge rate and the sustained rate is due to synaptic adaptation, which probably results from the inability of the inner hair cell to release chemical transmitter continuously at its synapses with the terminals of cochlear afferents. After the end of the stimulus, the spontaneous rate is temporarily depressed, eventually returning to prestimulus levels. Recovery of spontaneous activity is not completed for the 9450-Hz tone pip within the 50-ms window of the histogram, but is evident for the 500-Hz histogram.

The most prominent feature of the PSTH in response to the 500-Hz tone pip (Fig. 4, bottom) is the presence of multiple peaks, each corresponding to one period of the stimulus tone. Although cochlear afferents rarely fire at high enough rates to be able to discharge during every stimulus cycle, they always respond preferentially at a particular phase of any stimulus with fundamental frequency less than about 4 kHz. In responses to such low-frequency stimuli, intervals between action potentials may span one, two, or multiple stimulus cycles, but when spikes do occur, they tend to happen during a restricted portion of the stimulus period (i.e., at a specific phase). Thus, the temporal structure of the spike train reflects the periodicity of the stimulus wave form. When the phases of cochlear neurons' responses to low-frequency tones are plotted against their CFs [Fig. 8(b)], it is seen that phase lag increases as CF decreases. Because of the tonotopic organization of the cochlea (see Sec. 1), such an increasing lag implies that neural excitation occurs progressively later as a function of distance from the cochlear base. We shall show in Sec. 4.2 that this progressive delay in neural excitation arises from the finite time required for sound-evoked disturbances to travel from base to apex along the basilar membrane.

The ability of cochlear afferents to synchronize their responses to specific phases of low-frequency stimuli, known as "phase locking," provides a potential mechanism for encoding low-frequency (<4 kHz) information. In such a hypothetical temporal code, stimulus frequency would be conveyed to the cochlear nucleus in the temporal pattern of activity of all excited neurons. It is noteworthy that such a code would be effective irrespective of either the site of innervation of the cochlear afferent or the stimulus level, since any cochlear afferent that responds to low-frequency (<4 kHz) stimuli does so in a phase-locked manner.

2.3 Responses to Broadband Stimuli

Linear systems that are frequency tuned respond to an impulse or click with an oscillation whose period is the inverse of the center frequency and whose envelope decays at a rate that varies inversely with the sharpness of tuning. Although the response of cochlear neurons is highly nonlinear, their responses

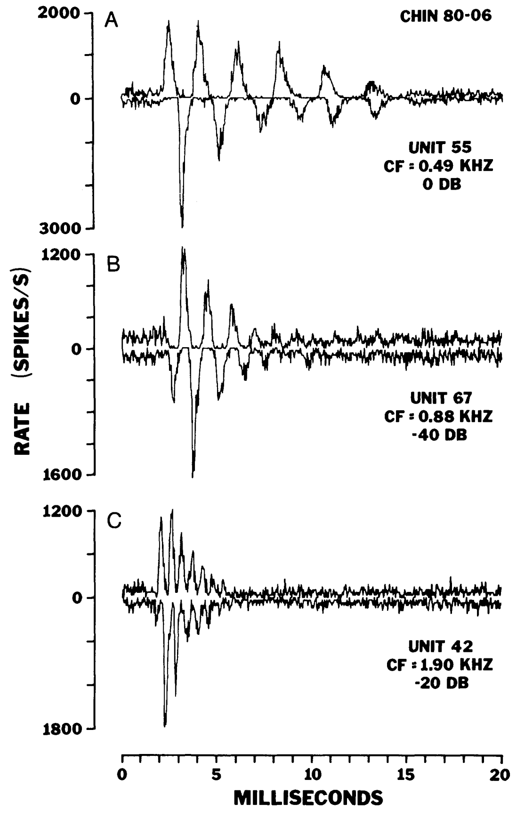

FIG. 5. Responses to clicks of three cochlear afferents from one chinchilla auditory nerve. Responses to stimuli of both polarities are shown jointly as compound poststimulus time histograms (PSTHs). In each of the three panels, the PSTH for responses to rarefaction clicks is plotted in the usual manner, and the PSTH for condensation clicks is plotted upside down. Characteristic frequency of the cochlear afferent and click intensity (expressed as attenuation) are indicated in each panel (unpublished data of M. A. Ruggero).

to clicks are to some extent predictable from the frequency tuning of their responses to tones (Fig. 2). All cochlear neurons can be excited by clicks (Kiang *et al.*, 1965). Figure 5 shows compound PSTHs of the responses to rarefaction and condensation clicks of three neurons (CFs of 490, 880, and 1900 Hz) in one chinchilla cochlear nerve. Each compound histogram is made up of two histograms: responses to rarefaction clicks are plotted as usual, while responses to condensation clicks are inverted. Upon presentation of the rarefaction click (at time zero), there is a brief delay during which the neuron continues to fire at its spontaneous rate. The response to the click consists of multiple peaks, spaced at intervals corresponding to the inverse of the neuron's CF. Upon reversing the polarity of the stimulus click, the times of occurrence of the responses remain periodic but shift to times at which there were few responses to rarefaction clicks: in other words, responses to clicks of opposite polarity interleave with each other. This is consistent with the phase locking noted above in responses to tones.

The shape of PSTHs for responses to clicks changes with the intensity of the stimuli. The PSTHs depicted in Fig. 5(a) are typical for intense clicks in that the earliest responses are elicited by rarefaction clicks and that the sizes of the peaks decay monotonically as a function of time. For lower-intensity clicks, the envelopes of the histograms are more spindle-shaped, with the largest peak being flanked by smaller ones [e.g., PSTHs for condensation in Fig. 5(b) and rarefaction in Fig. 5(c)]. The change in PSTH shape as a function of click intensity is, to a large extent, due to the adaptive properties of the synapse between the inner hair cell and the cochlear afferent terminal (Sec. 2.2), but it also probably reflects cochlear mechanical nonlinearities (Sec. 4.3).

Multiple peaks are characteristic of the PSTHs for responses to clicks of low-CF (<3 kHz) cochlear afferents; in higher-CF neurons, their inability to phase lock to CF tones is reflected in the absence of multiple peaks in their click-response PSTHs. In addition to the spacing between consecutive PSTH peaks, the latency of responses to intense clicks also changes systematically as a function of CF, diminishing from about 3 ms for very-low-CF neurons (e.g., 150 Hz) in the chinchilla to an asymptotic value of about 1 ms for neurons with CFs above 3 kHz. The 1-ms asymptotic value can be accounted for by two principal delays: the delay of chemical synaptic transmission, mostly due to the diffusion time of the chemical transmitter from the inner hair cell to the peripheral terminal of the cochlear neuron, and the axonal conduction time of action potentials from the terminal to the site of the recording microelectrode. Irreducible CF-dependent response delays longer than 1 ms correspond to the CF-dependent phase lags previously noted in responses to tones (Sec. 2.2.2); such delays will be shown in a later section (Sec. 4.2) to reflect corresponding delays in cochlear mechanics.

Responses of cochlear neurons to noise are understandable according to the same principles used to interpret responses to clicks. All neurons can be excited by acoustic white noise. The responses of low-CF neurons contain time fluctuations with a frequency spectrum similar to the frequency-tuning curves for their responses to tones. High-CF neurons, on the other hand, respond to white noise with an increased average discharge rate but with no periodicity evident in the train of discharges.

2.4 Nonlinear Interactions in Responses of Cochlear Afferents to Tone Pairs

2.4.1 Two-Tone Suppression. As seen in previous sections, cochlear afferent responses are not linear and, therefore, responses to stimuli with multiple frequency components (such as clicks) cannot be well predicted on the basis of responses to single tones. In order to gain some understanding of the underlying nonlinear processes that preclude linear synthesis, it is convenient to study the responses to relatively simple stimuli, such as tone pairs, in which nonlinear interactions are evident but whose complexities are still amenable to analysis. One of the better studied nonlinearities in cochlear nerve responses is "two-tone rate suppression" (Galambos and Davis, 1944; Sachs and Kiang, 1968). This is defined as the reduction in the response to one tone due to the presence of a second tone. Figure 6 shows the responses of a cat cochlear afferent to two tones presented individually [Figs. 6(a) and 6(b)] and together [Fig. 6(c)]. The neuron, which had little spontaneous activity, was moderately excited by both a continuous 360-Hz (CF) tone [Fig. 6(a)] and a 720-Hz tone pip [Fig. 6(b)]. When the two tones were presented simultaneously, however, the neuron almost ceased firing throughout the duration of the 720-Hz, suppressive, tone pip [Fig. 6(c)].

Whether or not one tone causes suppression of another depends strongly on the levels and frequencies of the two tones. Figure 7 shows, superimposed on a frequency-threshold tuning curve, shaded regions indicating tonal stimuli that suppressed responses to a near-CF tone (triangle). The regions of overlap of the excitatory tuning curve and the shaded suppressive areas in Fig. 7 indicate that tones that are excitatory by themselves can suppress responses to a CF tone. One of the most significant properties of two-tone suppression is its dependence on the frequency of the excitatory tone: only tones with frequencies close to the neuron's CF can be strongly suppressed. This frequency selectivity suggests that suppression arises in cochlear mechanics since, as we shall discuss later (Sec. 4.3), sharp frequency tuning is established early in the chain of transduction events, being evident in the vibrations of the basilar membrane. This suggestion is consistent with the latency of suppression onset, which is as short as the latency of response to excitatory tones (Arthur *et al.*, 1971), and with the demonstration that two-tone suppression persists after sectioning of the auditory nerve central to the site of recording from cochlear

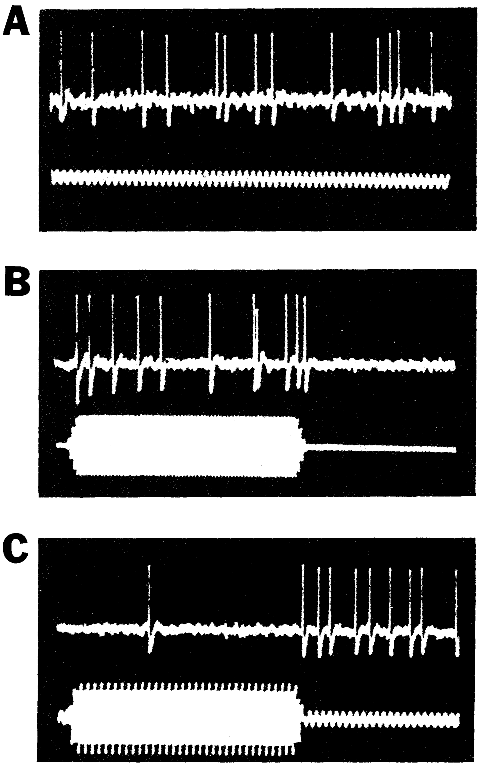

FIG. 6. Two-tone suppression in a cat cochlear afferent. The upper oscilloscope tracing in each panel shows spike trains elicited by stimulation with two tones presented singly (a and b) and together (c). The lower tracing in each panel indicates the duration of a continuous 360-Hz, 40-dB SPL tone (a and c) and/or of a 720-Hz, 60-dB SPL tone pip (b and c). Note diminished rate of firing when both tones are presented together (c). Reproduced by permission from Arthur *et al.* (1971), Fig. 2(a).

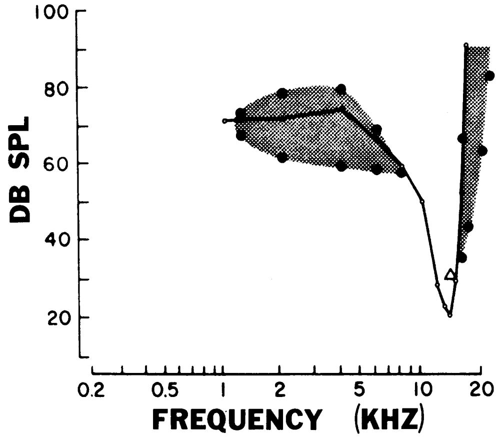

FIG. 7. Two-tone suppression areas and frequency-threshold tuning curve for one chinchilla cochlear afferent. The continuous line indicates the tuning curve in response to tone pips with frequency and intensity indicated in the abscissa and ordinate, respectively. The triangle indicates a probe tone, responses to which are suppressed when second tones are presented with frequency/intensity combinations demarcated by the shaded areas. Reproduced by permission from Harris (1979), Fig. 13.

afferents (Kiang *et al.*, 1965). These observations rule out involvement of the olivocochlear efferent system (see Fig. 1 and Secs. 2.6 and 11.1) in two-tone suppression, since sound-evoked activation of olivocochlear neurons has a long latency and sectioning of the auditory nerve prevents actions potentials traveling along olivocochlear axons from reaching the cochlea.

2.4.2 Combination-Tone Generation. Another well-studied example of nonlinear interactions between two tones is the generation of so-called "combination tones," also known as "intermodulation distortion products" or "Tartini pitches." Giuseppe Tartini, an 18th century Italian musician, is reputed to have first recognized that, upon presentation of two tones with frequencies f_1 and f_2 ($f_2 > f_1$), humans often perceive tones not physically present in the acoustic stimulus. Physiological correlates of these distortion products, the most prominent of which have frequencies equal to $2f_1 - f_2$ and $f_2 - f_1$, exist in the responses of cochlear afferents to pairs of tones with appropriate frequencies and intensities. Figure 8 presents evidence suggesting that the combination tone $f_2 - f_1$ is a product of nonlinear cochlear mechanics and that it propagates on the basilar membrane in a manner similar to that of a tone of the same frequency present at the input to the cochlea. The responses of cochlear afferents to a two-tone stimulus (3680 and 4000 Hz) were recorded from one auditory nerve in a chinchilla and they were compared to responses to a separately presented single tone with frequency of 320 Hz (i.e., equal to the combination frequency, $f_2 - f_1$). The spike trains were binned into time histograms, with the abscissa equal to the fundamental repetition period of the stimulus wave form. Subsequent Fourier transformation of the histograms revealed the magnitudes and phases of the spectral response components which were phase locked (Sec. 2.2.2) to 320 Hz, the frequency of the single tone (crosses and dashed lines) and of the combination tone $f_2 - f_1$ (filled circles and solid lines). Since there is a strict frequency-to-place mapping along the cochlea (Fig. 1), plotting the values of the spectral components against CF is equivalent to assessing the distribution of the spectral response components as a function of cochlear location. This equivalence is indicated in Fig. 8 by the two abscissa scales. For the two-tone stimulus, responses were strongly phase locked to the combination-tone frequency at two separate cochlear locations: at the basal regions with CFs equal to the primary frequencies (3680 and 4000 Hz) and at the apical location with CF equal to the combination frequency (320 Hz). In the absence in the stimulus of energy at the combination-tone frequencies, and given that the middle ear responds linearly, it is clear that neural responses phase locked to the combination-tone frequency indicate a cochlear origin of the combination tone. In the apical region, the spatial distributions of the 320-Hz components of the responses to the two-tone stimulus (filled circles and solid lines) and to the 320-Hz single tone stimulus (crosses and dashed lines) were very similar in both magnitude [Fig. 8(a)] and phase [Fig. 8(b)]. The similarity between the phase distributions is especially significant, since it suggests that the combination-tone component propagates from base to apex along the basilar membrane in a manner very similar to that of the single tone (see Secs. 2.2 and 4.2). Further, the presence of a strong $f_2 - f_1$ response at locations with CFs equal to the primary-tone frequencies, f_1 and f_2, suggests that the me-

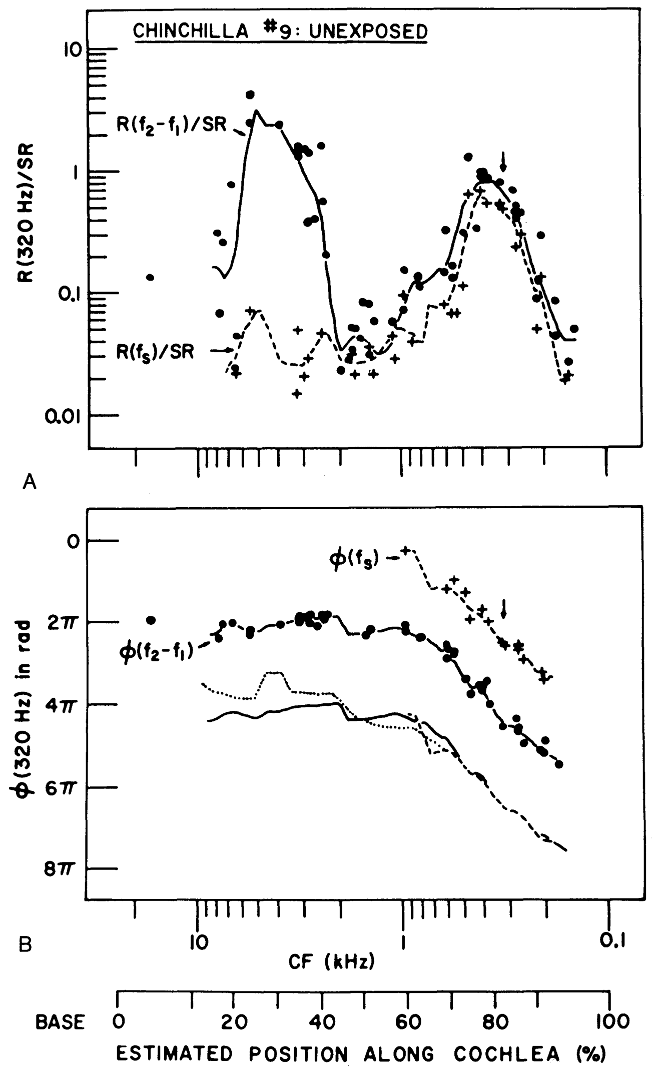

FIG. 8. Comparison of the spatial distribution of the 320-Hz Fourier component in responses of chinchilla cochlear afferents to 320-Hz single tones and to two-tone stimuli. The single-tone responses (crosses and dashed lines) were evoked by 320-Hz, 5-dB SPL stimuli; the two-tone data (filled circles and solid lines) were obtained with paired 3680-Hz and 4000-Hz tones, presented at 50-dB SPL. The magnitudes (a) and phases (b) of the 320-Hz response components are plotted as functions of characteristic frequency or, equivalently, cochlear location. The lines drawn through the data points are moving-window averages. In (b) these lines have been plotted twice, once after vertical displacements to facilitate comparison of their slopes. The dotted line indicates averages for responses to 50-dB, 320-Hz single tones. Reproduced by permission from Siegel *et al.* (1982), Fig. 4.

chanical distortion products originate at these primary sites and subsequently propagate, in an apical direction, toward locations with CFs matching the combination-tone frequencies. More convincing evidence for this hypothesis comes from studies of cochleae with hair cell loss.

2.5 Effects of Hair Cell Loss upon Cochlear Afferent Responses to Sound

Procedures such as exposure to very intense sound or chronic administration of certain antibiotics destroy some or many of the hair cells of the cochlea, while leaving most other cells intact. Recordings from the cochlear afferents of animals partially deafened by such procedures permit one to ascertain the role that the missing elements normally play in the encoding of sound (reviewed by Harrison, 1988). When inner hair cells are destroyed, the afferents formerly innervating them lose their spontaneous activity and do not respond even to very intense sounds at any frequency. When outer hair cells are destroyed, the CF thresholds for responses to tones of neurons innervating adjacent intact inner hair cells are selectively raised. In other words, the neurons lose some or most of their frequency tuning (Fig. 9). The implication is that the loss of outer hair cells somehow influences, in a frequency selective manner, the responses of Type I cochlear afferents, al-

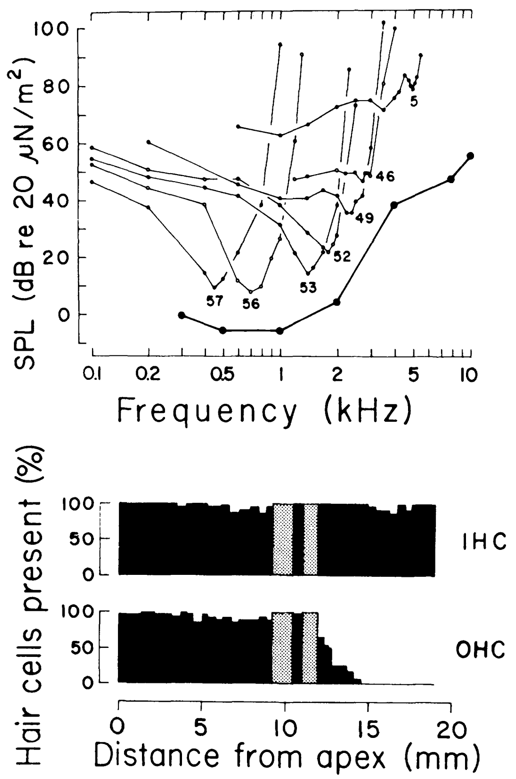

FIG. 9. Frequency-threshold neural tuning curves and behavioral audiogram (top panel) for a chinchilla whose basal cochlea is denuded of outer hair cells as a result of chronic administration of kanamycin, an ototoxic antibiotic (bottom panel). The thin lines in the top panel show three relatively normal tuning curves and four others with threshold elevations at CF. The thick line indicates the behavioral audiogram. The bottom panel graphically shows the location of surviving hair cells. (The gray bars indicate cochlear regions where, for technical reasons, hair cells could not be counted.) Note that threshold elevation of both the tuning curves and the behavioral audiogram occurs at high CFs, corresponding to the basal locations of outer hair cell loss. Reproduced by permission from Dallos and Harris (1978), Figs. 2 and 9.

though these innervate exclusively the (intact) inner hair cells.

Another effect of outer hair cell loss is to eliminate combination tones when the CF of the site of loss corresponds to *either* the primary frequencies or the frequency of the combination tone itself (Sec. 2.4). Such effects, demonstrated both in neurophysiological studies in animals (Siegel *et al.*, 1982) and in psychophysical measurements in hearing-impaired humans (Smoorenburg, 1972) indicate that the cochlear site with CF equal to the combination-tone frequency is the place that the brain attends to in detecting a combination tone, while the cochlear region with CFs equal to the primary tones is responsible for the generation of the mechanical distortion product: the combination tone propagates apicalward on the basilar membrane to reach the site with CF equal to its frequency, where it is transduced by the inner hair cells and its presence is relayed to the brain. The effect of hair cell loss upon combination-tone generation at the site of the primaries is very significant: it suggests that hair cells normally feed back upon, and thus influence, the mechanics of the basilar membrane (Goldstein, 1967; Smoorenburg, 1972). As we shall discuss in Sec. 4.5, it is now almost certain that a bidirectional (feedback) relationship indeed exists between outer hair cells and the basilar membrane.

2.6 Effects of Stimulation of the Olivocochlear Efferent System upon Cochlear Afferent Responses to Sound

Important clues to the processes of mechanical-to-neural transduction have emerged from experiments in which the responses of cochlear afferents to sound have been recorded during transient alterations of the functional state of the cochlea. One of these manipulations of the cochlea consists of electrical stimulation of the olivocochlear efferent system, which originates in the region of the superior olivary complex of the brainstem (see Secs. 7 and 11.1). A large proportion of these efferents make up the crossed olivocochlear bundle, which projects to the cochlea from the contralateral superior olivary complex and passes close to the dorsal surface of the brainstem, where it is easily accessible for electrical stimulation. The terminations of the crossed olivocochlear neurons are principally upon the outer hair cells and secondarily upon the Type I afferent neurons, close to their synapses with inner hair cells (Fig. 1 and Sec. 4.1). When the olivocochlear bundle is electrically stimulated, the responses to sound of the vast majority of cochlear afferents are inhibited in a frequency-selective manner: whereas the threshold of responses to tones near each afferent's CF may be raised by 20 dB or more, responses at other frequencies are hardly affected (Wiederhold, 1986). It should be noted that, while some terminals of the crossed olivocochlear bundle innervate Type I afferents directly (Fig. 1) and could conceivably inhibit them, this inhibition can hardly be CF specific, since neurons are essentially untuned signal-transmission devices. Qualitatively, therefore, the effect of olivocochlear efferent activation is similar to the effect of outer hair cell loss and poses the same puzzle: how can a CF-specific effect be mediated by the outer hair cells, given that Type I afferents innervate only inner hair cells? It will be seen in Secs. 4.3 and 4.5 that the answer to the puzzle appears to be that normal function of the outer hair cells is necessary for the maintenance of sharp tuning in the basilar membrane, which in turn determines the frequency tuning of inner hair cells and, ultimately, of cochlear afferents.

3. THE INPUT TO THE COCHLEA: THE EXTERNAL AND MIDDLE EARS

3.1 External Ear

The external ear of humans, chinchillas, and many other mammals consists of a roughly cylindrical canal, terminated internally by the tympanic membrane (eardrum), and flaring out externally into a cartilaginous, skin-covered pinna (Fig. 10). The geometry of the ear canal causes frequency-selective enhancement of sound-pressure waves at its tympanic-membrane end, relative to pressures at its entrance. The enhancement is greatest for sound frequencies with wavelengths about four times the length of the ear canal. In the chinchilla the canal length amounts to 3 cm and, correspondingly, as shown in Fig. 11, sound pressures at frequencies close to 2.8 kHz are increased by as much as 15 dB (von Bismarck, 1967). Figure 11 also shows that the frequency-selective pressure enhancement varies according to the location of the sound source relative to the ear. This directional selectivity results from such factors as shadowing of sound waves by the pinna and head (when the sound source is located on the opposite side of the head or widely off-axis from the ear) and destructive interference between directly arriving waves and waves scattered off the edge of the pinna. There is evidence that the external ear's directional selectivity permits the discrimination of sounds originating behind the head from those located in front. While human pinnas are essentially immobile, many mammals can orient their (often large) pinnas voluntarily, thus aiding in sound localization.

3.2 Middle Ear Anatomy

The middle ear of mammals (Fig. 10) consists of a mostly bone-enclosed, air-filled cavity containing the bony (ossicular) chain that transfers sound-induced vibrations from the peripheral "window" of the middle ear, the tympanic membrane, to the membranous oval window, which is the input to the fluid-filled cochlea; another membranous window, the round window, also communicates with the cochlea. The middle ear pressure is usually kept equalized with atmospheric pressure via the Eustachian tube, which opens into the pharynx. The ossicular chain is made up of three tiny bones: the malleus ("hammer"), the incus ("anvil"), and the stapes ("stirrup"). The malleus is firmly attached peripherally to the tympanic membrane and centrally to the incus; in some animals, such as the chinchilla, the malleus and incus are completely fused. Both the malleus and incus have single "long" projections which swing jointly around a shared axis. The long projection of the incus is joined to the stapes by means of a ligament. The stapes footplate abuts against the oval window, which it almost entirely fills. In addition to several ligaments that lightly suspend the ossicles from the middle ear's walls, two muscles, the stapedius and the tensor tympani, are attached to the stapes and to the malleus, respectively.

3.3 Impedance Matching by the Middle Ear

The function of the middle ear is to transfer efficiently the acoustic pressure waves from air into the fluid medium of the cochlea (see reviews by Zwislocki, 1975, and Møller, 1983). The cochlea consists of three fluid-filled, tubelike compartments, two of which (scala vestibuli and scala tympani) sandwich between them the third compartment, the scala media. The sensory organ proper, the organ of Corti, is located between scala media and scala tympani (Fig. 13). The middle ear ossicles direct the output of the external ear, namely, the vibrations of the tympanic mem-

brane, into one cochlear window, the oval window (adjacent to scala vestibuli), while shielding the second cochlear window, the round window (in contact with scala tympani), from the free-field sound waves that cause eardrum vibrations. Were the two cochlear windows exposed to the same sound field, pressure waves at the windows would interfere destructively and there would be little transfer of energy from the free field into the cochlea.

Because of the different acoustic impedance (i.e., pressure divided by volume velocity) of air and cochlear fluids, if sound waves were to impinge directly upon the oval window, most of their energy would be reflected and little would be available to drive the mechanical-to-electrical cochlear transduc-

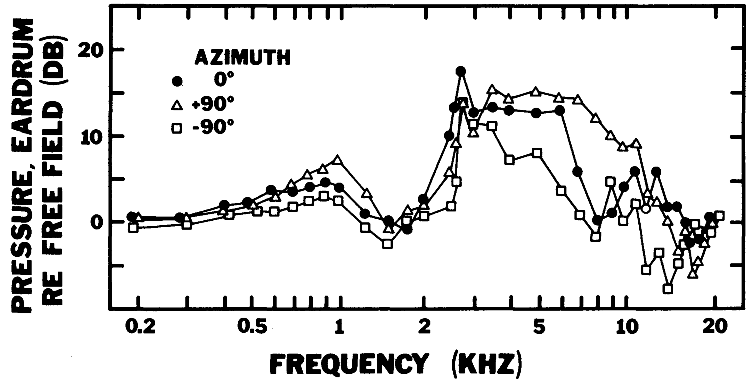

FIG. 11. The average acoustic pressure gain near the eardrum of the chinchilla, relative to pressure in the free field, plotted as a function of frequency. Symbols indicate measurements with the sound source facing the chinchilla's snout (azimuth zero, filled circles), closest to the experimental ear (azimuth of +90°, triangles) and closest to the opposite ear (azimuth of −90°, squares). Redrawn from von Bismarck (1967), Fig. 15.

tion processes. Thus, an important aspect of middle ear function is its role as an impedance-matching device that converts the relatively high-velocity, low-pressure air vibrations external to the tympanic membrane into higher-pressure, lower-velocity vibrations at the oval window. This impedance transformation is accomplished in two principal ways: (1) via the large area ratio between the middle ear input, the tympanic membrane, and its output, the footplate of the stapes; and (2) via the mechanical lever ratio of the malleus–incus complex. In the chinchilla, the area of the tympanic membrane is 0.56 cm^2 and the stapes footplate area is 0.02 cm^2 (Vrettakos *et al.*, 1988). Because the tympanic membrane vibrates little near the attachment to its bony frame, its effective area is reduced to about 0.37 cm^2. The pressure at the stapes footplate is therefore increased by a ratio of $0.37/0.02 = 18.5$ times. The long projections of the chinchilla malleus and incus are 0.45 and 0.16 cm in length, respectively, resulting in a lever ratio of $0.45/0.16 = 2.81$ (Vrettakos *et al.*, 1988). Because this lever ratio both reduces the magnitude of motion by a factor of 2.81 and multiplies force by the same amount, it increases the pressure-to-velocity ratio (i.e., the impedance) by $(2.81)^2 = 7.9$ times. Thus, the combined effects of the tympanic membrane/stapes footplate area ratio and of the malleus/incus lever ratio is to reduce the apparent cochlear input impedance by $18.5 \times 7.9 = 146$ times. The specific cochlear input impedance (i.e., pressure in scala vestibuli near the stapes divided by stapes velocity) at 1 kHz is about 16 000 dyn $\mathrm{s/cm}^3$ (Ruggero *et al.*, 1990). The transformer ratio of 146 reduces this impedance to $16\,000/146 = 110$ dyn $\mathrm{s/cm}^3$, which approaches (within 9 dB) the specific impedance of air, 42 dyn $\mathrm{s/cm}^3$.

3.4 Transfer Function of the Middle Ear

The calculation of the transformer ratio of the middle ear provides a first-order estimate of its signal transformations but it neglects relevant factors such as the compliance of the tympanic membrane and of the air trapped in the middle ear cavity, the elasticity and friction at the joints between the ossicles, and the inertia of the ossicles, ligaments, and muscles, all of which tend to impair transmission of vibrations to the cochlea. The effects of these factors are frequency dependent: in systems that include elastic and inertial components, elasticity tends to control low-frequency responses, while inertia is the dominant factor at high frequencies. The simplest way to assess the effectiveness of middle ear transmission is to measure its output, normalized to a constant input (i.e., constant sound pressure level at the eardrum), as a function of frequency. Since the middle ear ossicles vibrate linearly even at rather high stimulus intensities (e.g., 100 dB SPL), such a transfer function completely specifies its input-output characteristics and permits computation of the middle ear output for any arbitrary input. The output of the middle ear may be taken to be either the motion of the stapes footplate at the oval window or the pressure generated by this motion in scala vestibuli (pressure in scala vestibuli being given by the product of cochlear input impedance and stapes volume velocity, itself the product of the velocity of the stapes times the area of its footplate). The magnitudes of both these quantities in the chinchilla are plotted in Fig. 12 against frequency, expressed as stapes volume velocity per unit of stimulus pressure, and as pressure in scala vestibuli relative to stimulus pressure.

Both the velocity and pressure curves are mildly tuned, with similar bandpass characteristics in the frequency range 300–16 000 Hz; this similarity is consistent with the cochlear input impedance being resistive and constant in the midfrequency range (Zwislocki, 1975). The pressure curve has a maximum gain, at about 1 kHz, of 32 dB relative to pressure near the eardrum. This gain is very close to that predicted from the combined effects of the tympanic membrane/stapes footplate area ratio and of the force gain due to the malleus/incus lever ratio: $18.5 \times 2.8 = 51.8$ times, or 34 dB. However, at frequencies above and especially below 1 kHz, the pressure gain diminishes. The positive stapes velocity/frequency slope, which is almost exactly 6 dB/oct, is principally due to the air trapped within the middle ear, which acts like a cushion opposing the motion of the eardrum, shunting away some of the energy which otherwise would be spent in moving the ossicular chain. The milder negative slope of the pressure and velocity curves above 1 kHz is not yet well understood; in particular, it seems that it cannot solely reflect inertial

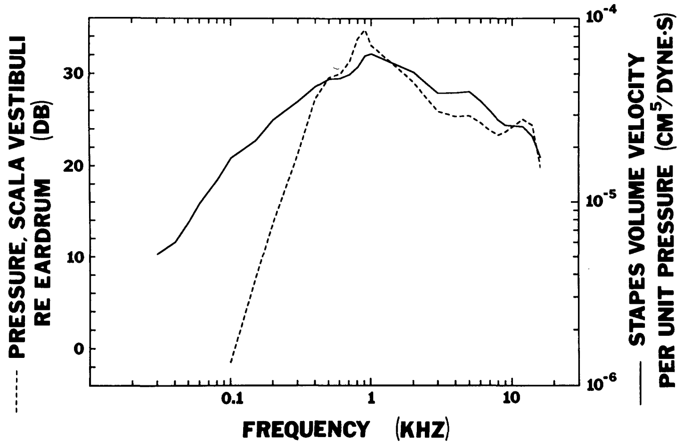

FIG. 12. Alternative transfer functions of the chinchilla middle ear. Shown are the volume velocity of the stapes per unit pressure in the external ear canal near the eardrum, expressed in c.g.s. units (continuous line, right ordinate), and the pressure in scala vestibuli near the stapes, expressed in decibels relative to pressure at the eardrum (dashed line, left ordinate). The curves are based on data from Ruggero *et al.* (1990) and Décory *et al.* (1990).

components of the middle ear, since their contributions to the transfer function should cause a −6 dB/oct slope.

3.5 Middle Ear Muscles

The effect of contraction of the middle ear muscles, the stapedius and the tensor tympani, is to stiffen the ossicular chain by pulling on the stapes and the malleus, respectively. Accordingly, middle ear muscle contraction interferes mainly with the transmission of low-frequency sounds (by as much as 15 dB) and has little effect on ossicular responses to sound frequencies above 1.5 kHz. Bilateral middle ear muscle contraction can be elicited by intense acoustic stimulation of either ear, by activity of the muscles involved in chewing and vocalization, and during the rapid-eye-movement stage of sleep. The function of the middle ear muscles is obscure. Their sound-activated contraction, the acoustic reflex, could play some role in protecting the ear against intense prolonged sounds (although not against impulsive sounds, because of the long latency of the reflex). However, such a role is questionable from an evolutionary perspective, due to the near absence of intense natural (i.e., non man-made) low-frequency sounds. Because contraction of the middle ear muscles produces selective attenuation of low-frequency transmission, their activation may be useful in reducing the masking of meaningful mid- and high-frequency sounds by low-frequency noise.

4. THE COCHLEA

4.1 Anatomy of the Cochlea

4.1.1 Cochlear Compartments. The cochlea derives its name from the Greek word for "land snail" whose coiled and cone-shaped shell it very much resembles in most mammals [Figs. 10 and 13(a)]. It consists of two fluid-filled tubes, with bony external walls and membranous inner walls (scala vestibuli and scala tympani), flanking a third tube (scala media) which is also fluid filled [Figs. 13(a) and 13(b)]. Scala vestibuli and scala tympani are separated for most of their length (18 mm in chinchillas) by scala media; because scala media stops short of the apical end of the cochlea, scala vestibuli and scala tympani communicate with each other via a channel at the apex, called the helicotrema. Scala media is separated from scala vestibuli by a thin cellular membrane (Reissner's membrane) and from scala tympani by the organ of Corti, which includes the sensory hair cells, and by the basilar membrane [Figs. 13(b) and 13(c)]. At the basal end of the cochlea scala vestibuli ends at the oval window, a flexible membrane against which the stapes footplate abuts (Fig. 10). Also at the basal end of the cochlea, another thin and flexible membrane, the round window, separates scala tympani from the middle ear (Fig. 10).

Perilymph, the fluid which occupies scala vestibuli and scala tympani, is similar in composition to cerebrospinal fluid (which surrounds and cushions the central nervous system) and other extracellular fluids in that it

FIG. 13. Anatomy of the cochlea. Magnification and detail increase from (a) through (c). (a) A cross section of the entire cochlea of a chinchilla. The darker shading indicates bone; the lighter shading represents the cochlear nerve, with its axons in the central pillar of the cochlea (modiolus) and its cell bodies (somata) in the spiral ganglion. Note that because of their spiral nature ($3\frac{1}{2}$ turns in 18 mm), the three scalae (vestibuli, tympani, and media) and the spiral ganglion are cut in several places as they coil around the central axis of the cochlear cone. (b) A slice of the three scalae at a single cochlear site. (c) Details of the organ of Corti. (b) and (c) are reproduced by permission from Bloom and Fawcett (1975), Figs. 36-11 and 36-14.

contains high sodium-ion and low potassium-ion concentrations. In contrast, endolymph—the fluid filling scala media—is unique among extracellular fluids: it contains high potassium-ion and low sodium-ion concentrations. Also in contrast with all other extracellular compartments in the body, scala media sustains a rather high electrical potential, +80 mV relative to the perilymph or distant extracellular sites. Both the unusual ionic composition and the high electrical potential of the endolymph are generated by energy-consuming metabolic pumps located in cells of the stria vascularis, a highly vascularized "ribbon" located in the lateral wall of scalamedia [Fig. 13(b)]. The high positive electrical potential of the endolymph drives positively charged potassium ions into the hair cells. As discussed in a later section (Sec. 4.4), the transduction process modulates this potassium current.

4.1.2 Basilar Membrane and Supporting Cells. The sensory hair cells are located in the organ of Corti, which rests on the basilar membrane and upon which, in turn, lies the tectorial membrane; the organ of Corti's main components also include the "supporting" cells and the peripheral terminals of afferent and efferent neurons [Fig. 13(c); reviewed by Lim, 1980]. The basilar membrane is held (but not under tension) at its central edge by the bony spiral lamina and at its peripheral edge by the spiral ligament. It consists largely of acellular materials, mostly protein fibrils arranged radially (relative to the modiolus) within an amorphous matrix. The thickness of the basilar membrane diminishes systematically from base to apex, while its width increases from the base to the apex. In the chinchilla the basilar membrane is 200 μm wide near the stapes and 420 μm wide at the helicotrema (Bohne and Carr, 1979; Lim, 1980).

Several types of supporting cells rest on the basilar membrane, some of them providing a pedestal for the hair cells [Fig. 13(c)]. The most prominent supporting cells are the inner and outer pillars, which contain fibrils that impart stiffness to them; together they divide the organ of Corti longitudinally into a narrow inner region, close to the spiral lamina, and a wider outer region. Because of its overall geometry, the outer region of the organ of Corti, which contains three rows of outer hair cells, is capable of relatively wide transverse movement; in contrast, the inner region, which includes a single row of inner hair cells, moves little as a whole, since it rests partly on the immobile edge of the bony spiral lamina. The outer phalangeal cells support the outer hair cells and, like the pillar cells, contain stiffening fibrils. A thin beam (phalanx) reaches up from each outer phalangeal cell to join the tops (apical surfaces) of inner and outer hair cells, inner pillars, and other supporting cells to form the regular cellular mosaic of the reticular lamina. The reticular lamina constitutes a (probably stiff) structural boundary of the scala media and also an ion barrier: the extracellular fluid bathing the basolateral walls of hair cells and supporting cells is perilymph or is perilymph-like in composition, while the apical surface of the hair cells and supporting cells are in contact with the endolymph of scala media.

4.1.3 Inner and Outer Hair Cells. Hair cells of the mammalian cochlea, like all other sensory hair cells (such as those in the vestibular organs of balance), are characterized by tufts of "hairs" or stereocilia, thin cylinders that protrude from their apical surface. Each stereocilium consists of a core, made of protein (actin) filaments, enveloped by plasma membrane, which is continuous with that of the rest of the cell. The actin molecules are organized into orderly arrays, almost crystalline in appearance, which make the stereocilium quite stiff. Inner and outer hair cells differ in the arrangement of their stereocilia, inner hair cells having fewer and thicker stereocilia. In both cases, stereocilia are arranged as a letter "v," with its concavity pointing toward the modiolus. In the inner hair cell, the "v" is quite shallow; in the outer hair cell, in which the stereociliar arrangement is reminiscent of the ranks of pipes in an organ, the "v" is deeper. The tallest of the outer hair cell stereocilia are well attached to the overlying tectorial membrane, whereas in inner hair cells such attachment is flimsy, if it exists at all. Inner and outer hair cells also differ in the shape of their bodies, in the organization of certain cytoplasmic organelles, and in their spatial relations to supporting cells. Inner hair cells are flask shaped, with a narrow apical region and a wider, round basal region. Their plasma membrane is completely surrounded by closely juxtaposed supporting cells. Outer hair cells, in contrast, have cylindrical bodies and only the basal (bottom) part of their basolateral plasma membrane is in direct contact with supporting (outer phalangeal) cells. Most of the outer hair cell basolateral plasma membrane is underlain by a membranous cistern; this structure is absent in inner hair cells.

4.1.4 Afferent and Efferent Innervation. The mode of innervation, both afferent and efferent, is fundamentally different in inner and outer hair cells (reviewed by Spoendlin, 1988). Inner hair cells, comprising only 20% of the hair-cell population, receive terminals from 90% of cochlear afferents, whereas only

10% of afferents innervate outer hair cells, which constitute the vast majority (80%) of hair cells. In the chinchilla, each of the 1800 inner hair cells is innervated by 10–20 of the 27 000 Type I cochlear afferents, with each afferent innervating a single inner hair cell (Bohne *et al.*, 1982; Ruggero *et al.*, 1982). In contrast, each of some 2700 Type II afferents innervates many of the numerous (7400) outer hair cells. While outer hair cells receive many synaptic endings of the olivocochlear efferents, no such terminals exist on inner hair cells. However, there are olivocochlear efferent endings on the terminals of Type I afferents, near their synapse with the inner hair cell (see Sec. 11.1). Thus one may justifiably think of an "inner hair cell system" and an "outer hair cell system." The inner hair cell system is the one whose output we have described in terms of the responses of the Type I afferents (Secs. 2.1–2.6); of the responses of Type II afferents, which presumably convey the signals transduced by the outer hair cells, we know almost nothing.

4.2 Passive Aspects of Basilar Membrane Motion

Until less than two decades ago, the first words of this section's title would have been redundant: all aspects of cochlear mechanics were viewed as "passive" and independent of the "active" metabolic processes of living cells and, hence, as essentially similar in live and dead animals. Whatever differences did exist between the mechanics of living and dead ears were deemed unimportant. That view of cochlear function had its roots, at least partially, in the historical accident that what was known empirically about basilar membrane motion was uncovered almost exclusively by measurements in ears of human cadavers and of dead animals. Such measurements were the solitary work of an extraordinary Hungarian-born physicist, George von Békésy. What follows in this section summarizes this work, for which Békésy was awarded the 1961 Nobel Prize for Physiology or Medicine.

4.2.1 The Traveling Wave. When the ossicular chain vibrates at very low (infrasonic) frequencies, the perilymph of the scala vestibuli and scala tympani is set in motion as a whole, with inward displacement of the stapes being accompanied by bulk flow of fluid from scala vestibuli, through the helicotrema, into scala tympani, and by an outward bulge of the round window into the middle ear cavity. At higher (audio) frequencies, the motion of the stapes generates pressure waves that propagate very rapidly (in a few microseconds) throughout the cochlea. Békésy, using relatively insensitive microscopy methods that required very intense stimulation (120–140 dB SPL), observed in cochleae of human cadavers that the basilar membrane sustained a much slower (transverse) displacement wave that always propagated (longitudinally) from the basal cochlea toward the apex, independent of the site of application of the vibration input [Fig. 14(a)]. Thus, although the usual physiological route for airborne sound is through vibration of the oval window by the stapes, Békésy found identical base-to-apex propagation patterns of

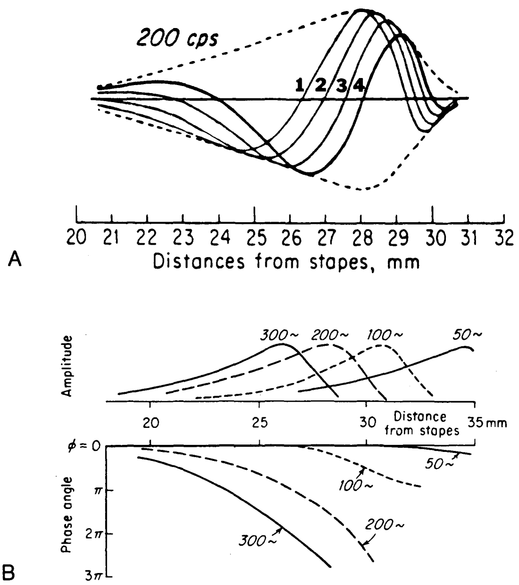

FIG. 14. The basilar-membrane traveling wave, as measured by Békésy in human cadavers. (a) "Snapshots" at four times (1 = earliest) of the basilar membrane displacement patterns elicited by a 200-Hz tone; the scale of the ordinate is greatly exaggerated relative to that of the abscissa. The dashed lines indicate the peak displacements of the basilar membrane toward scala vestibuli and scala tympani at each cochlear location. (b) Peak-to-peak displacements as a function of distance for responses to tones with four different frequencies (upper section), and the corresponding phase patterns (lower section). Reproduced by permission, with modifications, from Békésy (1960), Figs. 12-17 and 11-58.

the displacement wave when he applied sound to the cochlea via an artificial apical window or via bone conduction. The speed of travel of the displacement wave is not uniform as a function of distance: at the basal end propagation is fast and therefore, for sinusoidal stimulation, the wavelength is long; as the wave proceeds toward the apex, it slows down and the wavelength shortens. The finite speed of travel implies an accumulating delay as a function of distance from the stapes; for sinusoidal stimulation this translates into accumulating phase lag [Fig. 14(b); see also Fig. 8(b)]. The longer latency of responses to clicks of low-CF cochlear afferents relative to the latency of high-CF afferents (Sec. 2.3) originates in the time required by the traveling wave to reach the apical region of the basilar membrane. This time, about 2 ms in the chinchilla cochlea, is two to three orders of magnitude greater than the time required by sound to travel between the oval window and the helicotrema.

4.2.2 Frequency Tuning and Tonotopicity. Whatever the frequency of stimulation, the shape of the vibration envelope was found to be similar in that, in each case, the envelope's basal portion (corresponding to the region of long wavelengths) had a shallow spatial gradient, there was a maximum at a particular longitudinal location, and the maximum was followed on the apical side by a relatively steep slope [Fig. 14(a)]. For low-frequency stimuli, the displacement of the basilar membrane was largest near the apex. As stimulus frequencies were increased, the displacement envelopes were confined to progressively more basal locations [Fig. 14(b)]. Thus, a tonotopic map is laid out along the cochlea, in which each longitudinal location of the basilar membrane vibrates maximally at some particular frequency, its CF. Because Békésy found that basilar membrane responses grew linearly with stimulus level, it was considered justifiable to estimate, by extrapolation, basilar membrane displacements at levels much lower than those used in the experiments. At intensities corresponding to the lowest threshold of hearing in normal humans (about 0 dB SPL), such extrapolation suggested that the basilar membrane vibrates at CF with peak amplitudes of 1 pm, approximately equivalent to 1/100 of the radius of a hydrogen atom.

For several apical locations of the human basilar membrane, Békésy was able to measure responses to tones as a function of frequency. For a CF of 150 Hz, the tuning curve was broad, with a Q_{10} of only 0.8. [For comparison, recall that in chinchillas Q_{10}'s of cochlear afferents are as low as 1 for CFs around 150 Hz and as high as 7 for CFs of 16 kHz (Sec. 2.2).] When basilar membrane recordings were obtained in the basal (high-CF) cochlear region of live guinea pigs, they yielded responses that were as poorly frequency-tuned as those from Békésy's measurements in the apical (low-CF) region of human cadaver cochleae. The mismatch in the live guinea pig between the poorly tuned responses of the basal basilar membrane and the sharply tuned responses of afferents innervating the same cochlear region led to the belief that a "second filter," presumably located in the hair cells, must further filter the mechanical responses before encoding takes place in the cochlear nerve (Evans and Wilson, 1975).

4.2.3 Physical Basis of Passive Cochlear Mechanics. In addition to measurements of basilar membrane responses to sound, Békésy also measured the static compliance of the basilar membrane; he accomplished this by sealing the helicotrema, applying hydrostatic pressure to scala tympani, and measuring the deformation of Reissner's membrane at various locations. As might be expected from the longitudinal variations in basilar membrane width and thickness, Békésy found that at the cochlear base the (narrow and thick) basilar membrane is relatively stiff, becoming progressively more elastic toward its (wider and thinner) apical end. The variation of basilar membrane elasticity as a function of distance (amounting to a ratio of 1 to 100 between the extremes of the human cochlea) is thought to be the physical characteristic that dominates the passive aspects of the hydrodynamics of the cochlea. Accordingly, mathematical and hardware models of the cochlea that consist of little more than two fluid-filled chambers separated by a membrane with smoothly varying elasticity are able to mimic, at least qualitatively, the main features of cochlear motion observed by Békésy in cadaver ears, including the existence of displacement waves that travel from base to apex and a tonotopic or-

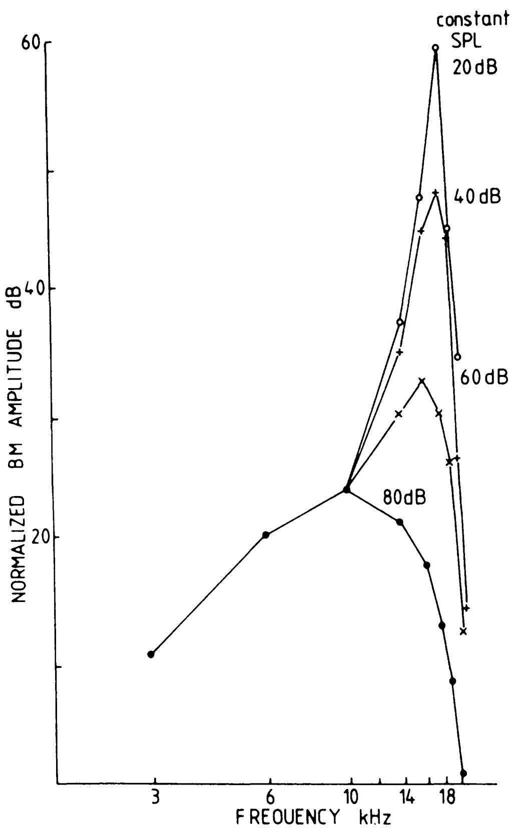

FIG. 15. Frequency response of the guinea pig basilar membrane at a site 3.4 mm from the cochlear base. Displacement gains (i.e., displacement magnitudes divided by stimulus levels) are expressed in decibels. Note that sensitivity near CF diminishes at higher stimulus levels (parameter). Because of this (frequency-selective and nonlinear) change in sensitivity, the frequency response is sharply tuned at low stimulus levels and poorly tuned at high levels. Reproduced with permission from Johnstone *et al.* (1986), Fig. 4.

ganization, with high-frequency responses localized to the basal end.

4.3 Active Aspects of Basilar Membrane Motion

4.3.1 Basilar-Membrane Nonlinearities and their Lability. The earliest indication that the metabolic state of the cochlea might be crucial in determining basilar membrane response came from experiments by Rhode (1971) in the cochleae of live (anesthetized) squirrel monkeys, using the then new Mössbauer technique. This technique, based on the detection of the Doppler shift of gamma radiation due to motion, permits the measurement of much lower velocities (e.g., 0.1 mm/s, equivalent to 1.6 nm at 10 kHz) than is possible using classical microscopy. In many monkeys, Rhode found that basilar membrane responses to near-CF tones grew with stimulus intensities at rates lower than linear, while response growth was linear at other frequencies. Because of the frequency-selective nature of the (compressive) nonlinearity, basilar membrane responses were more sharply tuned for low-level stimuli than for high-level ones (see Fig. 15). Most significantly, the CF responses became linear and less sensitive after the death of the animal, while off-CF responses remained largely unchanged (see Fig. 16).

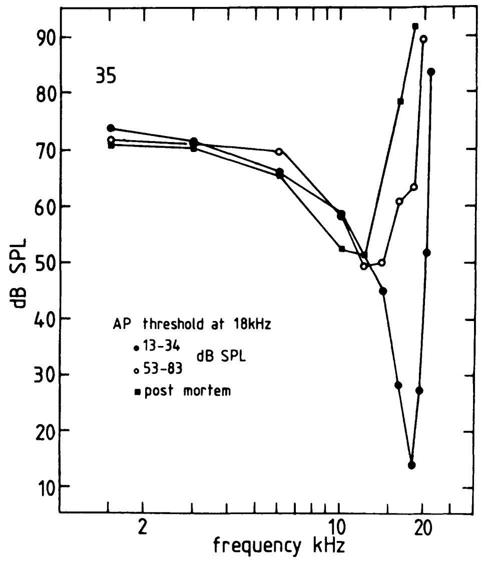

FIG. 16. Correlation between basilar membrane tuning and neural thresholds in a guinea pig cochlea. The basilar membrane recording site is near that of Fig. 15. The isovelocity curves indicate sound pressure levels, as a function of frequency, required to elicit a basilar membrane velocity of 0.04 mm/s. The state of the cochlea was assessed by recording the threshold levels for evoking compound action potentials ("AP": the synchronized response of many cochlear afferents) in response to tone pips with frequency identical to the CF of the basilar membrane recording site. Initially, the basilar membrane was sharply tuned (closed circles) and neural thresholds, accordingly, were low (13–34 dB SPL); as neural thresholds rose (53–83 dB SPL), basilar membrane responses deteriorated (open circles) and tuning was nearly lost. A further basilar membrane response loss at CF occurred upon the animal's death (squares). Reproduced by permission from Sellick *et al.* (1982), Fig. 15(b).

For about a decade, Rhode's findings were controversial because they could not be replicated (e.g., Evans and Wilson, 1975). In retrospect, it is evident that what prevented replication was irreversible damage to the cochlea caused unwittingly by experimenters during their surgical manipulations preparatory to mechanical recordings from the basilar membrane. Eventually, however, the nonlinear growth of near-CF basilar membrane responses was confirmed, first in the guinea pig (Sellick *et al.*, 1982) and then in the chinchilla (Robles *et al.*, 1986). Figure 15 shows response magnitude curves, as a function of frequency, for a healthy guinea pig basilar membrane site located 3 mm from the basal end. In order to facilitate comparison of tuning and sensitivity as a function of stimulus level, the curves have been normalized to stimulus magnitude (i.e., they are presented as gain curves, with the parameter being stimulus level). At moderate and intense stimulus levels, the tuning is broad. At low stimulus levels, however, responses are sharply tuned because of the selective sensitivity increase at near-CF frequencies; responses at off-CF frequencies are linear and remain constant.

Figure 16 demonstrates that, even before death of the animal, deterioration of the 3-mm guinea pig cochlear site, as indicated by threshold elevation of the compound response of the cochlear nerve ("AP threshold"), is accompanied by loss of sensitivity of the basilar membrane mechanical response at near-CF (18 kHz) frequencies. The sensitivity loss, which amounts to more than 40 dB, converts the normal, highly frequency-selective tuning curve into a shallow band-pass curve, reminiscent of those obtained by Békésy in human cadavers. The fact that the mechanical sensitivity loss occurs at near-CF frequencies also suggests a unifying explanation for the CF specificity of the effects of hair cell loss and olivocochlear efferent stimulation upon cochlear afferent responses (Secs. 2.5 and 2.6): it is hypothesized that both of these effects arise ultimately from alterations of the basilar membrane mechanical response.

4.3.2 Mechanical Origin of Cochlear Afferent Response Properties. Although it has not yet been directly shown that the effects upon cochlear afferents of outer hair cells loss or activation of the olivocochlear efferent system are due to underlying parallel effects upon the basilar membrane, it is clear that the normal frequency selectivity of cochlear afferent responses derives, largely or entirely, from mechanical (i.e., basilar membrane) frequency tuning. This is illustrated in Fig. 17, which shows the frequency tuning of the basilar membrane at a site 3.5 mm from the basal end of the chinchilla cochlea, together with an average neural tuning curve derived from responses of cochlear afferents with appropriate CF (about 8.4 kHz). Comparison between the neural and mechanical tuning curves suggests that, at neural threshold, the basilar membrane peak displacement is about 2 nm; at the behavioral hearing threshold, presumed to be 20 dB lower than neural threshold (Fig. 2), basilar membrane displacement would be 0.2 nm. Although very small, this estimate (equivalent to the diameter of a hydrogen atom or 1/50 of the thickness of a neuron's plasma membrane) is more than two orders of magnitude larger than the threshold displacement derived by extrapolation from Békésy's measurements in cadaver cochleae. Excellent matches between neural and mechanical tuning curves have been demonstrated in guinea pig (Sellick *et al.*, 1982) and cat (Khanna and Leonard, 1982), as well as chinchilla. It seems, therefore, that the previously hypothesized "second filter" (Sec. 4.2.2) is unnecessary, since the sharpness of tuning appears to be fully established in the "first" filter, i.e., the basilar membrane. In the same manner that the sharp frequency selectivity of cochlear afferent responses originates in basilar membrane mechanics, a mechanical counterpart of neural two-tone suppression (Sec. 2.4.1) also exists at the level of the basilar membrane: it is possible to reduce the basilar membrane response to a CF tone by introduction of a second tone with frequency either above or below CF, which may or may not cause basilar membrane vibration when presented alone (Robles *et al.*, 1989). As is the case for sharp frequency selectivity and nonlinear growth of responses, two-tone suppression in the basilar membrane is physiologically vulnerable, being reduced by cochlear deterioration and disappearing after the animal's death.

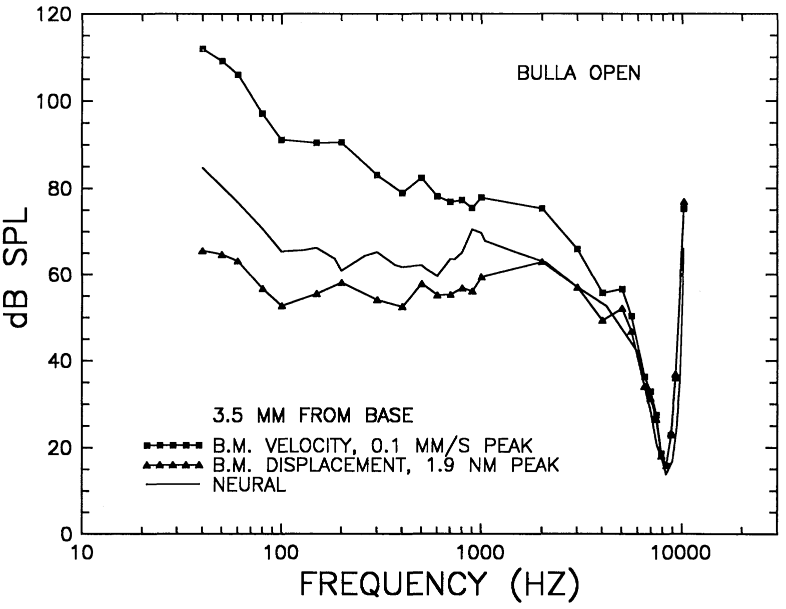

FIG. 17. Comparison of frequency tuning in the basilar membrane and in the auditory nerve of the chinchilla. The basilar membrane data, presented as both isovelocity (0.1 mm/s, square symbols) and isodisplacement (1.9 nm, triangular symbols) curves, are averages of recordings from five chinchillas at sites about 3.5 mm from the basal end of the cochlea. The neural curve (no symbols) is an average of recordings from many cochlear afferents with CFs close to that of the basilar membrane recording site. There is an excellent match between neural and mechanical tuning but it is unclear whether neural tuning is more closely related to basilar membrane displacement or to its velocity. Slightly modified from Ruggero *et al.* (1990), Fig. 22.

4.4 Hair Cell Receptor Potentials

In the absence of effective stimulation, inner and outer hair cells are electrically polarized across their plasma membrane, their cytoplasm being 45 and 70 mV, respectively, negative relative to the fluid that bathes their basolateral surfaces, or −125 and −150 mV relative to the endolymph that contacts their stereocilia. Upon displacement of their stereocilia bundles along their axis of symmetry (Sec. 4.1), hair cells respond by depolarizing or hyperpolarizing, depending on whether the displacement is toward the vertex of their "v" or away from it, respectively (Russell *et al.*, 1986). These electrical potential changes result from modulation of standing currents, carried by potassium ions, that flow passively across the apical surfaces of hair cells, from the endolymph (with its high positive potential) into their (negative-potential) cytoplasm (see reviews by Nuttall, 1986, and Roberts *et al.*, 1988). In the case of outer hair cells there is little doubt that basilar membrane displacement moves their bodies, hence causing shearing of the stereocilia tips against the tectorial membrane (Davis, 1965); thus, displacement of the basilar membrane toward the scala vestibuli leads to displacement of the stereocilia tips toward the "v" vertex, causing depolarization, while basilar membrane displacement toward scala tympani causes hyperpolarization. Such response polarity is in accordance with the firm attachment between the tallest outer hair cell stereocilia and the tectorial membrane; it is also in agreement with the radial position of outer hair cells in the region of the basilar membrane where transverse motion is greatest. In the case of the inner hair cell, the situation is unclear: their stereocilia are not firmly attached to the tectorial membrane and may not contact it at all; in addition, since inner hair cells are located at the edge of the bony spiral lamina, their bodies may move little upon basilar membrane displacement. Stimulation of inner hair cells, therefore, may be mediated by motion of the endolymph or the tectorial membrane.

Whatever the exact micromechanical mode of their stimulation, inner and outer

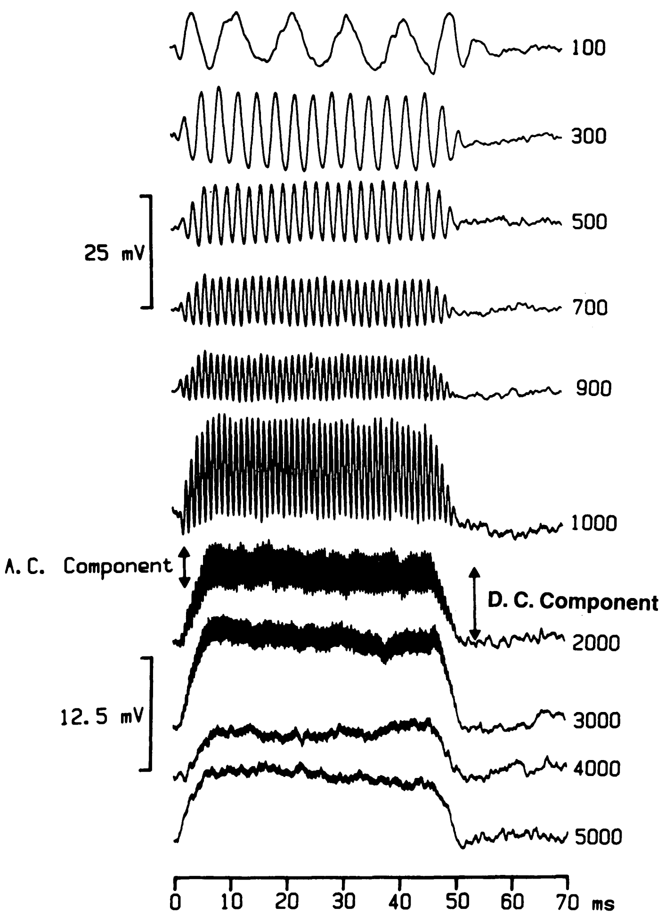

FIG. 18. Inner hair cell receptor potentials in response to tone pips. The hair cell was located at the base of a guinea pig cochlea and had a CF close to that of the inner hair cell in Fig. 19. The frequency (in Hz) of the tone-pip stimulus is indicated at the right of each trace. The lower ordinate scale applies to the bottom five traces. Note that the ac component is insignificant in responses to the higher-frequency tone pips. Reproduced by permission from Palmer and Russell (1986), Fig. 9.

hair cells respond to acoustic stimuli with intracellular voltage oscillations that, to some extent, mimic the stimulus waveshape (Fig. 18). The inner hair cell recordings of Fig. 18 were obtained from the same (basal) region of the guinea-pig cochlea from which the basilar membrane data of Figs. 15 and 16 were obtained. When the acoustic stimulus consists of a low-level, low-frequency tone pip (e.g., 300 Hz, top of Fig. 18), the intracellular voltage response consists of a relatively faithful replica of the stimulus. Such ac response is believed to account for the phase-locked responses of cochlear afferents; as in chemical synapses elsewhere in the nervous system, action potentials are triggered principally during the depolarizing half cycle of the receptor potential. As the stimulus frequency is raised, the ac voltage response diminishes progressively, probably as a result of capacitive shunting across the hair cell's plasma membrane. Nevertheless, high-CF inner hair cells are able to signal the presence of high-frequency acoustic stimuli by means of a (nonlinear) depolarizing dc shift. The frequency-dependent shift from an ac-dominated response to a dc-predominant response matches the progressive frequency-dependent deterioration of phase locking in high-CF cochlear afferents (Palmer and Russell, 1986).

By measuring the stimulus levels at which a given depolarization magnitude is attained as a function of frequency, it is possible to construct receptor-potential tuning curves comparable to those for the responses of cochlear afferents (Figs. 2, 7, and 9) or of the basilar membrane (Figs. 16 and 17). Such iso-response curves are presented in Fig. 19 for an inner hair cell from the basal end of the guinea pig cochlea. For dc responses of 2.7 mV, the inner hair cell is sharply tuned to a CF of about 23 kHz. For higher dc-response levels, tuning becomes less prominent be-

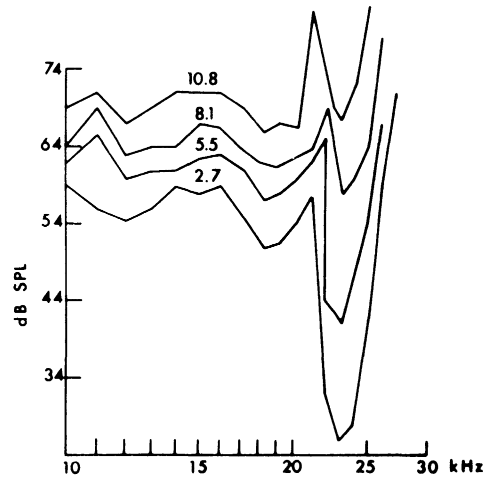

FIG. 19. Isopotential tuning curves for the dc responses to tone pips of a guinea pig inner hair cell. The parameter indicates the magnitude of the dc voltage response. Note the dissimilar rates of response growth at frequencies near CF and at lower frequencies; also note the sharper frequency tuning at lower response levels. Reproduced by permission from Russell and Sellick (1977), Addendum, Fig. 2(d).

cause responses at near-CF frequencies grow at slower-than-linear rates, while responses at other frequencies grow linearly. In most respects, including frequency tuning, the responses to sound of outer hair cells are similar to those of inner hair cells. Comparison of low-level dc tuning curves (such as those in Fig. 19) with threshold tuning curves of cochlear afferents with the same CF indicate that the frequency selectivity of cochlear afferents is a direct reflection of that of the inner hair cells they innervate. A further generalization is possible: with few exceptions, each inner hair cell's response to sound is an accurate voltage analog of the instantaneous rate of firing in cochlear afferents that innervate it. The most important exception is the absence of adaptation in hair cell potentials; adaptation of cochlear afferent responses, which is believed to arise at the chemical synapses between inner hair cells and cochlear afferents (Sec. 2.2.2), causes the "overshoot" at the onset of neural responses to tone pips and some of the nonlinear intensity-dependent aspects of neural responses to clicks (Sec. 2.3).

Among cochlear-nerve response properties that have clear counterparts in the voltage responses of inner hair cells (reviewed by Nuttall, 1986) are two-tone suppression (Sec. 2.4) and the inhibitory effects of activation of the olivocochlear efferents (Sec. 2.6). In the case of electrical stimulation of the olivocochlear efferents, which causes CF-specific inhibition of inner hair cell responses, intracellular recordings have shown that no transmembrane current change accompanies efferent stimulation; this is what is expected, given the absence of efferent synapses upon inner hair cells. These findings are significant because they strengthen the conclusion (based on cochlear afferent recordings; see Secs. 2.5 and 2.6) that the outer hair cells can somehow determine the responses of Type I cochlear afferents. While other modes of action of outer hair cells upon inner hair cells are conceivable, the most parsimonious mechanism is one in which outer hair cells are able to alter the mechanical input to the inner hair cell transduction process.

4.5 The Cochlea as a Sound Generator

4.5.1 Otoacoustic Emissions. The discovery by Kemp (1978) of otoacoustic emissions, sounds that are emitted by the ear, was one of the central developments that revolutionized our understanding of inner-ear physiology during the last decade. Kemp showed that when the normal human ear is stimulated by impulsive-type sounds (clicks or short tone pips) the ear responds, after a fairly long delay (about 10–15 ms), by broadcasting narrow-band, usually low-frequency echoes (Fig. 20). As stimulus levels are raised, these echoes grow at less-than-linear rates and stop growing altogether (saturate) when they reach levels of about 20 dB SPL. Subsequent to Kemp's initial discovery, he and others have demonstrated, in many species, identical or related phenomena, which are collectively known as otoacoustic emissions (Zurek, 1985). Among the most spectacular, particularly when intense, are the narrowband spontaneous otoacoustic emissions. As their name implies, spontaneous otoacoustic emissions do not require an external stimulus and emanate continuously from the ears of a substantial proportion, indeed perhaps the majority, of humans and primates, and also from the ears of some other animals. An extreme instance among the latter is a dog that produces intense (60 dB SPL), high-pitched "whistles" from both of its ears, audible from across a quiet room (Ruggero *et al.*, 1984).

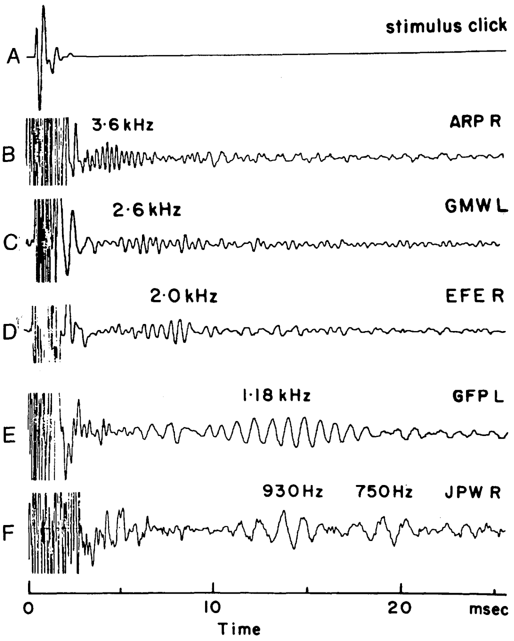

FIG. 20. Impulsively evoked otoacoustic emissions from human ears. The upper tracing indicates the time wave form of the acoustic-click stimulus. The lower five traces show averages of the acoustic wave forms recorded by microphones inserted in the external ear canals of the subjects (identified by name initials and "L" or "R" for left and right ear, respectively). Note that each ear produces different emissions and that lower-frequency emissions have longer latencies. Reproduced by permission from Wilson (1980), Fig. 2.

The more usual levels of spontaneous otoacoustic emissions, however, do not exceed 20 dB SPL.

While it is doubtful that spontaneous otoacoustic emissions play any role in normal hearing (and, in fact, there are reasons to believe that they may result from minor pathology of the organ of Corti), their existence is highly significant: it demonstrates that biological (biochemical) energy can be transduced in the ear into mechanical energy (i.e., sound). Indeed, upon stimulation by low-frequency tones (<2000 Hz), the cochlea responds by broadcasting tones at the same frequencies. The existence of such low-frequency emissions, known as "stimulus-frequency otoacoustic emissions," suggests that the cochlea may be capable of producing echoes to sounds throughout the audible frequency spectrum. The ability to generate sound implies the ability to generate motion. An important clue to the cellular nature of this motility is that subjects affected by sensorineural deafness (usually caused by hair cell loss) in a given frequency range lack otoacoustic emissions over the same frequency range, implying that hair cells are necessary for the generation of otoacoustic emissions.

Another clue to the origin of cochlear motility comes from the experimental manipulation of a fourth type of otoacoustic emissions, namely, distortion-product otoacoustic emissions. In Sec. 2.4.2 it was noted that cochlear afferents respond to certain pairs of tones (primaries) as if in fact three or four tones were present in the cochlea, namely, the two primaries plus one or two combination tones (Fig. 8). An acoustic correlate of such a phenomenon has been demonstrated in the external ear canals of humans and other animals: when two primaries (with frequencies f_1 and f_2) are presented, a sensitive microphone detects an extra (combination) tone, with frequency equal to $2f_1-f_2$. It is possible to alter the level of the combination tone by manipulation of the endolymphatic potential (Sec. 4.1.1) and, most significantly, by electrical stimulation of the crossed olivocochlear efferent system (Mountain, 1980). Since these efferents terminate mostly upon outer hair cells (see Sec. 4.1)—the remainder of their innervation being upon afferents, which can hardly be expected to act as effectors—it is concluded that the synaptic activity of the efferent terminals upon outer hair cells is capable of altering cochlear mechanics. A corollary is that outer hair cells must be motile (i.e., capable of self-induced or active motion), at least to the extent that they are capable of transducing a synaptic (chemical) efferent effect into pressure or displacement.

4.5.2 Outer Hair Cell Motility. Demonstration that outer hair cells are indeed motile, at least under certain circumstances, has been obtained in experiments in which the organ of Corti has been disaggregated into its cellular components and studied microscopically. When isolated outer hair cells are exposed to an electric current generated between two extracellular electrodes, they respond mechanically by shortening or lengthening, depending on the polarity of the current. Identical stimuli fail to cause motion responses in inner hair cells or in supporting cochlear cells (Brownell *et al.*, 1985). If the electrical stimulation consists of ac current, outer hair cell motion can follow the stimulus, albeit with amplitudes that are inversely related to its frequency, at least up to 8000 Hz (Ashmore and Brownell, 1986). There are many as yet unspecified details of the hypothetical feedback mechanism whereby the outer hair cells might act as frequency-tuned motion amplifiers. Nevertheless, the outer hair cell motility demonstrated *in vitro* goes a long way in accounting for the existence of otoacoustic emissions, the fragility of the sharply frequency-tuned response of the basilar membrane, and the hitherto poorly understood but undeniable role of outer hair cells in several other cochlear phenomena (see review by Dallos, 1988). In particular, if it is presumed that the motile response of the outer hair cell is responsible for boosting the low-level, near-CF responses of the basilar membrane *in vivo* (which has not yet been shown directly), then the apparent paradox posed by the frequency-specific effects upon cochlear afferents both of outer hair cells loss and of electrical stimulation of the olivocochlear efferents (see Secs. 2.5 and 2.6) is resolved thus: both effects are mediated by removal or alteration of the feedback normally provided by the outer hair cells upon basilar membrane motion; the altered basilar membrane motion causes concomitant changes in the receptor potential of the inner hair cells and in the responses of afferents that innervate them.

5. OVERVIEW OF THE CENTRAL AUDITORY SYSTEM

The remaining sections of this chapter, devoted to the central auditory system, are less extensive than the preceding account of the auditory periphery. This emphasis on peripheral, rather than central, auditory processes is admittedly disproportionate, because the connections of the auditory centers of the brain are vastly more complex and numerous than are those in the auditory periphery; however, the focus on the periphery is necessitated at present by our still limited understanding of central auditory mechanisms. The central auditory pathways are arguably the most complicated of all sensory systems. Even a simplified diagram of the major neural pathways (Fig. 21) reveals a maze of connections, loops, and branches: pathways conveying information from each ear converge at multiple levels of the brain and each terminus receives inputs from multiple sources. What cannot be appreciated from the diagram is the considerable heterogeneity of structural and functional properties within each central auditory nucleus. Presumably, the divergence and convergence of the multiple pathways permit the abstraction, within the auditory nuclei, of various features of the acoustic stimulus and, ultimately, their synthesis into the percepts embodied in the hearing sensation.

Our account of the central auditory system begins with an outline of the structural features of the principal auditory centers of the brainstem (in ascending order: the cochlear nuclear complex, Sec. 6; the superior olivary complex, Sec. 7; the midbrain, Sec. 8; and the auditory thalamus and cortex, Sec. 9). These sections provide a basis for Sec. 10, which deals with many of the functional aspects of central auditory processing, including responsiveness to frequency, level, sound location, and complex sounds. Although it is more usual to treat central auditory system physiology on a structure-by-structure basis, examining the properties of neurons at each level of the system in isolation from other levels, we shall adopt a perspective encompassing the entire central auditory system, comparing properties at different levels. The chapter concludes with a discussion of centrifugal auditory pathways (Sec. 11) that may regulate the afferent flow of acoustic information.

6. THE COCHLEAR NUCLEAR COMPLEX

After entering the brainstem, each auditory nerve fiber branches to provide innervation to three divisions of the ipsilateral cochlear nuclear complex (Fig. 22): one branch goes to the anteroventral cochlear nucleus (AVCN), while the second branch projects to the posteroventral cochlear nucleus (PVCN) before ascending to innervate the dorsal cochlear nucleus (DCN). The fiber bifurcation occurs ventrally for low-CF fibers and progressively more dorsally for higher-CF fibers. Each fiber then terminates in an orderly fashion, as illustrated in Fig. 22, to maintain its relative position within the frequency matrix

FIG. 21. A simplified diagram of the central auditory system, illustrating some of its many branches and connections. Only primary ascending pathways are shown, although many secondary and descending projections are recognized. For clarity, and because pathways are generally routed to the contralateral side of the brain, projections are shown as arising from a single ear. At higher levels on the left side (gray background) only connections with the contralateral hemisphere are shown. Broken lines indicate minor pathways. (and, hence, its relative location within a map of the cochlear partition). Because the input to each division of the cochlear nuclear complex derives from the entire cochlea, each division contains a complete spatial representation of stimulus frequency. This tonotopic order is maintained in the ascending outputs of the cochlear nuclear complex and throughout the ascending central auditory pathways.

The three divisions of the cochlear nucleus project to higher levels of the auditory system in three major fiber bundles (Fig. 21). Although there are sparse projections that ascend the auditory system on the same side, the three major tracts are directed medially and contribute to pathways that ascend primarily on the contralateral side. One tract, the ventral acoustic stria, carries fibers destined for binaural interaction at the core nuclei of the superior olivary complex. Another tract, the intermediate acoustic stria, provides input to "periolivary" regions surrounding the core binaural nuclei. The third tract, the dorsal acoustic stria, bypasses the superior

olivary complex entirely and has endings in the nuclei of the lateral lemniscus and in the inferior colliculus.

The projections arising from the cochlear nuclear complex originate from morphologically distinct neuron types. For example, the core binaural nuclei of the superior olive are innervated by neurons with bushy dendritic fields located in AVCN. Fibers of the dorsal acoustic stria arise primarily from fusiform neurons of the DCN whose dendrites are organized in a pyramidal form. A distinctive cell type of the PVCN, with a dendritic field described as octopus-shaped, sends its axon via the intermediate acoustic stria to the periolivary regions of the superior olivary complex. Thus, morphological specialization within the cochlear nuclear complex is associated with divergence in the pattern of its efferent pathways: the input provided by each auditory nerve fiber gives rise to multiple pathways that perform specialized functions in the processing of acoustic signals.

7. THE SUPERIOR OLIVARY COMPLEX

The superior olivary complex (Fig. 23) consists of three core nuclei—the lateral superior olive (LSO), the medial superior olive (MSO), and the medial nucleus of the trapezoid body—and several periolivary nuclei. The MSO and LSO provide the first opportunity in the auditory system for information received by the two ears to be compared and, hence, they may play a role in sound localization. In most species, the MSO is a thin sheet of elongate neurons whose dendritic fields appear bipolar when viewed in the frontal plane. As illustrated in Fig. 23(c), the major dendrites extend medially and laterally across the width of the nucleus, giving MSO the appearance of a highly organized stack of neurons. The LSO has a somewhat similar structure, but the neural sheet is folded [Fig. 23(b)]. The principal cells of LSO extend their dendrites in a bipolar fashion, perpendicular to the curvature of the nucleus. In both MSO and LSO, axons conveying information from the left ear project to the dendritic pole oriented towards the left, while axons derived from the right side influence dendrites oriented towards the right.

As illustrated schematically in Fig. 23(a), each neuron in MSO receives input from AVCN of both cochlear nuclear complexes (Warr, 1982). MSO neurons are sensitive to differences in the time of arrival of sounds at each ear, one of the major cues for sound localization. Although LSO is also a major site for binaural interaction, a direct projection from the cochlear nucleus comes only from the ipsilateral side [Fig. 23(a)]. Input derived from the contralateral ear comes indirectly via the third core nucleus of the superior olivary complex, the medial nucleus of the trapezoid body. It is generally assumed that the ipsilateral innervation has an excitatory influence whereas the contralateral input is converted to an inhibitory influence at the medial nucleus of the trapezoid body. The probability of an action potential being generated is increased by excitation and decreased by inhibition. Excitation and inhibition are indicated, respectively, as "+" and "−" in Fig. 23(a).

8. THE AUDITORY MIDBRAIN

8.1 Nuclei of the Lateral Lemniscus

The large tract of fibers known as the lateral lemniscus (Fig. 21) contains fibers from several sources in the cochlear nuclear and superior olivary complexes. Many of these fibers terminate at the inferior colliculus, but many also innervate the ventral and dorsal nuclei of the lateral lemniscus, two loose aggregations of neurons within the homonymous fiber tract. The ventral nucleus of the lateral lemniscus receives a strong projection from the contralateral cochlear nuclear complex, whereas the dorsal nucleus of the lateral lemniscus receives significant input from the ipsilateral medial superior olive and from both lateral superior olives (Glendenning and Masterton, 1983). The difference in the innervation patterns of the ventral and dorsal nuclei of the lateral lemniscus result in a major functional difference: the vast majority of neurons in the ventral nucleus respond only to stimulation of the contralateral ear, whereas those in the dorsal nucleus are usually binaural (Brugge *et al.*, 1970).

8.2 The Inferior Colliculus

The inferior colliculus is a prominence on the dorsal aspect of the midbrain. Its largest subdivision is the central nucleus (ICC), an ovoid core of densely packed cell bodies. Principal neurons are organized into a series of parallel sheets separated by afferent fibers, giving the central nucleus a laminated appearance. The dendritic fields of most neurons add to the lamination by ramifying only within the plane of their local neuronal sheet (Morest and Oliver, 1984). The ICC is the primary midbrain relay in the ascending auditory system and receives input from many sources in the lower brainstem (Fig. 21): contralaterally from the three divisions of the cochlear nuclear complex and the other inferior colliculus; ipsilaterally from the medial superior olive and ventral nucleus of the lateral lemniscus; and bilaterally from the lateral superior olive and dorsal nucleus of the lateral lemniscus (Aitkin, 1986).

Given its numerous sources of input, it is remarkable that ICC contains a single, very precise tonotopic organization. The foundation for this tonotopicity is the laminar organization: neurons within a given lamina have similar CFs; those located in dorsal laminae have low CFs and those located at successively more ventral sites have progressively higher CFs. Surrounding the ICC are fields of more diffusely distributed neurons that are not part of the primary auditory system and respond poorly to tones. Laterally, there is a region in which neurons responsive to sounds are intermingled with others sensitive to touch (Aitkin, 1986).

Most neurons in ICC project ipsilaterally via the brachium of the inferior colliculus to innervate the principal auditory relay of the thalamus, the ventral division of the medial geniculate body. Some fibers cross the midline in the commissure of the inferior colliculus and either ascend to the contralateral auditory thalamus or descend to innervate the contralateral inferior colliculus (Calford and Aitkin, 1983). In addition to the primary projection from ICC to the ventral division of the medial geniculate body, fringe regions of the inferior colliculus provide secondary projections to the dorsal and medial divisions of the medial geniculate.

9. THE AUDITORY THALAMUS AND CORTEX

9.1 The Medial Geniculate Body

A common parcellation scheme for the auditory thalamus divides the medial geniculate body into ventral, medial, and dorsal divisions. The ventral division contains cells of medium size organized in a laminated pattern similar to that found at the inferior colliculus. Intermingled with these principal cells, whose axons project to the auditory cortex, are interneurons with short axons that ramify only locally within the ventral division. These interneurons apparently modulate the activity of the principal cells by inhibitory circuits. Physiologically, the ventral division is characterized by sharp frequency tuning and tonotopicity. In contrast, the large, multipolar neurons of the medial division are often characterized by broad frequency tuning and complex response patterns that include habituation and variable discharge rate (Aitkin, 1973). Habituation and variability are also evident in responses of neurons in the superficial regions of the dorsal division, but sharper tuning and reliable, short latency responses can be found in deep dorsal regions (Calford and Aitkin, 1983).

9.2 The Auditory Cortex

The final destination in the primary central auditory pathway is the auditory cortex. Like the auditory midbrain and thalamus, the auditory cortex consists of a primary core surrounded by secondary fields. The primary auditory cortex (AI) is organized into functional cylinders or "columns" extending orthogonal to the cortical surface. Neurons in a given column usually respond to the same narrow band of frequencies. Columns representing similar frequencies are aligned, giving rise to a tonotopic organization of isofrequency slabs. In the cat, the species for which there is the most complete data concerning auditory cortex, there may be as many as seven cortical fields surrounding AI (Fig. 24); of these, the "anterior," "posterior," "ventral," and "ventro-posterior" fields are known to be organized tonotopically. In addition, there is a "secondary" auditory field (AII in Fig. 24) containing neurons that respond poorly to tones or have very broad frequency tuning. Little is known of the physiology of other auditory cortical fields.

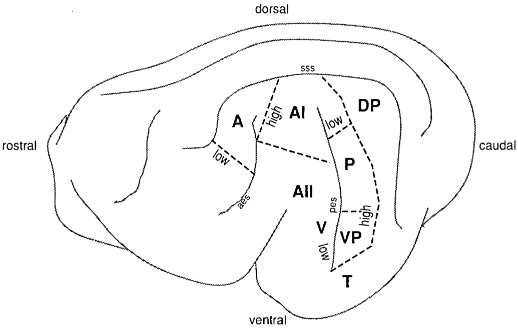

FIG. 24. A lateral view of the left cerebral hemisphere of the cat, showing the auditory cortical fields and their frequency organization. For the four tonotopic fields (A, AI, P, and VP), CF progressions from low to high are indicated, respectively, by "low" and "high." Significant portions of some fields are hidden within the three sulci (i.e., infoldings of the cortical surface): suprasylvian (sss), anterior ectosylvian (aes), and posterior ectosylvian (pes). Adapted from Imig and Reale (1980), Fig. 1.

Each cortical field receives input from multiple sources in the thalamus, but while the ventral division of the medial geniculate body provides the predominant source of input to the primary auditory cortex (AI), the nonprimary thalamic auditory nuclei figure more prominently in projections to the nonprimary auditory cortical fields. Apparently reflecting these differences in sources of input, auditory cortical neurons located in the fields surrounding AI often have lower discharge rates and greater response variability than are typical of AI. In addition to thalamocortical projections, there are numerous intracortical connections among the auditory cortical fields, and AI provides a significant projection within the corpus callosum to the contralateral AI (Imig and Reale, 1980).

9.3 Some Behavioral Consequences of Cortical Lesions

One way to explore the function of a brain structure is to examine the consequences of its removal. A striking result of extensive damage to the auditory cortex of both hemispheres is that a variety of auditory discriminations involving manipulations of pitch and loudness remain largely unimpaired. Deficits consequent to bilateral auditory cortical lesions include disturbances in detection of the duration of tone pips and the temporal patterning of tone sequences. It has been argued (Elliott and Trahiotis, 1972) that the common feature of such deficits is that they involve the differential response to more than one type of change in the auditory environment. One of the more profound deficits of unilateral auditory-cortical ablation is the inability to localize sounds in the contralateral sound field (Jenkins and Masterton, 1982).

10. RESPONSE PROPERTIES IN THE CENTRAL AUDITORY SYSTEM

10.1 Discharge Patterns

In contrast to the relative homogeneity of response patterns in the auditory nerve (Sec. 2), discharge patterns of central neurons are diverse. Patterns similar to those of auditory nerve fibers (Fig. 4) occur within lower brainstem nuclei, but are rare at levels above the midbrain. Even within the cochlear nucleus several other response types are common. An example of a "primarylike" pattern recorded in the superior olivary complex is shown in Fig. 25(a). A second pattern commonly observed in the cochlear nucleus and superior olive, but rarely seen at higher brain levels, is the "chopper" [Fig. 25(b)]. This pattern is characterized by regular, evenly spaced peaks that are reminiscent of phase locking. However, chopper peaks are not synchronized with the stimulus wave form, and the regularity is apparently generated by the resonant properties of the postsynaptic neural membrane (Wu and Oertel, 1984). "Onset" responses [Fig. 25(c)] are relatively uncommon at lower levels of the auditory system, but become increasingly more prevalent at higher levels. At auditory cortex, most responses in the anesthetized animal are of this form. The "pauser" pattern [Fig. 25(d)] is so named because of the pause in discharge that occurs just after the response onset. Pausers are common throughout the brainstem. Finally, there is the "buildup" pattern [Fig. 25(e)], which is unique in not containing a strong onset component. This pattern, seen at many levels of the auditory system, is most common in the dorsal cochlear nucleus.

Certain discharge patterns are well-correlated with cell morphology and innervation. For example, the primarylike patterns of spherical cells of AVCN are thought to arise from the specialized morphology of their input: a large synaptic terminal, the end bulb of Held, that may completely encapsulate the cell body (Brawer and Morest, 1975). The function of such a synapse appears to be to preserve temporal information. At the level of the cochlear nucleus, the onset pattern is rarely observed outside the "octopus cell" region of PVCN. These neurons are thought to integrate convergent inputs from fibers of different CF, thus enabling them to respond over an unusually broad range of frequency and intensity, with very precise onset timing (Smith, 1988). Chopper responses are the most common pattern observed in the ventral cochlear nucleus, apparently arising in multipolar neurons receiving a myriad of small bouton endings, which may derive from a small number of cochlear afferent fibers (Rhode and Smith, 1986).

10.2 Phase Locking

The temporal synchronization known as phase locking, evident in the discharges of auditory nerve fibers in response to low-frequency stimuli (Sec. 2.2.2), is preserved to some extent in the discharges of many central neurons within the brainstem. The upper frequency limit for phase locking is reduced progressively at each higher level of the system. At the auditory midbrain, synchronization is evident only at very low frequencies, and at the thalamus and cortex it is essentially absent. Phase locking is thought to play a critical role in binaural processing within the brain. In the cochlear nucleus, the end bulbs of Held (Sec. 10.1) minimize degradation of the temporal information at the synapse upon

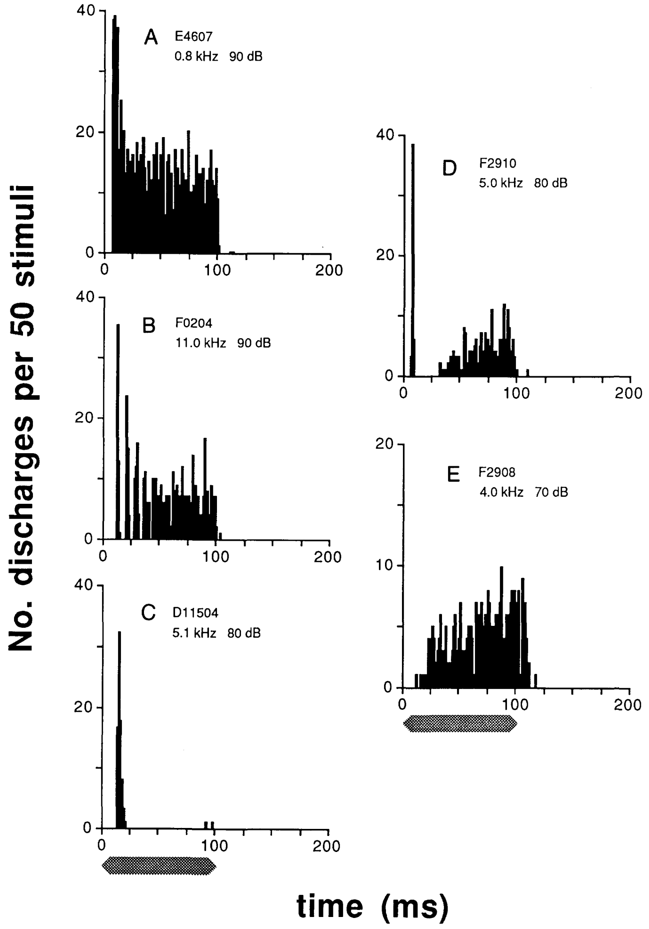

FIG. 25. Some discharge patterns of neurons in the superior olivary complex of the gerbil. Each post-stimulus-time histogram represents responses to 50 repetitions of a 100-ms CF-tone burst presented ipsilaterally at 2/s. The ordinate is the number of discharges per bin (see Sec. 2.2). Histograms illustrate five discharge patterns: (a) "primarylike," (b) "chopper," (c) "onset," (d) "pauser," and (e) "buildup." Unpublished data of M. N. Semple.

AVCN neurons. This permits the second-order fibers destined for binaural convergence in the superior olive to retain phase synchronization and hence to allow extraction of interaural phase difference information, a major cue for sound localization (Sec. 10.6.1). More generally, phase locking also offers a potential means for encoding low-frequency information, perhaps augmenting the frequency information inherent in the (tonotopic) central representation of cochlear place (Sec. 2.2.2).

10.3 Frequency Tuning

For a given CF, the frequency-tuning curves of most neurons of the primary (or principal) central auditory pathways are similar to those seen at the auditory periphery (Fig. 2), suggesting that frequency tuning in the central auditory system is essentially determined by the tuning at the basilar membrane (Fig. 17). Neurons whose responses reflect binaural influences usually have similarly tuned inputs from each ear (Semple and Kitzes, 1985). The sharp frequency tuning of the primary central pathways is contrasted by broad and sometimes quite irregular tuning in regions of the surrounding, diffuse auditory system (Secs. 8.2, 9.1, 9.2), such as the medial division of the auditory thalamus (Aitkin, 1973). Specification of a single CF is often difficult in these nonprimary areas.

When spontaneous activity is sufficiently high, it is possible to demonstrate that excitatory threshold tuning curves of many central neurons are flanked by inhibitory areas. These inhibitory sidebands, which can occur above and/or below the excitatory band, may serve to sharpen the excitatory tuning. Frequency selectivity at suprathreshold levels, assessed by determining discharge rate as a function of frequency for a variety of SPLs, is usually similar to that of auditory nerve fibers (Sec. 2.2.1 and Fig. 3). In some neurons, however, the frequency dependence of discharge rate varies considerably with SPL, so the "best" frequency can be more level dependent than is the case in cochlear afferents.

10.4 Response Latency

Response latency reflects mechanical delays within the cochlea (Sec. 2.3 and 4.2.1), conduction time along ascending axons, and the delay at each synapse. Thus, the minimum latency to the initial discharge at primary auditory cortex is several milliseconds longer than that occurring in the cochlear nucleus. For most central auditory neurons, the initial discharge latency is negatively correlated with stimulus level. For a given SPL, the latency is minimal at CF and becomes progressively longer as the frequency departs from CF. The effects of these determinants of latency are evident in Fig. 26 for a neuron recorded in the anteroventral cochlear nucleus.

The relative latency of responses in a population of stimulated neurons could well play a part in central processing, such as in the coding of level differences at the two ears, a cue for sound direction. The monotonic relationship between stimulus level and response latency suggests that when the information derived from each ear converges on a central cell, interaural level sensitivity could be achieved through a mechanism of temporal comparison.

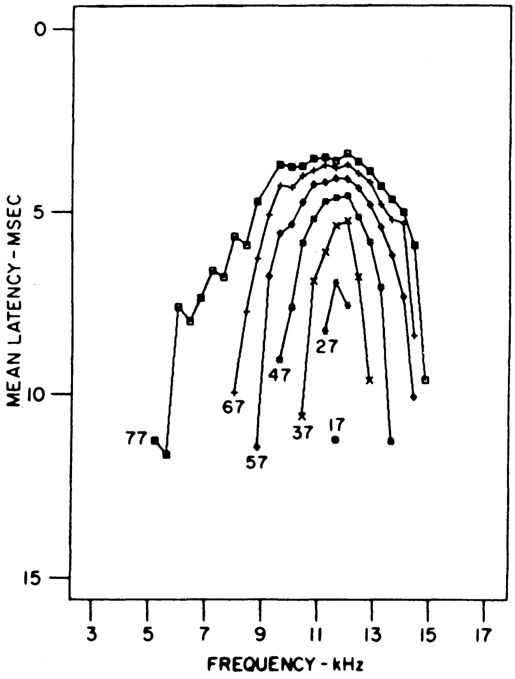

FIG. 26. Mean initial discharge latency as a function of frequency and SPL for a neuron from the anteroventral cochlear nucleus of the cat. As is typical of central auditory neurons, shorter latencies occur at higher SPLs and near CF. Data based on 50 presentations of a 50-ms tone burst at 4/s. Reproduced with permission from Kitzes *et al.* (1978), Fig. 1(b).

10.5 Level Sensitivity

The auditory system is extremely sensitive to sound level. A young and healthy human listener has a dynamic range of about 120 dB. The neural mechanism underlying this ability has long been an issue of contention. A single auditory nerve fiber representative of the majority (about 84%; Liberman, 1978) characterized by high (> 18 spikes/s) or medium (0.5–18 spikes/s) spontaneous rates has a dynamic range of only about 20–40 dB (Sec. 2.2), some 80–100 dB short of the dynamic range of behavioral discrimination. A broader dynamic range could be encoded by a population of fibers, each responding over different ranges of sound pressure level. This could be achieved if CF thresholds were broadly distributed, allowing recruitment of new fibers as a function of increasing stimulus strength. However, CF thresholds among high-spontaneous-rate fibers are uniformly low and occupy a very restricted range: for a given CF region, thresholds are contained within a range of about 10 dB (Liberman, 1978). The CF thresholds of medium-spontaneous-rate fibers are slightly higher, but they too have a quite restricted CF threshold range (about 15 dB for a given CF region), implying that even considered collectively the majority of auditory nerve fibers can encode only a limited dynamic range at relatively low SPLs. The encoding of higher SPLs may well depend on the smaller group of auditory nerve fibers characterized by low spontaneous rates. These fibers have relatively high CF thresholds with a 20–50 dB range for a given CF region and, in addition, have especially wide dynamic ranges. The operating range

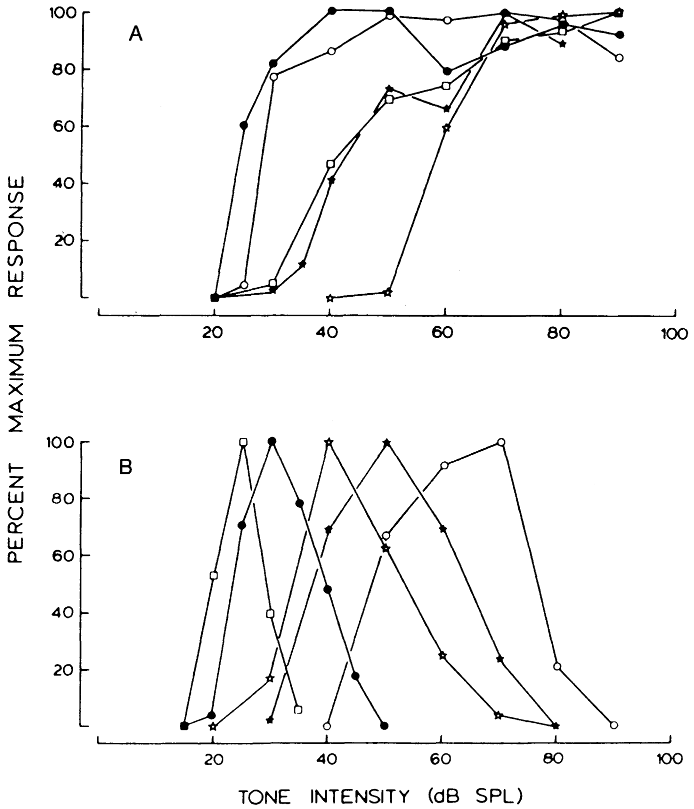

FIG. 27. Representative examples of (a) monotonic and (b) nonmonotonic rate-level functions, derived from primary auditory cortex in the cat. Discharge rates derived from 50 repetitions of CF tones are normalized. Reproduced with permission from Phillips *et al.* (1985b), Fig. 1.

may be extended further by progressive recruitment, at higher stimulus levels, of fibers tuned to lower and higher frequencies. Finally, it should be noted that the onset component of responses to sound can encode a much wider dynamic range than can the steady state component (Smith, 1988).

Perhaps the most striking transformation in level sensitivity within the central auditory system is the generation of nonmonotonic rate-level functions, in which discharge rate increases from threshold to some critical stimulus level, above which the rate declines. Although nonmonotonic rate-level relationships occur occasionally in the auditory nerve, the change in discharge rate is characterized by an abrupt decrease followed by a rapid recovery occurring within a very narrow range of SPLs (Kiang, 1984). By contrast, within the central auditory system the reduction in discharge rate can occur within 10 dB of threshold, is typically more gradual, and is not followed by a recovery of the rate at higher SPLs. In the lower brainstem, nonmonotonic responses are limited to DCN, but are very common at higher levels of the auditory system (e.g., approximately 50% of inferior colliculus neurons respond nonmonotonically; Semple and Kitzes, 1985). The mechanism for this phenomenon seems to be a convergence of excitation and inhibition tuned to the same frequency with the inhibitory threshold being higher. Examples of monotonic (a) and nonmonotonic (b) rate-level functions representative of primary auditory cortex in the cat (Phillips *et al.*, 1985b) are shown in Fig. 27. Note that for the monotonic functions [Fig. 27(a)], discharge rate rises from threshold to saturation within a variable range (10–40 dB). A similarly variable range exists for both the rising and falling slopes of nonmonotonic functions. Because each nonmonotonic function has a single, "best" SPL associated with peak responsiveness, and because best SPLs can vary considerably among a population of neurons, it has been suggested that intensity might be encoded centrally by a population of neurons tuned to a broad range of stimulus levels (Brugge and Merzenich, 1973).

Although the dynamic range of most central auditory neurons does not differ appreciably from that of most auditory nerve fibers, there are exceptions: some neurons of the cochlear nuclear complex, for example, respond over a wide range of levels, occasionally exceeding 80 dB (Rhode *et al.*, 1983). These neurons are characterized by transient discharge patterns and often by broad frequency tuning, suggesting that the broad rate-level functions result from convergence of cochlear fibers of different CFs.

10.6 Binaural Sensitivity and Mechanisms for Sound Localization

10.6.1 Binaural Cues for Sound Localization. Although sound localization is possible with only one ear, binaural cues significantly enhance localization resolution. Because of diffraction and reflection by the head, torso, and ears, sound waves rarely stimulate the left and right cochlea equivalently. Interaural differences in time and amplitude provide information about the location of a sound source. The interaural level difference (ILD) arises from sound scattering by the head and torso, coupled with the directionality of the pinnas (Sec. 3.1 and Fig. 11). Since these interactions are significant only when the physical dimensions of the body parts are large in relation to the incident wavelength, ILD is of biological relevance only at relatively high frequencies. Although under most conditions there is a considerably greater change in ILD with horizontal displacement than with vertical displacement, ILD does not specify a direction uniquely in either plane: a given ILD is produced by several angles of incidence.

The second major binaural cue is the interaural time difference (ITD), which depends on the difference in path length and the consequent difference in arrival time of the incident wave at each ear. For low frequencies, ITD is approximated by the equation

$$\mathrm{ITD}=\left(\frac{3a}{c}\right)\sin\theta_{\mathrm{inc}}, \qquad (1)$$

where a is the radius of a sphere approximating the head, c is the ambient speed of sound, and θ_{inc} is the angle of incidence (Kuhn, 1987). Interaural time differences are greatest for lateral angles of incidence at low frequencies. As a cue for source direction, ITD becomes ambiguous at high frequencies: when the period is less than the maximum possible interaural delay, a given phase disparity can occur for multiple angles of incidence.

Interaural time and amplitude disparities for low-frequency sounds are adequately approximated by modeling the head as a rigid sphere (Kuhn, 1987). At higher frequencies, however, the pinna becomes highly directional and reflections within the pinna and auditory meatus produce spectral maxima and minima (Fig. 11). For sounds incident in the midsagittal plane of the head, there are minimal interaural disparities. If the head, torso, and ears are perfectly symmetrical, disparity is zero. However, vertical displacement does change the spectral interference patterns at the ears and localization is possible in this plane if the sound is spectrally rich. In fact, artificial manipulation of spectral maxima and minima has been shown to produce the perception of shifts in the elevation of the sound source (Watkins, 1978). Thus, spectral cues are considered a third major source of directional information.

10.6.2 Central Processing of Binaural Information. Since each auditory nerve contains information that is exclusively monaural, the nervous system can only utilize binaural disparity cues by central comparison. As discussed earlier (Sec. 7 and Fig. 23), the first site of central comparison is the superior olivary complex. Neurons in the medial superior olive are sensitive to the relative phases of the stimuli at the two ears. The influence of ITD on the responsiveness of a typical MSO neuron is shown in Fig. 28(a). Discharge rate is a cyclic function of interaural delay, with a period equivalent to that of the stimulus wave form. Superimposed on the rate/delay function is a plot of vector strength, a measure (with a range from 0 to 1.0) of the magnitude of phase locking. Optimal delays produce maximum discharge rates and high vector strengths; unfavorable delays produce low discharge rates and low vector strengths. Sensitivity to ITD in the MSO arises from the convergence of phase-locked inputs from the anteroventral cochlear nuclei: ipsilateral inputs terminate on lateral dendrites of MSO neurons, while contralateral inputs terminate on medial dendrites. Optimal binaural stimulation occurs when the phase-locked discharges

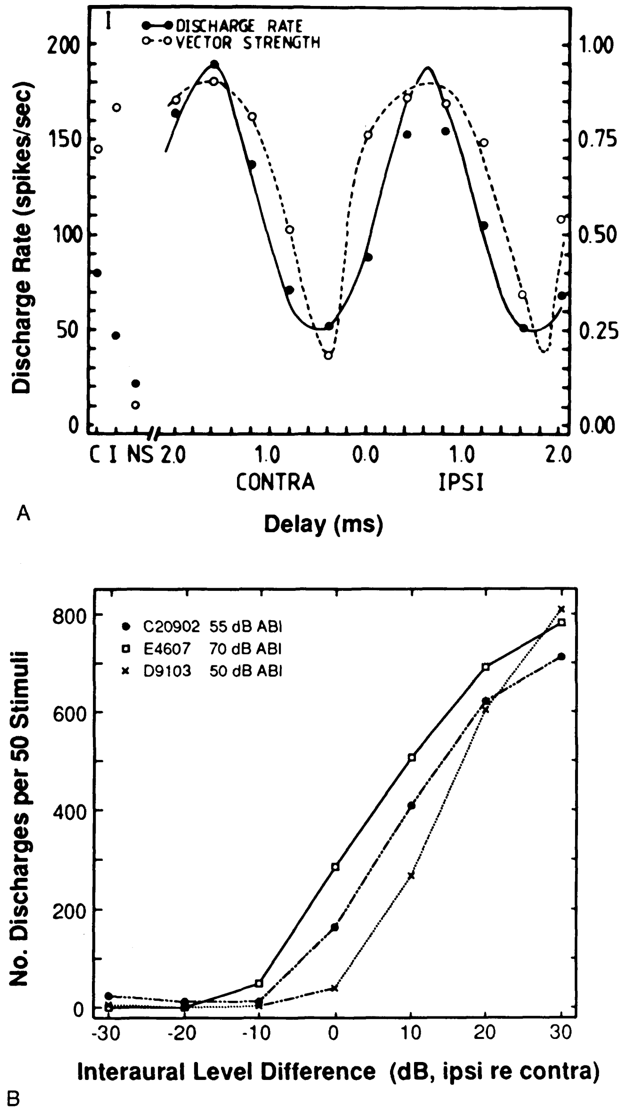

FIG. 28. Neural sensitivity to (a) the interaural time difference and (b) interaural level difference. (a) Discharge rate and phase synchrony (vector strength) are plotted as functions of interaural delay for a medial superior olivary neuron in the dog. Stimulus was a CF tone of 444.5 Hz at 70 dB SPL. Points at left of abscissa are the discharge rates for monaural contralateral (C), ipsilateral (I), and no stimulus (NS). Slightly modified, with permission, from Goldberg and Brown (1969), Fig. 8. (b) Number of discharges in response to 50 presentations of a 100-ms CF tone as a function of ILD for three neurons in the gerbil lateral superior olive. The average binaural level was maintained constant as ILD varied. The abscissa indicates the SPL at the ipsilateral ear minus that at the contralateral ear. The response is maximal when the excitatory (ipsilateral) input is relatively more intense and is reduced progressively as the ILD balance shifts to favor the inhibitory (contralateral) input. (Unpublished data of M.N. Semple.)

arrive simultaneously at the lateral and medial dendrites. Because the axons converging on a single MSO neuron are of unequal length, coincident arrival of the inputs does not necessarily occur at zero ITD: the optimal delay is different for different neurons. In addition, apparently because phase locking is limited to low frequencies (<4 kHz in most species), the CF distribution for ITD-sensitive neurons in MSO is biased towards low frequencies.

One useful system for classifying binaural responses is based on defining the monaural influences as either excitatory or inhibitory. Two major binaural classes are recognized: neurons receiving an excitatory input from one ear and an inhibitory input from the other ear are classified "EI"; bilaterally excitable units are classified "EE." At the superior olivary complex, the EI class is particularly sensitive to ILD and relatively insensitive to the mean binaural level, whereas the reverse is true for EE neurons (Goldberg and Brown, 1969). Sensitivity to the level difference potentially provides information about the angular displacement of the sound source relative to the ears of the observer, whereas sensitivity to mean binaural level provides intensity information that is less dependent on the incident angle. Thus, EI units may participate in the mechanisms for sound localization and EE units may be involved in the processing of intensity information. Within the superior olivary complex, the EE class is predominant for high-CF neurons within medial cell groups, including the medial superior olive (Goldberg and Brown, 1969), whereas EI neurons are dominant within the lateral superior olive (Tsuchitani, 1977). There is also evidence for differential distributions of EE and EI responses at higher levels of the auditory system (Semple and Aitkin, 1979). Figure 28(b) illustrates ILD sensitivity in three LSO neurons. In each instance, discharge rates are maximal when the SPL is greater at the ear providing excitation (i.e., ipsilateral), but the response diminishes progressively as the balance shifts in favor of the contralateral ear, whose influence is inhibitory. Consistent with the observation that ILD is most relevant for high-frequency signals, there is a marked skew toward high frequencies in the CF distribution of ILD-sensitive neurons within LSO and at other levels of the central auditory system.

Although the monaural responses of many neurons can readily be classified as excitatory or inhibitory, the responses of some neurons are more consistent with a monaural mixture of excitation and inhibition. Mixed monaural influences are more common at higher levels of the auditory system and are particularly apparent in responses of ITD-sensitive neurons, so the EE/EI classification is less useful for characterizing low-CF neurons. Mixed binaural interactions have also been noted for some high-CF neurons; thus, using a classification system closely related to the EE/EI scheme, Imig and his colleagues (1986) have identified three distinct types of topographically segregated binaural interaction in cat primary auditory cortex: regions of binaural summation, characterized by a greater response to stimulation of both ears than to stimulation of just one; regions of suppression, characterized by a reduction of responsiveness under binaural conditions; and regions of mixed interaction. An example of a suppression band in relation to the tonotopic organization of AI is shown in Fig. 29. Isofrequency lines from 4.9 to 22.7 kHz run vertically, with lower frequencies represented caudally (to the right in this figure). The elongated suppression band (solid outline) is oriented orthogonal to the isofrequency contours. Surrounding the suppression band is a belt in which interactions are summative.

The functional significance of cortical binaural bands remains unclear. They may well play a role in the central processing of sound source location and, accordingly, a given suppression band would presumably contain neurons sensitive to displacement in azimuth. However, these neurons would not respond exclusively to a specific spatial location and, hence, the band would not constitute a mapping of the acoustic field onto neural tissue. In fact, studies adopting the direct approach of presenting sounds from sources in the free field have failed to find neural maps of acoustic space in the central auditory system of the cat or other mammals. There is, however, convincing evidence for such a map in the barn owl (Konishi, 1986). The lower brainstem of this species contains two anatomically distinct pathways that respectively encode ITD and ILD. The convergence of these pathways at the auditory midbrain provides the basis for a representation of acoustic space. Individual neurons are selectively responsive to sounds deriving from a particular direction and are organized topographically; thus, sound emanating from a particular direction results in neural activation of a very limited region of the neural field.

10.7 Complex Sounds

10.7.1 Background Noise. The presentation of a tone against a background of broadband noise has different consequences for neural responses at peripheral and central levels of the auditory system. At both sites, background noise has the common effect of elevating tonal thresholds, but the threshold shift occurs equivalently across the frequency response area of auditory nerve fibers (Geisler and Sinex, 1980), whereas in cortical responses the shift is usually most pronounced at CF (Phillips, 1989). In most auditory nerve fibers, the threshold shift is accompanied by compression of the dynamic range for tonal stimuli: background noise elevates the baseline discharge rates of auditory nerve fibers, thus reducing the range of discharge rates available for encoding the intensity of the tone. In contrast, dynamic range compression rarely accompanies the noise-induced

FIG. 29. An example of a suppressive binaural band running orthogonal to the frequency organization of primary auditory cortex in the cat. A mapping electrode was inserted into the cortex many times, at different positions across the frequency organization of AI. At each recording site, the CF and the binaural interaction were determined. The low-to-high frequency progression in AI is from caudal to rostral (i.e., from right to left in this figure). Dashed lines indicate selected isofrequency contours; + and − indicate summative and suppressive interactions, respectively. Slightly modified, with permission, from Imig and Adrián (1977), Fig. 7.

threshold shift in auditory cortical neurons: cortical neurons do not respond tonically to continuous noise stimuli, so their full range of discharge rates remains available for encoding the tonal stimulus. In effect, the cortical neuron's discharge rate encodes the signal level not relative to an absolute sound pressure, but referenced to background (Phillips, 1989). In the minority of cortical neurons whose dynamic range for tonal stimuli is reduced by background noise, the compression is caused by an increase in the slope of the rate-level relationship. Hence, in contrast to auditory nerve fibers, these neurons have a greater range of discharge rates available for encoding the reduced dynamic range.

10.7.2 Amplitude and Frequency Modulation. There are clear differences in peripheral and central responses to amplitude modulation (AM) of the acoustic signal. Discharges in the auditory nerve are well synchronized to the wave-form periodicity of an AM signal over a broad frequency range (Smith and Brachman, 1980), but at higher levels of the central auditory system both the resolution and the upper limit of entrainment are significantly reduced (Creutzfeldt *et al.*, 1980). A major determinant of these differences is that each additional synapse in the ascending auditory pathway progressively adds temporal jitter, reducing the accuracy of entrainment to rapid temporal changes.

Neural responses to AM are customarily described using the so-called "temporal modulation transfer function," a measure that may be expressed in terms of rate or synchronization of the neural discharge as a function of modulation frequency. The modulation transfer functions of auditory nerve fibers are characteristically low-pass, regardless of

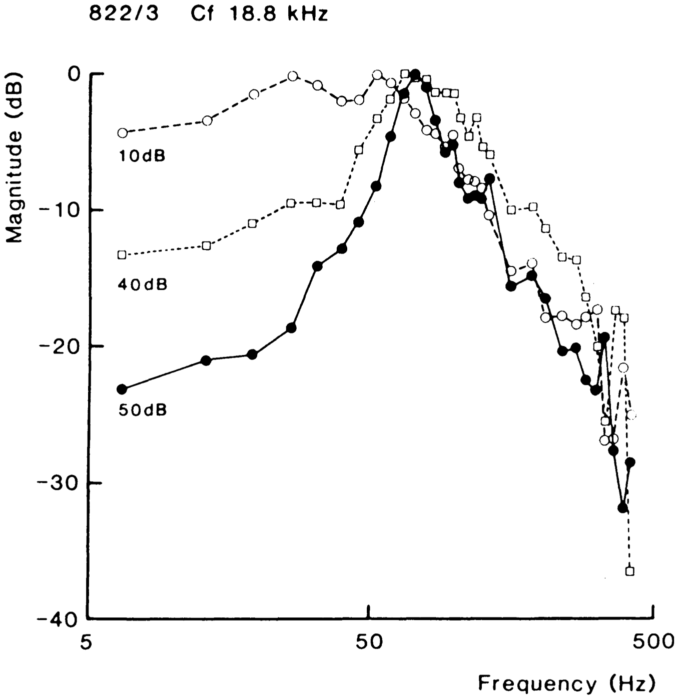

FIG. 30. Amplitude modulation transfer functions from a single neuron in the rat inferior colliculus, showing the effects of stimulus level. At three sound pressure levels, a CF tone carrier was amplitude modulated (depth 15% rms) with pseudorandom noise and presented for 5–10 min. Neural discharges were collected as 2048-bin histograms synchronized to the periodicity of the pseudorandom noise. Each histogram was then cross-correlated with the pseudorandom noise to yield a modulation transfer function. Reproduced with permission from Rees and Møller (1987), Fig. 2.

stimulus level, whereas those of at least some central neurons are quite level-dependent. Figure 30 provides an illustration of such level dependence in modulation transfer functions derived from a single neuron in the inferior colliculus of the rat (Rees and Møller, 1987); the response functions change from essentially low pass at 10 dB (i.e., comparable to the auditory nerve) to clearly bandpass at 50 dB. Modulation transfer functions of such neurons not only become more bandpass with increasing mean level, but their phase-locking peak is elevated to higher modulation frequencies. Hence, the concept of a "best modulation frequency," as proposed by some, is of limited utility.

Frequency modulation (FM), like AM, is an important component of speech and other complex sounds and, like AM, its representation is significantly transformed within the central auditory system. Within the auditory nerve, there is no sensitivity to the direction of a given FM sweep, nor is there any sensitivity to FM outside the steady-state (pure-tone) response area (Sinex and Geisler, 1981). Although the FM sensitivity of some central auditory neurons is similarly predictable on the basis of their responses to pure tones, for many neurons the influence of FM is more complex. Within the cochlear nuclear complex, the direction of modulation does not influence the responses of primarylike neurons, but many pauser, buildup, or onset neurons do respond asymmetrically to ascending and descending FM sweeps. The FM-induced responses of auditory cortical cells are frequently even more complex, with significant responsiveness occurring in frequency ranges outside the pure tone response area and many responses containing sharp sensitivity to the direction of modulation [Phillips *et al.*, 1985(a)].

10.7.3 Vocalizations. It may be argued that the most important acoustic stimulus is speech or, more generally, a species-specific vocalization. Conceivably, recognition of such vocalizations could be mediated by individual "feature-detector" neurons, each responding specifically to a particular vocalization feature. Of course, given a finite number of available neurons, the brain would be limited in the diversity of vocalizations that could be encoded by such feature detectors. An alternative, perhaps more likely, mechanism for the recognition of vocalizations may involve the integrated activities of many neurons, each responding somewhat broadly to components of the vocalization.

There appears to be a broad range of specificity in the responses of cortical neurons to vocalizations. Certain neurons are very sensitive to a small component of the vocalization or to the context in which the component occurs. For example, a neuron responding to a specific vocalization may not respond at all when the vocalization is played backwards (Glass and Wollberg, 1983), even though the spectral content of the stimulus is maintained. For other neurons, the temporal pattern of their discharge may be reversed or otherwise modulated.

11. CENTRIFUGAL INFLUENCES

The ascending components of the central auditory system, conveying acoustic information from the periphery to higher auditory processing centers, are complemented by a sizable system of descending projections whose role may be to regulate the incoming flow of information. Centrifugal control mechanisms may originate in auditory cortex and ultimately influence cochlear hair cells, via synapses at the inferior colliculus and periolivary regions. In addition, certain auditory reflexes (such as startling, pinna movements, and orienting responses) mediated via the brainstem may also be influenced by higher auditory centers (Aitkin, 1986).

11.1 Olivocochlear Efferent System

This projection arises bilaterally in the superior olivary complex and projects via the auditory nerve to terminate on cochlear outer hair cells and on the Type I afferents that innervate inner hair cells (Fig. 1 and Sec. 4.1.4). There are two separate (medial and lateral) subsystems of olivocochlear neurons (Warr *et al.*, 1986). The medial system arises near the medial superior olive from large neurons projecting via large axons that terminate on outer hair cells predominantly in the contralateral cochlea. Some of the medial olivocochlear axons branch en route to innervate the ventral cochlear nucleus, sometimes ramifying extensively within granule cell regions encapsulating the ventral cochlear nucleus. The lateral system arises in or near the lateral superior olive, from smaller cells whose fine-caliber axons terminate on Type I auditory nerve afferents, almost exclusively in the ipsilateral cochlea at the base of inner hair cells. Lateral olivocochlear fibers do not appear to provide collateral branches to the cochlear nuclear complex.

The functional significance of the two olivocochlear systems remains unclear. The efferent fibers terminate tonotopically and their responses to acoustic stimuli can be as sharply frequency-tuned as those of the cochlear afferents (Robertson and Gummer, 1985). The responsiveness of the efferent fibers is significantly depressed by anesthesia and, hence, the functions of the descending feedback systems in the awake and behaving animal might be difficult to infer from physiological studies that are usually conducted in anesthetized animals. The response-latency distribution of cochlear efferents is very broad, suggesting that efferent control of the cochlea may involve pathways arising at levels of the brain far higher than the superior olivary complex, perhaps at the cortex (Robertson and Gummer, 1985).

11.2 Other Descending Pathways

Each auditory cortical field sends descending projections to its source of input in the thalamus and to the auditory midbrain regions surrounding the central core nucleus of the inferior colliculus (Pickles, 1988). There are two major centrifugal projections arising in the inferior colliculus. One tract descends in the lateral part of the lateral lemniscus to innervate mostly nonauditory regions of the lower brainstem, whereas the second tract descends medially, terminating bilaterally in the dorsal cochlear nucleus and ipsilaterally in the periolivary area, apparently making contact with cells that give rise to the olivocochlear projection. The cochlear nuclear complex receives extensive descending input from several brainstem sources, including the contralateral cochlear nucleus, the periolivary nuclei bilaterally, the nuclei of the lateral lemniscus, and the inferior colliculus.

GLOSSARY

Acoustic Striae: Three fiber bundles projecting from the cochlear nuclear complex to higher levels of the central auditory system.

Action Potential: A brief all-or-none "depolarization" of the plasma membrane of a neuron that travels at speeds of tens of m/s along the neuron's axon; action potentials constitute the fundamental means of rapid signal transmission over long distances in the nervous systems of animals.

Afferent Neurons: Neurons that conduct "action potentials" from relatively peripheral locations, such as a sensory organ, toward more central locations.

Afferents: See "afferent neurons."

AI: The primary region of the "auditory cortex."

AP: See "compound action potential."

Apical: In cochlear anatomy, referring to the region of the cochlear "cone" near its apex.

Audiogram: The curve describing detection thresholds for tonal stimuli as a function of frequency.

Auditory Cortex: The auditory area of the cerebral cortex; it includes a primary region (AI) and several other regions.

Auditory Midbrain: See "inferior colliculus."

Auditory Nerve: See "cochlear nerve."

Auditory Reflex: An involuntary, prompt, and stereotyped muscular response to sound.

AVCN: Anteroventral cochlear nucleus, one of the three divisions of the "cochlear nuclear complex."

Axon: The typically long and thin process, emanating from a neuron's cell body, that conducts "action potentials" toward terminals that make synaptic contact with other neurons.

Basal: In cochlear anatomy, referring to the region of the cochlear "cone" near the oval and round windows.

Basilar Membrane: The relatively long and narrow membrane that lies between the "spiral lamina" and the "spiral ligament" of the cochlea and extends longitudinally from the cochlear base to its apex; upon it rests the organ of Corti, where the sensory "hair cells" reside.

Binaural Classification: Neural categorization based on the balance of excitation and inhibition received from the two ears; bilaterally excitable neurons are classified "EE" and those receiving an excitatory input from one ear and an inhibitory input from the other ear are classified "EI."

Caudal: Located "near the tail"; in brain anatomy, referring to locations towards the spinal cord; see "rostral."

CF: See "characteristic frequency."

Characteristic Frequency: The stimulus frequency to which an auditory structure ("basilar membrane," "hair cell," or "neuron") is most sensitive.

Chemical Synaptic Transmission: The process whereby neurons or sensory cells, such as "hair cells," excite or inhibit the generation of "action potentials" by other neurons by releasing a specific chemical substance that diffuses across the narrow gap between the presynaptic and postsynaptic membranes.

Cochlear Nerve: The bundle of axons of "afferent" and "efferent neurons" that connects the cochlea to the brain.

Cochlear Nuclear Complex: The first auditory center in the brain, receiving input from the cochlea.

Compound Action Potential: The synchronized response of many cochlear "afferent neurons"; it can be recorded by an electrode in the vicinity of the cochlea.

Condensation Click: An acoustic pulse that causes a brief increase in air density near the "tympanic membrane."

Contralateral: Located in the opposite side of the body.

Cytoplasm: The cell substance outside its nucleus, bounded externally by the "plasma membrane."

dB: See "decibel."

DCN: Dorsal cochlear nucleus, one of the three divisions of the "cochlear nuclear complex."

Decibel: A dimensionless unit expressing the ratio of two values of power or pressure. One decibel equals 10 times the logarithm to the base 10 of the power ratio or, equivalently, 20 times the logarithm to the base 10 of the pressure ratio. A commonly used pressure reference in physiological and psychological acoustics is 0.0002 dyn/cm^2, which corresponds approximately to the lowest threshold of hearing in normal humans. When this reference is used pressures are referred to as "decibels sound pressure level," abbreviated as "dB SPL."

Dendrite: A relatively short projection from a neuron's cell body that receives synaptic inputs from other neurons.

Depolarization: Decrease in the negative intracellular electrical potential (e.g., from −60 mV to −40 mV) of neurons or sensory cells.

Discharge: Synonymous with "action potential."

Dorsal: Located in the back of a structure.

Eardrum: See "tympanic membrane."

EE and EI: See "binaural classification."

Efferent Neurons: Neurons that conduct action potentials from relatively central locations to more peripheral sites.

Efferents: See "efferent neurons."

Endocochlear Potential: The +80 mV electrical potential of the "endolymph" in the "scala media" of the cochlea.

Endolymph: The potassium-ion-rich fluid that occupies the "scala media" of the cochlea.

Excitation: In neural systems, a process that increases the probability of action potential generation.

Fiber: Synonymous with "axon."

Frontal Plane: Any plane orthogonal to the sagittal plane and parallel with the body's long axis; see "sagittal plane."

Hair Cells: Mechanosensitive sensory cells that transduce motion of their "stereocilia" ("hairs") into intracellular electrical potential changes.

Helicotrema: The site where "scala vestibuli" and "scala tympani" meet at the apical end of the cochlea.

Hyperpolarization: Increase in the negative intracellular electrical potential of neurons or sensory cells.

ICC: Central nucleus of the "inferior colliculus."

IHC: See "inner hair cells."

Inferior Colliculus: The auditory structure on the dorsal aspect of the midbrain, whose major component is the central nucleus (the primary midbrain relay in the ascending auditory system).

ILD: See "interaural level difference."

Inhibition: In neural systems, a synaptic process that decreases the probability of action potential generation.

Inner Hair Cells: The mammalian cochlear "hair cells" located in a single row on the modiolar side of the pillar cells of the organ of Corti; they are innervated by the "Type I cochlear afferent neurons," which collectively make up the main signal outflow of the cochlea.

In Vitro: In an artificial environment.

In Vivo: In the living body.

Interaural Level Difference: The difference in sound pressure level at the two ears, due to diffraction and reflection by the head, pinna, and torso; it provides a cue for sound localization, particularly at high frequencies.

ITD: See "interaural phase difference."

Interaural Phase Difference: The difference in phase of the acoustic stimulus wave form at the two ears, generated by differences in arrival time; it provides a cue for sound localization, particularly at low frequencies.

Lateral Lemniscus: A large tract of fibers connecting auditory centers in the lower brainstem to the auditory midbrain; it contains the nuclei of the lateral lemniscus.

LSO: Lateral superior olivary nucleus, one of the divisions of the "superior olivary complex."

Medial Geniculate Body: Part of a brain region known as the thalamus, it relays information between the auditory midbrain (inferior colliculus) and the auditory cortex.

Modiolus: The hollow, bony central axis of the cochlea.

MSO: Medial superior olivary nucleus, one of the divisions of the "superior olivary complex."

Neuron: The fundamental cellular constituent of the nervous system, made up of a cell body from which projections ("dendrites" and "axons") extend; it is specialized to integrate synaptic inputs at the cell body and dendrites, and to transmit "action potentials" to "axon" terminals that synapse upon other neurons or effector cells, such as muscles fibers.

Octave: The frequency interval between a frequency and twice its value.

OHC: See "outer hair cells."

Olivocochlear Efferent Neurons: Neurons that originate in the superior olivary region of the brainstem and terminate in the cochlea upon "outer hair cells" and "Type I afferent neurons."

Ossicles: See "ossicular chain."

Ossicular Chain: A series of three tiny bones ("ossicles") in the mammalian middle ear that transmits vibrations of the "tympanic membrane" to the "oval window" of the cochlea.

Otoacoustic Emissions: Sounds emitted by the ears of animals.

Outer Hair Cells: The mammalian cochlear "hair cells" located peripheral to the pillar cells in the organ of Corti; they are innervated by "Type II cochlear afferent neurons."

Oval Window: A membrane at the basal end of the "scala vestibuli" of the cochlea, against which the "stapes" footplate abuts.

Parcellation: Division or distribution into separate parts or regions.

Perilymph: The fluid that fills the "scala vestibuli" and the "scala tympani" of the cochlea; it is similar to other extracellular fluids, having high sodium-ion concentration and low potassium-ion concentration.

Periolivary: Surrounding the "superior olivary complex."

Pharynx: The sac connecting the back of the mouth and nose with the esophagus.

Phase Locking: The property whereby cochlear "afferents" and certain other auditory neurons respond preferentially to specific phases of low-frequency (<4 kHz) periodic stimuli.

Plasma Membrane: The outermost structure of living cells, consisting of a bimolecular lipid layer plus various other molecules; in neurons, the latter include proteins that act as receptors for chemical transmitters and as ion channels.

Poststimulus Time Histogram: A histogram depicting the time of occurrence of "action potentials" relative to stimulus onset.

PSTH: See "poststimulus time histogram."

PVCN: Posteroventral cochlear nucleus, one of the three divisions of the "cochlear nuclear complex."

Q_{10}: A measure of the sharpness of tuning of a frequency filter, defined as its center frequency divided by the 10-dB bandwidth.

Rarefaction Click: An acoustic pulse that causes a brief decrease in air density near the "tympanic membrane."

Rate-Level Function: The function relating the evoked neural discharge rate to the stimulus sound pressure level.

Receptor Potential: The graded changes in electrical potential evoked in sensory receptor cells by effective stimuli.

Reissner's Membrane: The cellular membrane that separates the "scala vestibuli" of the cochlea from the "scala media."

Rostral: Located "near the face"; in brain anatomy, referring to locations far from the spinal cord; see "caudal."

Round Window: A membrane at the basal end of the "scala tympani" of the cochlea, in contact with the middle ear cavity.

Sagittal: Parallel to the median plane of the body; see "frontal."

Scala Media: The "endolymph"-filled, inner membranous tube of the cochlea; it lies between "scala vestibuli" and "scala tympani."

Scala Tympani: The "perilymph"-filled cochlear tube which is separated from "scala media" by the "basilar membrane" and the organ of Corti, the "spiral lamina" and the "spiral ligament."

Scala Vestibuli: The "perilymph"-filled cochlear tube which is separated from "scala media" principally by "Reissner's membrane."

SOC: See "superior olivary complex."

Sound Localization: In a strict sense, referring to the detection of both the angle of incidence and distance of a sound source; in a more general sense, referring to the detection of angle of incidence only.

Spike: See "action potential."

Spiral Ganglion: Spirally shaped group of cell bodies of the cochlear "afferent neurons" located within the "modiolus."

Spiral Lamina: a bony shelf protruding radially from the cochlear "modiolus," whose edge provides the central attachment of the "basilar membrane" and through which the peripheral terminals of cochlear neurons travel on their way to the "hair cells."

Spiral Ligament: The cochlear structure whose edge provides the peripheral attachment of the "basilar membrane."

SPL: Sound pressure level; see "decibel."

Spontaneous Activity: Neural discharges occurring in absence of stimulation.

Stapes: The innermost middle ear "ossicle"; its footplate abuts against the "oval window" of the cochlea.

Stereocilia: The "hairs" of the "hair cells"; they consist of thin cylinders with a tightly packed core of protein fibrils, enveloped by "plasma membrane."

Sulcus (pl. sulci): Infolding of the cortical surface.

Superior Olivary Complex: a group of auditory nuclei located near the midline of the lower brainstem.

Synapse: The specialized cellular structure where communication between neurons takes place; see "chemical synaptic transmission."

Tectorial Membrane: A noncellular gellike flap which overlies the organ of Corti and makes contact with the tallest "stereocilia" of the "outer hair cells."

Tonotopicity: The property whereby stimulus frequency is mapped systematically onto space in the cochlea, the "cochlear nerve," and the auditory regions of the brain.

Transduction: In sensory systems, the conversion of a signal from one form of energy into another.

Tympanic Membrane: The membrane at the central end of the external ear canal; it is set in motion by sound waves.

Type I Cochlear Neurons: The cochlear "afferent neurons" that transmit signals from single "inner hair cells" to the cochlear nucleus; the "axons" of these neurons constitute the vast majority of those in the "cochlear nerve."

Type II Cochlear Neurons: The cochlear "afferent neurons" that innervate "outer hair cells" and project to the cochlear nucleus; these neurons constitute 5%–10% of cochlear "afferents."

Ventral: Located near the belly surface of a structure.

Volume Velocity: The rate of flow of the medium perpendicularly through a specified area.

Page 250. The first two sentences of section 10.7.1 Background Noise were incorrectly printed. They should read as follows:

The presentation of a tone against a background of broadband noise has somewhat different consequences for neural responses at peripheral and central levels of the auditory system. At both sites, background noise has the effect of elevating tonal thresholds, the threshold shifts being most pronounced at CF in responses of both auditory-nerve fibers (Geisler and Sinex, 1980) and cortical neurons (Phillips, 1989).

INTRODUCTION

Psychological acoustics is the study of hearing: the examination of how the auditory systems of humans and other animals process sound. The study of psychological acoustics closely parallels that of physiological acoustics. The basic difference between the two fields is that physiological acoustics is concerned with how various parts of the nervous system function in processing sound, while psychological acoustics investigates how the entire organism processes sound. Psychological acoustics seeks to establish functional relationships between the physical characteristics of the sound input and the behavioral output of the responding organism. These relationships often depend on knowledge gained from physiological acoustics about the function of individual neural elements, while information gained from psychological acoustics often shapes the types of questions asked by physiological acoustics. Historically the behavioral study of sensory processing has been called "psychophysics," after the man, 1974a), a 19th century physicist and philosopher. "Psychoacoustics" is the description of the psychophysical study of hearing.

1. THE AUDITORY CODE FOR SOUND

Hearing in humans and other organisms can be divided simplistically into three stages: coding, processing, and integration. "Coding" refers to those mechanisms that transduce the physical characteristics of sound into a neural code. "Processing" refers to the organization of the neural code. "Integration" refers to the integration of the organized neural information with information from other neural mechanisms, such as those dealing with other sensory input, memory, or motor output. Thus, recognizing a familiar melody begins with neural coding of the frequency, amplitude, and phase/timing characteristics of the acoustic wave form; this neural code is

FIG. 1. A schematic diagram depicting the various stages of sound processing assumed to occur within the peripheral auditory system. Sound is analyzed by a bank of bandpass filters with each filter having a different center frequency. The envelopes of the outputs of these bandpass filters are extracted through processes that mimic half-wave rectification and low-pass filtering. The analog nature of the vibratory signal is transduced to neural impulses where the rate at which the neural impulses occur is proportional to the frequency of the envelope rate. Certain processes accomplish various forms of temporal integration. The output of each bandpass filter is assumed to be a channel tuned to a particular frequency, carrying information about the intensity and timing/phase properties of the sound. In this figure the top row symbolizes a low-frequency channel and the bottom row a high-frequency channel. The actual processes are not necessarily organized in the manner depicted in the figure; however, these various aspects of sound processing are assumed to occur within the inner ear and bundle of nerves leaving the inner ear and traveling to the brain.

the melody; and then the organized code is integrated with memory and with other neural mechanisms allowing the listener to indicate that the melody is familiar.

Most of what has been studied in psychological acoustics, and, therefore, a great deal of what is known about hearing, concerns "coding." Less is known about "processing" and "integration." Figure 1 shows a simple, stimulus-processing model for establishing the neural code for sound. Sound waves vibrate the structures of the inner ear such that a spectral representation of sound is established, much as if the inner ear consisted of a bank of bandpass filters. The amplitude output of these filters is assumed to be squared, half-wave rectified, and low-pass filtered by processes that convert sound amplitude to energy and perform envelope extraction. The analog nature of these vibratory signals is converted to a digital code represented by all-or-none occurring neural impulses. Finally, some form of temporal integration is assumed to occur. The code for sound is a spectral code and many of the processes are nonlinear. The various processes described in Fig. 1 have been established by psychoacoustical and physiological experiments conducted over the past 100 years, and Fig. 1 contains components of the many "theories of hearing" (see Carterette and Friedman, 1974a, and Schubert, 1974) suggested over this period.

The neural output of the processes shown in Fig. 1 provides two types of codes for frequency: (1) the tuned channels containing the greatest amount of activity indicate which frequencies are present in the input (referred to as a "place code" for frequency), and (2) the periodicity of the neural activity in any one channel can code the periodicity and, hence, the frequency of the input (referred to as the "periodicity code" for frequency). Auditory neurons discharge in synchrony with the vibration pattern of the acoustic stimulus. Due to refractory limitations of neuronal function, such periodic information in a single nerve is available only up to approximately 5000 Hz. However, the nervous system may be able to extract timing information about an input stimulus for frequencies higher than 5000 Hz if it combines information from many similarly tuned neurons (referred to as the "volley principle," see Green, 1976).

Acoustic level is coded by increases in neural activity in any one tuned channel or from an increase in the number of tuned channels that are activated. Timing and phase information are coded by the time structure of the synchronous discharge firings of the neurons that make up the tuned channel.

The rest of this article will describe some of the basic characteristics of the auditory system as obtained from psychoacoustical data and will discuss some of the data that have been used to establish the model of coding shown in Fig. 1.

2. PSYCHOPHYSICS

A number of psychophysical paradigms have been established to measure the response of humans and animals to sound. When a human is asked, or an animal trained, to respond in a particular manner to sound, two classes of variables may affect the response: sensory variables and response bias variables (Watson, 1974). As an example, consider a situation in which a listener is asked to indicate if a tone has been presented. The tone may or may not be presented during a fixed trial marked by the onset and offset of a light and according to some random process. The listener indicates that the tone was present by saying "yes" and not present by saying "no." Thus, there are two possible stimulus situations (tone presented or tone not presented) and two responses ("yes" or "no"). Sensory variables are those dependent on processing the sound which might affect the response of the listener. Bias variables are all the other variables that may influence the listener to respond in a particular way (in this case to say "yes" or "no"). For instance, the properties of the assumed bandpass filters shown in Fig. 1 would be sensory variables. The instructions provided to the listener may be a bias variable. The instructions may be, "make sure the tone is present before responding 'yes,'" as opposed to, "respond 'yes' whenever the tone appears to occur." Under conditions in which the tone is not correctly detected 100% of the time, there would probably be more "yes" responses for the latter set of instructions than for the former. Clearly the number of "yes" responses depends on the instructions (bias) and on how the auditory system functions (sensory). Thus, unless the data are analyzed appropriately, measures of the listener's performance might reflect both types of variables (see Robinson and Watson, 1972).

Two general classes of psychophysical procedures are used to study sensory processing: *objective procedures*, usually used to measure thresholds; and *subjective techniques*, often used to obtain perceptual scales. Objective psychophysical procedures are designed to minimize or eliminate the influence of bias variables on the measured thresholds, while both bias and sensory variables can affect the listener's responses in subjective procedures. For instance, an objective psychophysical procedure would be used to measure the smallest difference in tonal frequency that a listener can discriminate. The smallest discriminable difference in frequency is called a threshold (in this case a difference threshold). A subjective procedure might be used to determine the perceived annoyance produced by aircraft noise. In this case, a scale of annoyance would be developed that might relate the magnitude of the perceived annoyance to the intensity of the airplane's acoustic output.

A threshold, as measured in objective psychophysical procedures, is obtained from a functional relationship between some measure of the listener's performance (e.g., percent correct in discriminating a low- from a high-frequency tone) and a physical measure of sound (e.g., the frequency difference between the low and high frequencies expressed

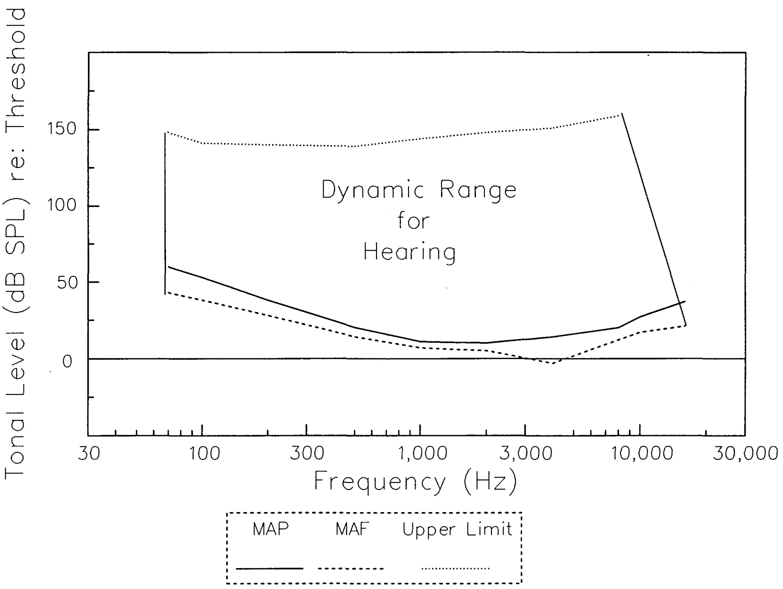

FIG. 2. The threshold levels (in dB SPL) for detecting the presence of a tone at different frequencies (MAP and MAF) are shown at the bottom of the figure, while the tonal levels leading to indications of damage to the auditory system (upper limit) are shown at the top of the figure. The two sets of functions define the dynamic range over which the auditory system operates. Thresholds in quiet have been measured when the tones have been presented from loudspeakers (MAF—Minimum Audible Field measures of thresholds) and over headphones (MAP—Minimum Audible Pressure measures of thresholds). Adapted from the data of Sivan and White (1933) as shown in Fig. 10.2 of Yost and Nielsen (1985).

in Hz). This function is called a "psychometric function." A threshold is the value of the physical measure (e.g., frequency in Hz) required for some arbitrary level of the listener's performance, chosen from the range of performance values between chance and perfect performance (e.g., 75% correct in discriminating a low- from a high-frequency tone). Thus, a threshold is a single stimulus value representing the approximate value for which the listener has difficulty performing the task. A threshold value is not an all-or-none level, meaning that if the stimulus exceeds the threshold the system always responds and if it is not exceeded the system never responds. This classical, all-or-none use of threshold is not supported by either psychophysical or physiological data (see Green and Swets, 1977). Rather, the performance of the listener represents a continuum, usually centered at the threshold, of the probability of responding.

Psychophysical scales can be obtained by a variety of subjective methods. In matching procedures, listeners are asked to adjust a physical variable (e.g., intensity) of one sound until this sound is judged to be subjectively equivalent (e.g., in loudness) to a standard sound. In magnitude estimation procedures, listeners are asked to estimate directly a subjective attribute of a sound by assigning numbers to the sound in proportion to the magnitude of the perceived perception (e.g., loudness). In both matching and scaling procedures, numeric scales are developed which relate the subjective perception (e.g., loudness) to a physical variable (e.g., sound level) (see Stevens, 1975).

3. ABSOLUTE SENSITIVITY TO SOUND

The absolute sensitivity of the auditory system to tones of different frequencies defines the frequency range over which the auditory system functions and determines the lower limit of sound pressure required for hearing. Thresholds for detecting the presence of sinusoidal tones are measured by two calibration methods using objective psychophysical paradigms. When sounds are presented over a loudspeaker, the thresholds are referred to as Minimal Audible Field (MAF) thresholds, while thresholds obtained from headphone-presented stimuli are referred to as Minimal Audible Pressure (MAP) thresholds. In the MAF procedure, the sound pressure level is measured in an anechoic (echo-free) room at the location where the listener would be (without the listener present). Both the direction of the sound relative to the listener and whether the listener uses one or both ears for listening determine the exact threshold values. In the MAP procedure, the sound pressure level is calibrated in an "artificial ear," which is a 6-cm^3 coupler affixed to the headphone. The artificial ear approximates the volume between the headphone and the eardrum, as well as simulating the combined acoustic impedance of the outer ear and eardrum for the average young listener. Thus, the MAP thresholds represent sound levels that would occur at the listener's eardrum, while the MAF thresholds represent those at the entrance to the outer ear.

The sound pressure levels are referenced to 20 micropascals (μPa), referred to as dB SPL (decibels of Sound Pressure Level); for instance,

$$20 \text{ dB SPL} = 20 \log(200\ \mu\text{Pa}/20\ \mu\text{Pa}),$$

where 200 μPa is the sound-pressure level being measured. 20 μPa is the international standard sound pressure level for the least intense sound the average young listener can detect. As a point of reference, the acoustic power represented by a sound pressure of 20 μPa (0 dB SPL), is approximately 20–30 dB more intense than the theoretic acoustic power existing at sea level due to thermal energy of the Brownian motion of air molecules (see Green, 1976). The term dB SL (SL for Sensation Level) is the level of sound relative to that measured for absolute threshold. Thus, the level of sound required for absolute threshold is determined and then used as the referent value for a SL decibel calculation.

Figure 2 depicts MAP and MAF thresholds as originally obtained by Sivian and White (1933), and Table 1 depicts standardized MAP thresholds. The standardized thresholds are used to determine hearing loss, and these procedures will be discussed in a later section of this chapter. The thresholds indicate that the human auditory system responds to frequencies over the range from 20 to 20 000 Hz and that the human auditory system is most sensitive to frequencies in the range of 1000–4000 Hz. The approximate 6-dB difference between the MAF and MAP measures of thresholds is due to the resonance, diffraction, and impedance properties of the outer ear and eardrum. Recall that MAF sound pressures are those at the entrance to the outer ear, while the MAP sound pressures are those at the eardrum.

Table 1. Standardized minimal audible pressure thresholds in dB SPL.

Frequency (Hz)	Range of thresholds[a]	Thresholds[b]
125	45.0–54.0	45.0
250	24.5–30.5	25.5
500	11.0–14.4	11.5
1000	6.5–8.0	7.0
2000	6.0–9.5	9.0
4000	3.5–13.5	9.5
6000	8.0–17.5	15.5
8000	9.5–20.5	13.0

[a] From American National Standards Institute (ANSI) 3.6-1989, American National Standard Specification for Audiometers, and ISO 389-1975, International Standards Organization (ISO) Standard Reference Zero for the Calibration of Pure-Tone Audiometers. A range of thresholds due to different headphones, cushions, and coupler combinations used in different countries.

[b] From ANSI 3.6-1989 for TDH-39 Headphones in a MX41/AR cushion and for a 9-A coupler.

The upper curve in Fig. 2 represents an estimate of the maximum sound pressure the human ear can tolerate. This estimate is obtained by increasing the level of a tone until the listener indicates that one of a number of sensations occurs: they "feel" the sound, there is a "tickling" sensation, or the sound is "uncomfortable." All of these sensations indicate that the sound pressure is close to the limit tolerated by the auditory system (a later section of this article will discuss some of the effects on hearing caused by intense sound presentations). The dynamic range of hearing can be as large as 120 dB, and the auditory system adapts to sound over this enormous range essentially instantaneously. A dynamic range of 120 dB exceeds that which can be achieved in almost all audio equipment.

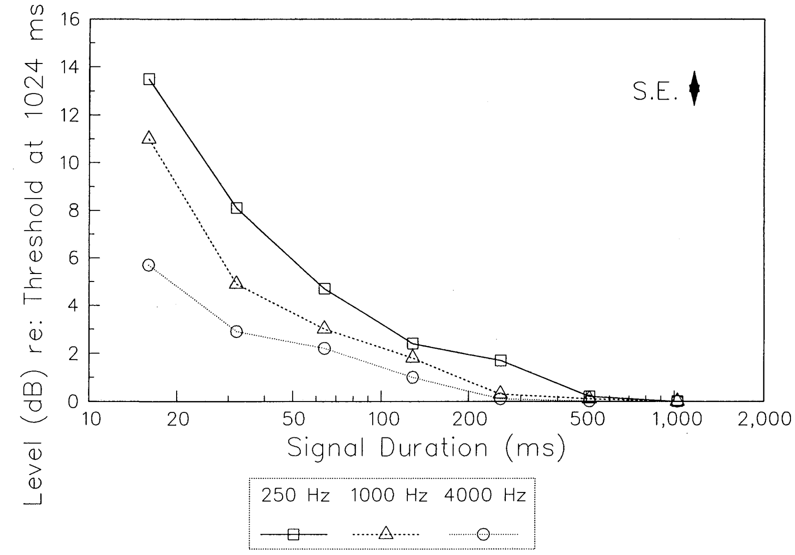

FIG. 3. The relative change in threshold level (in dB) required to detect the presence of a tone as a function of tonal duration. The change in thresholds is referenced to those obtained when the tones were 1024 ms long. Data for three frequencies (250, 1000, and 4000 Hz) are shown. As tonal duration decreases thresholds increase. The arrows labeled S.E. are an estimate of the standard error of measurement for these conditions and as such represent the expected variability about any data point. Adapted from the data of Watson and Gengel (1969) as shown in Fig. 10.3 of Yost and Nielsen (1985).

The thresholds displayed in Fig. 2 were obtained when the sounds were presented for half a second or longer. The thresholds forhearing are dependent on the duration of the sound, as shown in Fig. 3. When expressed as the total power of the signal, the thresholds decrease as duration increases to approximately 300 ms and then they remain constant as the duration is increased further. To a first approximation the thresholds change by approximately 10 dB for a tenfold change in duration down to durations of 20–50 ms; thus, between 50 and 300 ms the thresholds are actually total-equal-energy thresholds. At very short durations, the change in threshold is much steeper than 10 dB for a tenfold change in duration, and the slopes of the curves in Fig. 3 are frequency dependent.

The bandpass filtering, energy transformation, and temporal integration shown in Fig. 1 account for most of the effects of duration on absolute thresholds displayed in Fig. 3. As will be discussed in more detail in the section on masking, the auditory system is assumed to process information in channels (psychoacoustically referred to as "critical bands") narrowly tuned to each frequency, much as bandpass filters are tuned. Thus, detection of a tone is assumed to depend on the integrated energy in the channel tuned to the frequency of the tone. For detecting a pure tone, the integration time is assumed to be approximately 300 ms, accounting for the thresholds reaching an asymptote at a signal duration of 300 ms. For short durations, the energy of the signal is spread over a wider spectral range than that of the channel, which causes less energy to fall within the channel. If a certain amount of energy must be present within the channel for threshold performance, then the signal level must be increased at these short durations to obtain the necessary energy required for threshold. Thus, the increase in the slope of the functions in Fig. 3 at short durations is a result of energy spreading beyond the spectral region to which the processing channel is tuned. Because the spectral region over which the channels are tuned is different for each tuned channel, there would be a change in the thresholds as a function of frequency, resulting in the slopes of the functions changing with frequency as also shown in Fig. 3.

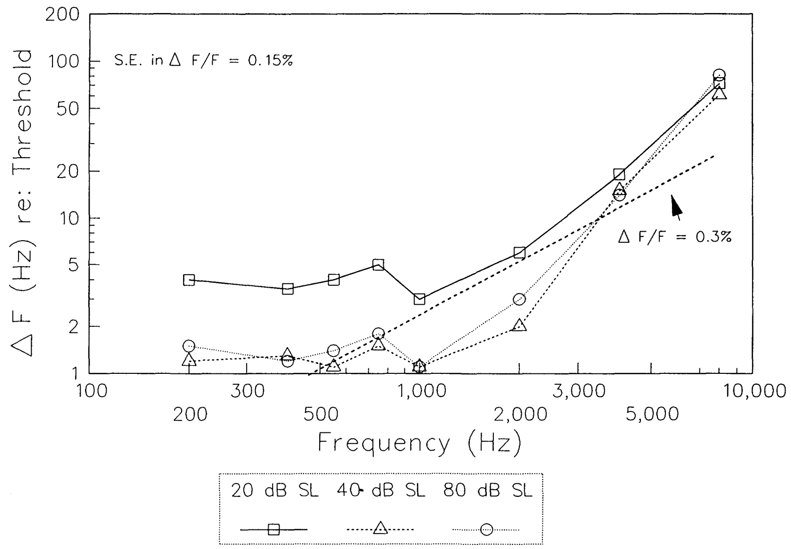

FIG. 4. The threshold for discriminating a change in frequency (Δ*F*) as a function of frequency. Data for three tonal levels (20, 40, and 80 dB SL) are shown. The dotted line labeled $\Delta F/F = 0.03\%$ indicates a Weber fraction showing a 0.03% change in frequency as a function of frequency. Below approximately 1000 Hz, a 1–2 Hz change in frequency can be discriminated, between 1000 and 5000 Hz approximately a 0.03% change in frequency is required for discrimination, and above 5000 Hz, frequency differences greater than 0.03% are required for discrimination. The Δ*F*/*F* labeled S.E. is an estimate of the standard error of measurement for these conditions and as such represents the expected variability about any data point. Adapted from the data of Weir, Jesteadt, and Green (1977) as shown in Fig. 10.6 of Yost and Nielsen (1985).

4. DIFFERENTIAL SENSITIVITY TO SOUND

The resolution of the auditory system can be estimated by measuring the smallest differences in frequency, sound level, and time that a listener can discriminate. The data plotted in Figs. 4–6 show the difference thresholds (sometimes labeled "just noticeable differences" or "jnds") for discriminating a change in frequency (*ΔF* as shown in Fig. 4), a change in sound level (*ΔI* as shown in Fig. 5), and a change in time (*ΔT* as in Fig. 6). As can be seen, the difference thresholds tend to increase as the variable under study increases. The ratio of the difference threshold to the variable (Δ*F*/*F*, Δ*I*/*I*, Δ*T*/*T*) is called the "Weber fraction." Over a significant range of frequency and intensity the Weber fractions for frequency (Δ*F*/*F*) and for sound level (Δ*I*/*I*) remain approximately constant. These data indicate that the resolution for discriminating a change in frequency is approximately 1–2 Hz for frequencies less than 1000 Hz and approximately 0.03% between 1000 and 5000 Hz. The threshold for discriminating a change in sound level for low and moderate level tones is approximately 1.0 dB [$10 \log_{10}(1+0.25)$]. Obviously the Weber fractions for frequency and sound level do not remain constant over the entire range of frequency and intensity. The departures of the data from a constant Weber fraction (sometimes referred to as the "near miss to Weber's law") are important for specifying completely the resolving capabilities of the auditory system (Laming, 1986).

The Weber fraction for time (Δ*T*/*T*) is constant only over a limited range of times, although the jnd (Δ*T*) does increase with increasing lengths of time. For all of these measures of discrimination, care must be used to ensure that the variable undergoing change is the only physical parameter actually varying. This is a difficult task when the duration of sound is changed. A sound's spectrum changes as a function of changing its duration. The auditory system is sensitive to the change in spectrum associated with a change in stimulus duration. Thus, the measure of time discrimination shown in Fig. 6 involves discriminating a change in the time separation between two pulsed noise stimuli.

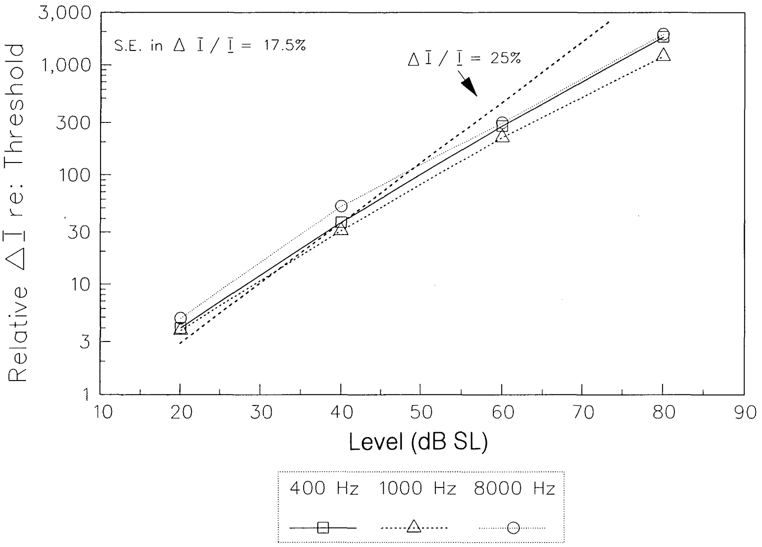

FIG. 5. The relative thresholds for discriminating a change in amplitude (ΔI) as functions of level (in dB SL). The values of ΔI were scaled such that 5 units of amplitude were required for threshold performance at 8000 Hz and 20 dB SL. Data for three tonal frequencies are shown (400, 1000, 8000 Hz). The dotted line labeled $\Delta I/I=25\%$ indicates a Weber fraction showing a 25% change in amplitude as a function of level. One can convert from $\Delta I/I$ for amplitude to the decibel difference between the two tonal levels being discriminated by $10 \log_{10}[1+(\Delta I/I)]$. A $\Delta I/I$ of 25% is approximately a 1-dB difference in tonal level. The $\Delta I/I$ labeled S.E. is an estimate of the standard error of measurement for these conditions and as such represents the expected variability about any data point. For tones presented at low stimulus levels listeners can discriminate approximately a 1-dB difference in level. At higher levels listeners can discriminate a smaller difference, representing a "near miss to Weber's law." Adapted from the data of Jesteadt, Weir, and Green (1977) as shown in Fig. 10.8 of Yost and Nielsen (1985).

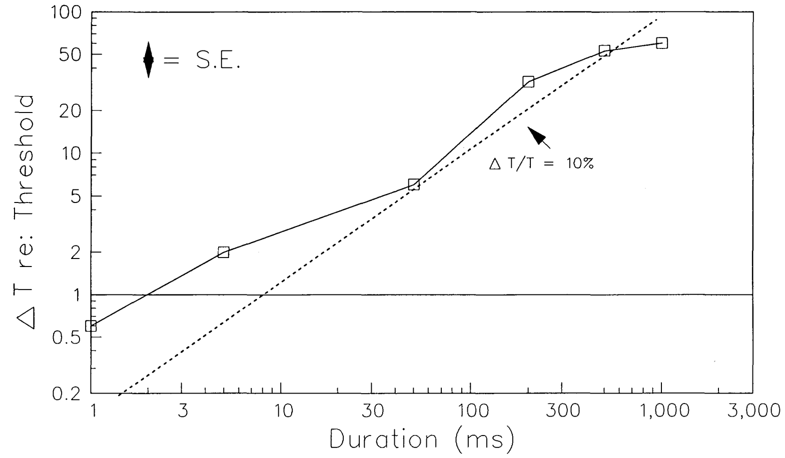

FIG. 6. The threshold for discriminating a change in the temporal separation between two sounds (ΔT) as a function of the temporal separation (in ms). The dotted line labeled $\Delta T/T=10\%$ indicates a Weber fraction showing a 10% change in time separation as a function of the separation. The data are described by a constant Weber fraction only over a small range of temporal separations. The arrows labeled S.E. are an estimate of the standard error of measurement for these conditions and as such represent the expected variability about any data point. Adapted from the data of Abel (1972) as shown in Fig. 10.9 of Yost and Nielsen (1985).

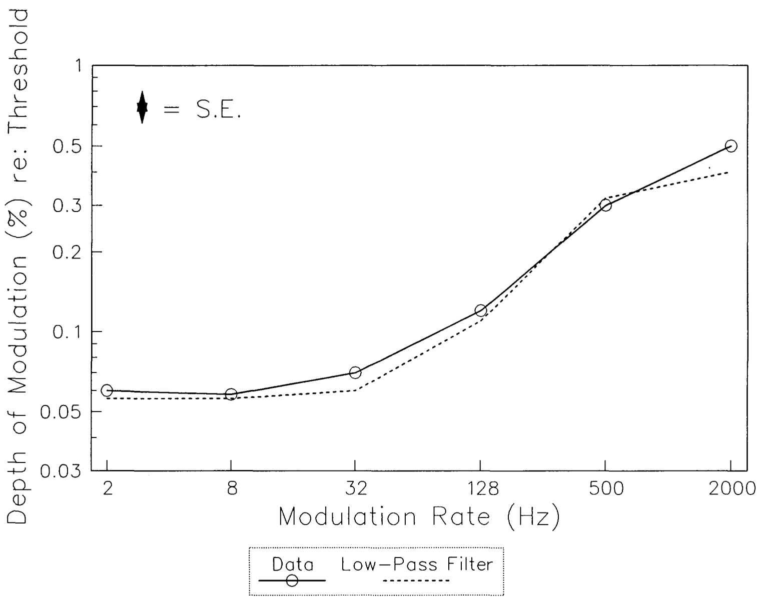

FIG. 7. The threshold depth (in %) of sinusoidal amplitude modulation (SAM) required to detect the presence of SAM for a noise stimulus, as a function of the rate of SAM (in Hz). The task was to discriminate between a nonmodulated noise $[n(t)]$ and the SAM noise $\{[1+m\cos(2\pi rt)]n(t)\}$. The depth of modulation (m expressed as a percentage) required for threshold performance was determined as a function of modulation rate (r expressed in Hz). The dotted curve represents the predictions based on a model that includes a low-pass filter with a time constant of approximately 3 ms. The arrows labeled S.E. are an estimate of the standard error of measurement for these conditions and as such represent the expected variability about any data point. Adapted from Fig. 1 of the chapter by Viemeister in Evans and Wilson (1977).

The spectral changes associated with varying the time between two acoustic markers are much less likely to influence discrimination performance than the spectral changes associated with varying the duration of a tonal signal.

5. TEMPORAL MODULATION PROCESSING

The data in Figs. 3 and 6 show some aspects of the auditory system's sensitivity to the duration of sound and the time separation between sounds. As explained above, obtaining estimates of the auditory system's sensitivity to changes in the temporal properties of sound is difficult due to the system's remarkable sensitivity to the spectral and sound level changes that accompany most temporal changes. Thus, a number of different procedures have been used to study auditory temporal processing (Green, 1971).

Procedures using amplitude modulated (AM) sounds offer a means of studying temporal processing, especially auditory processing of ongoing temporal changes of sound. Figure 7 shows the results from an experiment in which listeners were asked to discriminate between an unmodulated white, Gaussian noise $[n(t)]$ and a sinusoidally amplitude modulated (SAM) noise $\{[1+m\cos(2\pi rt)]\times[n(t)]\}$. The depth of modulation (m expressed as a percent) required to just discriminate the SAM noise from the unmodulated noise was determined for each frequency of modulation (r ranged from 1 to 2000 Hz). As the rate of modulation increases beyond approximately 50 Hz, greater and greater depth of modulation is required to process the temporal fluctuations due to amplitude modulation. Up to 50 Hz the temporal fluctuations are all approximately equally discriminable from the unmodulated noise. The low-pass filter characteristic of these data has been used to support the low-pass filter assumption shown in Fig. 1. The

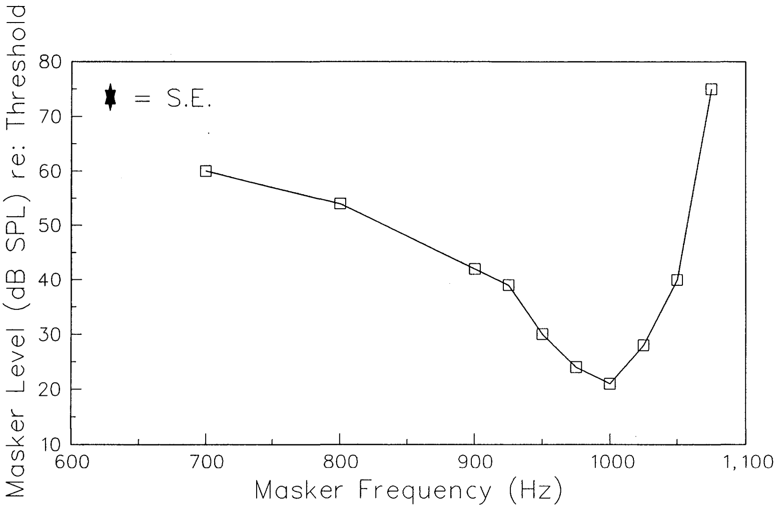

FIG. 8. The threshold level (in dB SPL) of a tonal masker required to mask a 1000-Hz tonal signal, as a function of masker frequency (in Hz). The lowest masker level is required for threshold performance when the masker and signal have the same frequency (1000 Hz), and greater masker level is required to mask the signal when the masker frequency differs from the signal frequency. These data are interpreted as indicating that the detection of the signal is mediated by neural channels tuned to the signal frequency. The arrows labeled S.E. are an estimate of the standard error of measurement for these conditions and as such represent the expected variability about any data point. Adapted from the data of Moore (1982a) as shown in Fig. 11.1 of Yost and Nielsen (1985).

curve fitted to the data was obtained from a model using a low-pass filter with a time constant of 3 ms. These and other data show that to a first approximation, the auditory system's ability to detect ongoing changes in sound can be modeled with a low-pass filter process as suggested in Fig. 1.

6. INTERFERENCE AMONG SOUNDS (MASKING)

The data discussed so far describe the auditory system's sensitivity to tones presented in isolation. Most of our daily experience with sound involves many sound sources. When there are many sound sources, it is possible that one sound will interfere with the ability to process other sounds. Masking is one procedure used in psychoacoustics to study interference. Masking is defined as the increase in the detection threshold of one sound (the signal sound) due to the presence of another sound (the masker sound). The amount of the threshold shift reflects the amount of masking (see Moore, 1986).

Figure 8 shows tonal masking data in which the signal was a brief duration (20 ms), 1000-Hz tone, presented at a low level (5 dB SL). The masker was a tone presented at different frequencies. The listener's task was to determine if the signal and masker were present or only the masker was present. Masker level was varied until a threshold for detecting the signal was obtained. The data are plotted as the masker level required to achieve threshold as a function of masker frequency. The form of the resulting data (Fig. 8) is explained by assuming that the auditory system monitors the neural channel tuned to the frequency of the signal. When the masker frequency is greatly different from the signal frequency, the neural channel tuned to the signal does not respond when the masker is present alone but does respond when the signal plus masker are present, requiring the masker level to be increased to obtain threshold. When the masker frequency is near that of the signal, the tuned channel responds to both masker and masker plus signal, requiring a decrease in the level of the masker to obtain a threshold. These data can be used to define the characteristics of the tuned channels which are usually modeled as bandpass filters (see Fig. 1).

Another procedure to study masking uses filtered white, Gaussian noise as a masker for tonal signals. In a use of this technique, a band-reject noise (a noise passed through filters such that the energy is reduced in a nar-

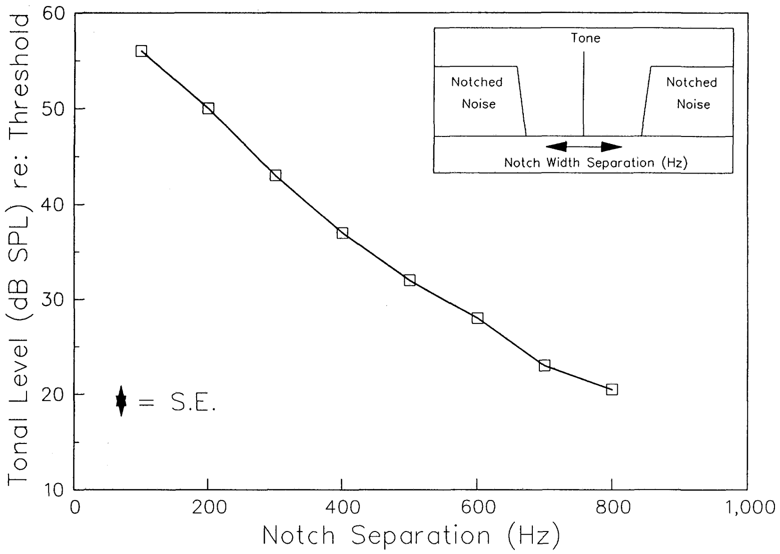

FIG. 9. The threshold level (in dB SPL) of a tonal signal as a function of the spectral notch separation (expressed in Hz) in a band-reject noise masker. The inset depicts the tonal signal with a frequency in the center of the spectral notch created by the band-reject noise. The threshold for detecting the signal is measured as the spectral width of the notch is increased. The threshold is lower at wide spectral separations between the two bands of noise that make up the band-reject noise. These data are consistent with the assumption that masking of a tonal signal is mediated by auditory channels tuned to the tonal-signal frequency. The arrows labeled S.E. are an estimate of the standard error of measurement for these conditions and as such represent the expected variability about any data point. Adapted from the data of Patterson (1976) as shown in Fig. 3.6 of the chapter by Patterson and Moore in Moore (1986).

row band of the noise) is used to mask a tonal signal, as shown in the inset of Fig. 9. The threshold for detecting the tonal signal is measured as a function of the spectral separation between the two bands of noise that comprise the band-reject noise. The results shown in Fig. 9 are explained in a manner similar to that used to explain the data of Fig. 8. When the frequency of the edge of the filtered noise is distant from the signal frequency (spectral notch is wide), the channel tuned to the signal frequency will respond when the signal plus masker are present, but not when the masker alone is present. Thus, the signal level can be reduced to obtain a threshold. When the frequencies of the edge of the filtered noise and that of the signal are close together (spectral notch is narrow), the tuned channel responds to both the masker presented alone and the signal plus masker. In this case, the signal level must be increased to obtain a threshold. The data from experiments like those depicted in Figs. 8 and 9 have been used to describe the characteristics of the tuned channels described as bandpass filters in Fig. 1.

Because only a band of masker frequencies near the signal frequency is critical for determining the amount of masking, the tuned channels have been called "critical bands" (see Moore, 1986). Figure 10 shows an estimate of the width of this critical band of frequencies as obtained for noise maskers and tonal signals of different frequencies. The critical bandwidth increases as signal frequency increases; however, the increase in bandwidth is not a fixed proportion of the center frequency as it is for physically realizable filters. To a first approximation, the bandwidth of the "critical band" filters changes as described in Fig. 10, but the shape of the filter does not change appreciably as a function of frequency.

Threshold detection in masking experiments is obtained when the signal-to-masker ratio remains approximately constant. The data of Fig. 11 show this constancy for conditions involving noise maskers and tonal signals. In addition, the estimated bandwidth of critical band filters is somewhat dependent on the overall level of the masker and signals used to measure the critical band. The

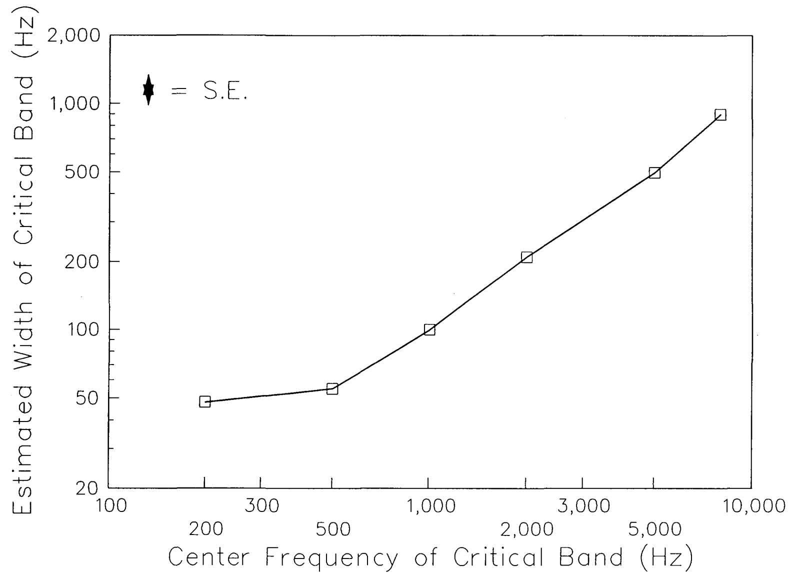

FIG. 10. The width (in Hz) of the band of frequencies critical for masking a pure tone, as a function of the center frequency of the band (in Hz), which would be the same frequency as the tonal signal. Only stimuli with frequencies within the critical band region are effective in masking tones at the center frequency. The arrows labeled S.E. are an estimate of the standard error of measurement for these conditions and as such represent the expected variability about any data point. Adapted from Moore and Glasberg (1983) as shown in Fig. 3.10 of the chapter by Patterson and Moore in Moore (1986).

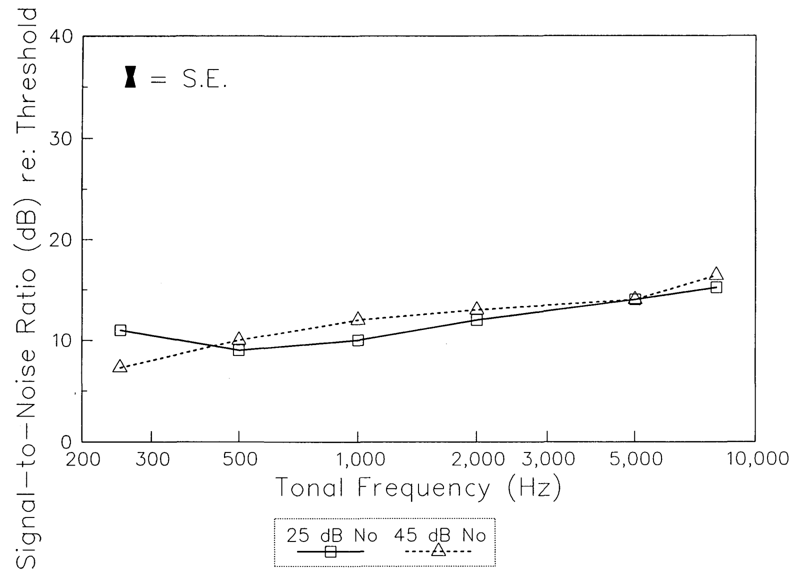

FIG. 11. The tonal signal-to-noise ratio (in dB) required for threshold detection of the signal, as a function of tonal-signal frequency (in Hz). Data for two noise spectrum levels are shown (25 dB No and 45 dB No). Spectrum level, designated as "No," is the noise power per unit band width assuming the noise has a relatively flat amplitude spectrum. The signal-to-noise ratio (energy of the signal at threshold divided by the spectrum level of the noise) required for threshold remains approximately constant in the range of 9–15 dB over a large range of frequencies and overall masker level. The arrows labeled S.E. are an estimate of the standard error of measurement for these conditions and as such represent the expected variability about any data point. Adapted from the data of Reed and Bilger (1973) as shown in Fig. 11.6 of Yost and Nielsen (1985).

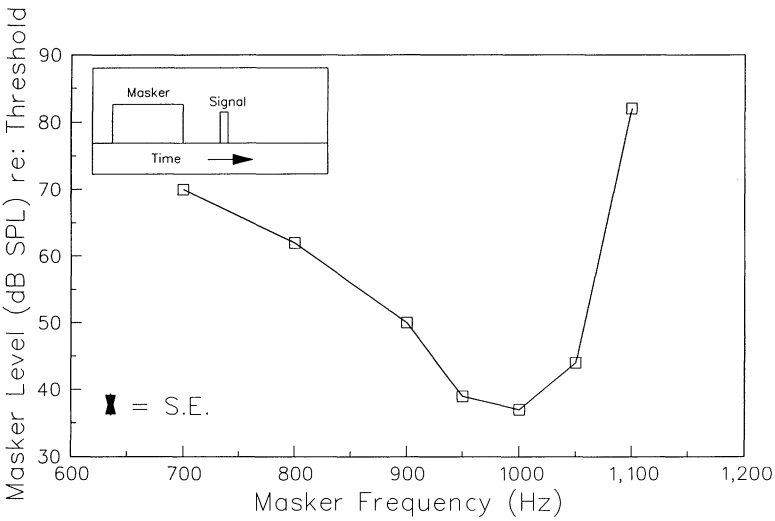

FIG. 12. The tonal masker level (in dB SPL) required for threshold detection of a 1000-Hz signal, as a function of the masker frequency (Hz). The tonal signal was presented after the offset of the masker as shown in the inset. In this forward-masking paradigm, the neural effect of the masker is assumed to remain after its offset, resulting in masking that is similar to that occurring when the signal and masker are presented simultaneously (see Fig. 8). The arrows labeled S.E. are an estimate of the standard error of measurement for these conditions and as such represent the expected variability about any data point. Adapted from the data of Moore, Glasberg, and Roberts (1984) as shown in Fig. 4.7 of the chapter by Moore and O'Loughlin in Moore (1986).

estimated critical bandwidth increases a small amount as a function of increasing stimulus level.

Figure 12 shows that results similar to those in Fig. 8 are obtained when the signal and masker do not occur at the same time. In the "forward masking" paradigm used to obtain these data, the short duration tonal signal occurred 1 ms after the masker was turned off. Forward masking is assumed to result from the neural effects of the masker persisting after the masker is terminated. The amount of forward masking decreases as the time separation between the masker and signal increases or as the signal increases in duration relative to that of the masker. Usually the data for the forward-masked signal imply narrower tuning (Fig. 12) than obtained when the masker and signal are presented simultaneously (Fig. 8). Explanations for the difference in the results assume that some nonlinear processes affect the signal and masker in the simultaneous conditions but not when the signal is presented after the masker in forward masking (see Moore and O'Loughlin, 1986). The shape of the data obtained in forward-masking experiments matches similar measures obtained from single auditory nerve fibers of the auditory nerve leaving the inner ear of the auditory periphery. This agreement suggests that the auditory system uses the neural information in the auditory nerve as the primary basis for detecting masked tonal signals.

In the masking studies described above, only the level of the signal or the masker was varied. In everyday life, sounds that are to be detected are often constantly changing in level and the task is to detect a change in the level of the signal *relative* to that of the masker. Figure 13 describes the stimulus conditions for a study that attempts to measure detection of a relative change in signal level for a masker whose level is also varied. In this example the masker consists of 11 equal amplitude tones spaced logarithmically in frequency, and the signal is a level increment to the middle, 1000-Hz component. The overall level of the masker was varied over a 40-dB range from condition to condition. The data in Fig. 14 show the results expressed as the level of the signal relative to that of the masking components as a function of the number of tonal components in the masker. The signal level required for threshold decreases as the number of components increases. With 11 components performance is nearly as good as that obtained with one masking tone. These

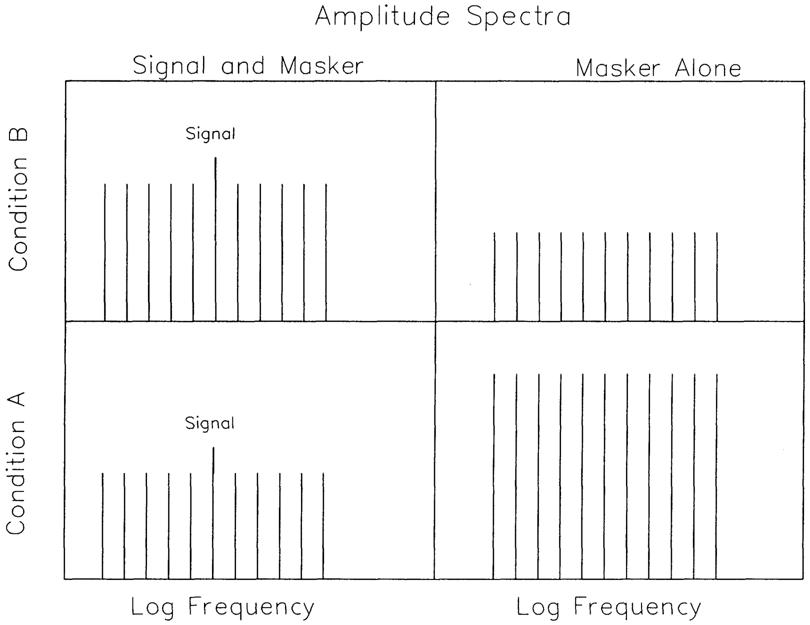

FIG. 13. A schematic diagram depicting the spectra of maskers and signals used in a masking study. The masker consists of 11 equal-amplitude tones with frequency spaced logarithmically. The signal is a level increment to the middle component of the masker. The listener is presented either the masker or the masker and signal and he/she must detect when the signal occurs. Conditions A and B represent two of the many possible comparisons (the overall level of the masker is randomly varied over a 40-dB range). In Condition A, the masker happens to be more intense during the signal presentation than when the signal was not present, while in Condition B the masker is less intense when the signal is present than when only the masker is present. As Fig. 14 will indicate, listeners are able to detect low-level signals in this procedure and, thus, detection is assumed to be based on comparing the outputs of many tuned channels to detect the relative increase in signal level in the spectral profile.

data are interpreted in terms of the auditory system's ability to compare the spectral profile when the signal is present to masker-alone conditions. When the signal is present, the spectral profile has a " bump" at the signal frequency. With many components in the masker, it is easier to define the spectral profile and hence to find the bump at the signal frequency. Such an explanation suggests that the auditory system compares the output of more than one tuned channel in order to define the profile. These data also indicate that the auditory system may not lose much resolving power when it is presented with a dynamically changing stimulus context in which to detect a signal (see Green, 1988).

7. LOCATING SOUND SOURCES

The experiments described above have helped shape our understanding of the auditory code for frequency, intensity, and temporal events. The auditory system is also capable of determining the spatial location of sound. A variety of mechanisms exist throughout the animal kingdom for locating sounds (see Yost and Gourevitch, 1987). In humans and most mammals, sound localization is achieved via binaural processing for determining the azimuthal location of sound and includes the spectral transform of sound as it travels from a source to the middle ear for vertical location. Little is known about our poor ability to judge distance when loudness is not a possible cue.

7.1 Localization

The cues for localizing sounds in the azimuth plane are the interaural difference in arrival time of the sound and the interaural level difference as depicted in Fig. 15. The interaural time difference is determined by the difference in sound travel time between the two ears, and the interaural level difference is

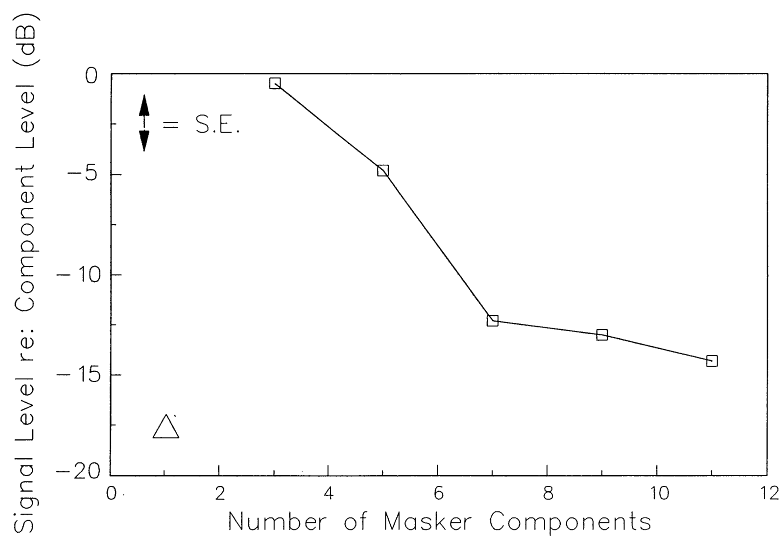

FIG. 14. The tonal-signal level (in dB relative to the level of the masker components) required for threshold detection, as a function of the number of equal-amplitude components in the masker (as shown in the spectral profiles of Fig. 13). The signal is always an increment in level to the middle component of the multitone masker when the components are spaced logarithmically in frequency. As described in Fig. 13, the overall level of the masker is randomly varied over a 40-dB range. As the number of components in the masker increases, the threshold for signal detection decreases. The triangle above one masker component represents the threshold for detecting an increment to a single tone. Thus, as the number of components in the masker increases, performance can approximate that obtained for a single tonal masker, even though the masker is varying randomly in level over a 40-dB range. The arrows labeled S.E. are an estimate of the standard error of measurement for these conditions and as such represent the expected variability about any data point. Adapted from the data of Green (1988, Fig. 4-2).

due to the sound shadow and diffraction produced by the head. In general, the further the sound source is from the center (0° in Fig. 15), the greater the interaural time difference and interaural level difference. Although there are cones of confusion where the interaural differences are the same for a number of positions (e.g., directly in front and directly behind a listener), asymmetries in the geometry of the head and torso and head movements eliminate most confusions by listeners. Figure 16 displays the complex patterns of interaural time differences [Fig. 16(a)] and interaural level differences [Fig. 16(b)] produced by the human head and torso for tones of different frequencies. These data indicate a complex relationship among the measures of interaural time and level, sound frequency, and sound location (see Kuhn, 1987).

Figure 17 displays the errors in localizing tones of different frequencies. The loss of acuity in the mid-frequency region near 2000 Hz is assumed to be due to the two cues (interaural time and interaural level) operating in different frequency regions (this theory has been called the duplex theory of sound localization; see Durlach and Colburn, 1978). Interaural level differences are most salient at high frequencies where the head's sound shadow is most pronounced. Interaural time differences for pure tones are ambiguous when the period of the tone is less than the maximum sound travel time difference between tween the ears. Thus, interaural time provides an unambiguous cue for frequencies below approximately 1600 Hz which corresponds to a period of 0.625 ms, approximately the maximum difference in travel time between the ears for a sound placed directly opposite one ear. The region near 2000 Hz (see Fig. 17) is the spectral region where neither cue works very well. Although the duplex theory of sound localization appears to account for the localization of sinusoidal stimuli, it does not predict localization performance for complex stimuli (see Yost and Hafter, 1987).

Figure 18 displays data from an experiment designed to determine the smallest separation between two sound sources that a listener can detect. These minimum audible angles (MAA) are plotted as a function of

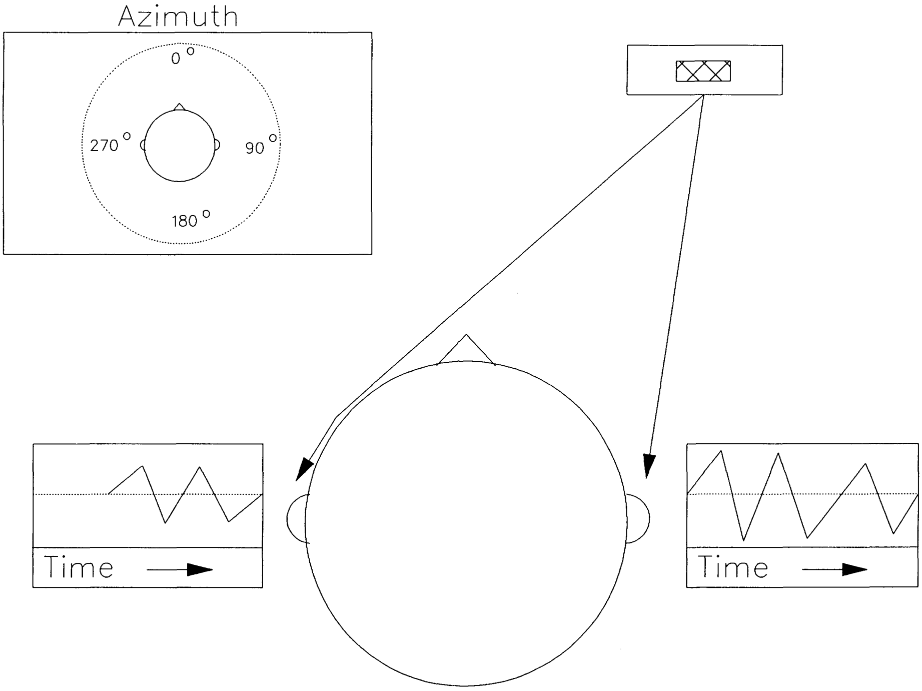

FIG. 15. A schematic diagram depicting the differences in interaural time and level at the ears when a sound source is presented to one side of a listener. The inset shows the normal reference system for describing azimuth position. Sound arrives first at the ear nearest the sound source, and because of the sound shadow produced by the head and body, the sound is also most intense at the ear closest to the source. Thus, as the source moves from in front to one side of a listener the interaural time and level differences increase.

tonal frequency and starting azimuth. Highest acuity is obtained for discriminations between sources directly in front of the listener and, as in Fig. 17, there is a loss of acuity in the mid-frequency region near 2000 Hz.

In most real-world listening environments sounds encounter many reflective surfaces before they reach a listener's ears. The sound waves reflected from these surfaces could be confused as additional sound sources. However, in most cases humans localize the sound as coming from the source and not from one or more of the reflective surfaces. It has been shown that the sound that reaches the ears first determines the location of the perceived source. In most situations, the first arriving sound is from the source. However, if the reflective environment prevents this, then a listener will hear a "phantom source" associated with the reflective surface which sends the sound to the ears first. The fact that the first arriving information at the ears determines sound localization is called the "precedence effect" (see Zurek, 1987).

7.2 Lateralization

In order to control the variables of interaural time and level, stimuli are often presented over headphones. Such headphone-delivered stimuli are usually perceived as being inside the head rather than externalized as real sound sources. Because such headphone-delivered stimuli are perceived to be located along an imaginary line between the ears, when the interaural time or level of a sound is varied, localization of headphone-delivered sounds is called "lateralization." In general, the lateralized image of the sound moves away from midline toward the ear receiving the sound first or receiving the higher level sound. Thus to a first approximation, the position of lateralized sounds concurs with their positions in real space as determined by their interaural time and level differences (see Yost and Hafter, 1987).

Figure 19 shows the difference thresholds for detecting a change in the interaural level [Fig. 19(a)] or interaural time differences of

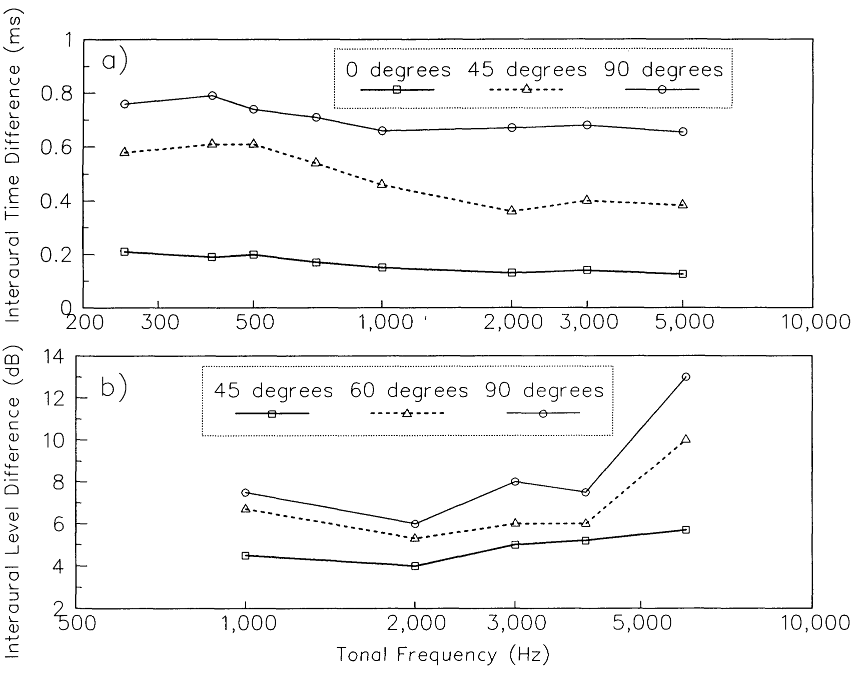

FIG. 16. The interaural time difference in ms (a) and interaural level difference in dB (b) measured between the ears of listeners, as functions of frequency (in Hz). The measurements were made at three azimuth positions [0°, 45°, 90° for (a); and 45°, 60°, 90° for (b); see Fig. 15]. The values of interaural time and level are complex functions of frequency and azimuth position. Adapted from the data of Kuhn (1987, Figs. 1.3, 1.7, and 1.8) in Yost and Gourevitch (1987).

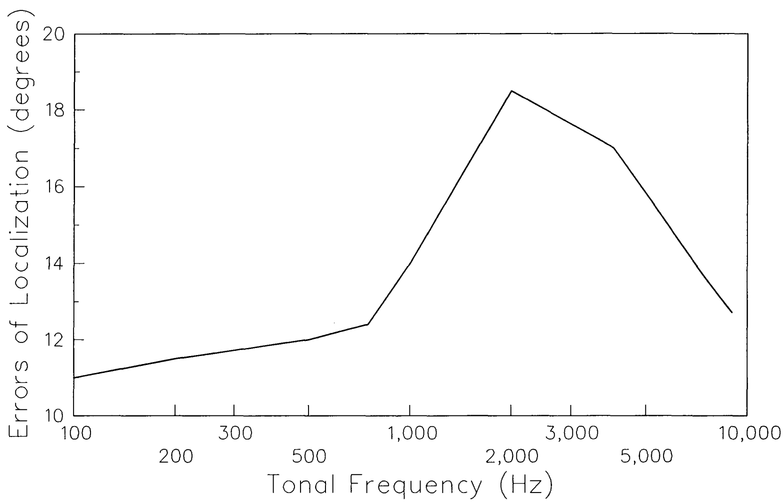

FIG. 17. Errors (expressed as degrees of azimuth) for locating tonal sound sources, as a function of tonal frequency (in Hz). Localization accuracy is worst in a frequency region between 1200 and 5000 Hz. These data are the basis for the duplex theory of localization. Adapted from the data of Stevens and Newman (1936) as shown in Fig. 2.1 of the chapter by Wightman, Kistler, and Perkins in Yost and Gourevitch (1987).

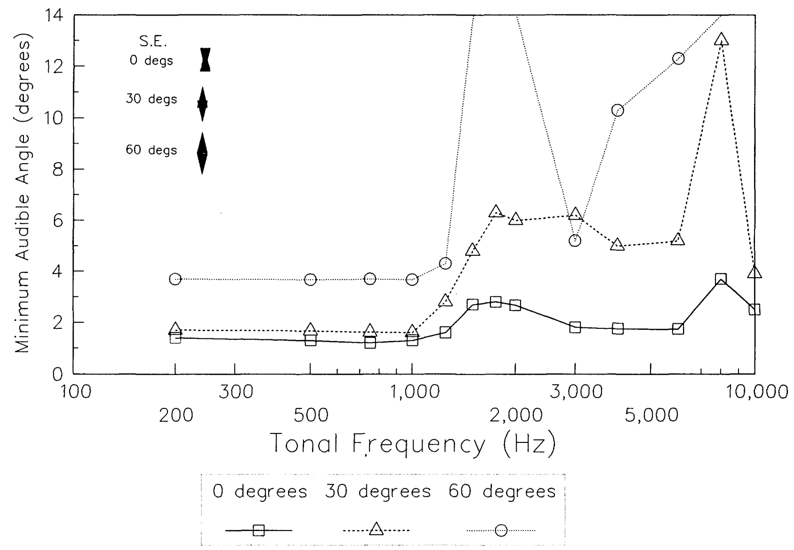

FIG. 18. The minimum audible angle (MAA shown in degrees of azimuth) required to discriminate between the location of two tonal-sound sources, as a function of frequency (in Hz). The MAAs were measured at three azimuths (0°, 30°, 60°). The MAA increases as the sources are moved from the front to one side of the listener, and performance is worst in the frequency region of 1200–5000 Hz. The arrows labeled S.E. are an estimate of the standard error of measurement for the three base azimuth conditions and as such represent the expected variability about any data point. Adapted from the data of Mills (1956) as shown in Fig. 2.1 of the chapter by Wightman, Kistler, and Perkins in Yost and Gourevitch (1987).

tones [Fig. 19(b)] as functions of frequency and the initial amount of interaural time or level. Best sensitivity to interaural level difference is approximately 0.5–1 dB across a large range of frequencies. However, sensitivity to changes in interaural time differences can be measured only for tonal frequencies less than 1600 Hz. Interaural time differences as small as 10 μs can be discriminated. When discriminations are made for sounds that have an initial interaural time or level difference (interaural differences greater than zero), the difference thresholds increase. Because increases in interaural time or level are perceived as images off midline, these data are interpreted as indicating that spatial acuity decreases as the location of a sound source is moved from midline or away from center (as was also shown in Fig. 18).

Complex high-frequency sounds with low-frequency temporal fluctuation(envelopes) can be discriminated on the basis of interaural differences of time even though high-frequency tones (above 1600 Hz) cannot be discriminated on the basis of interaural time. Figure 20 shows the results for lateralizing a 3900-Hz tone that was sinusoidally amplitude-modulated at 300 Hz. Listeners *cannot* discriminate a change in interaural time difference for the 3600-Hz tone but can make the discrimination when the 3900-Hz tone is amplitude modulated at 300 Hz. A 300-Hz sinusoidally amplitude- modulated 3900-Hz tone has a spectral component at 3600 Hz (the lower, side-band frequency associated with SAM). Thus, the lowest frequency in the SAM complex was 3600 Hz, and for this reason the 3600-Hz tone was used as the comparison frequency. The ability to localize high-frequency complex sounds on the basis of interaural time differences is assumed to be due to the binaural auditory system's use of the slow-frequency repetition in the envelope (300 Hz) of the amplitude modulated tone.

Thus, interaural level is potentially available as a localization cue at all frequencies, although in the real world very small interaural level differences (perhaps too small to be detected) actually exist at low frequencies. Interaural time differences for very narrow-band stimuli (e.g., pure tones) can be processed only for frequencies less than 1600 Hz. Interaural time differences can be discriminated for high-frequency sounds if the narrow-band stimuli contain a slow-frequency repetition. These conclusions per-

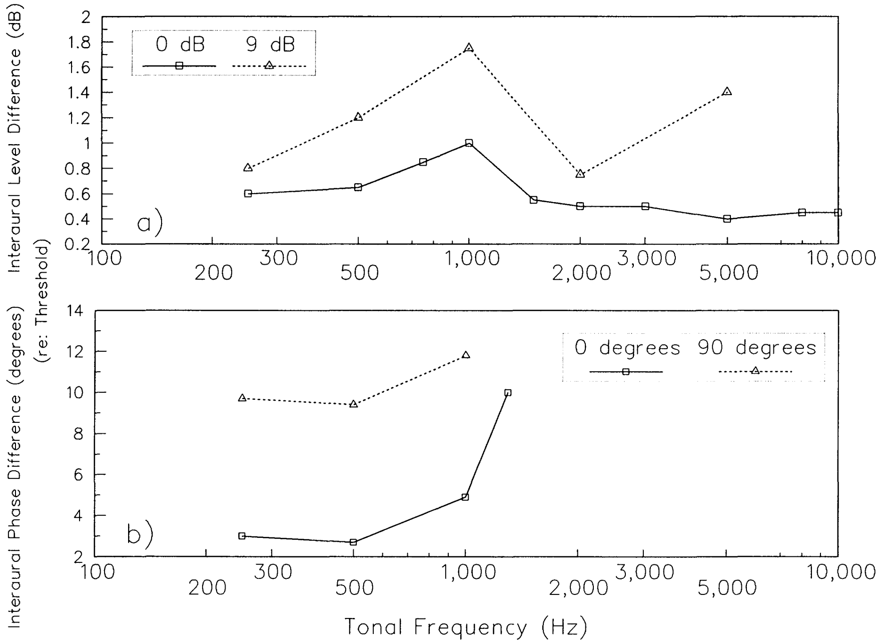

FIG. 19. The values of interaural level [in dB, (a)] and interaural phase [in degrees, (b)] required to discriminate a change in the interaural time (phase) or interaural level difference of a tone, as functions of tonal frequency (in Hz). The tones were presented over headphones with different base values of interaural level [0 dB or 9 dB in (a)] or interaural phase [0° or 90° in (b)]. The thresholds for discriminating a change in interaural level or phase increase as the value of the base interaural phase or interaural level differences increases. The smallest interaural level difference thresholds are between 0.5 and 1 dB except in a frequency region near 1000 Hz. Interaural phase-difference thresholds can be obtained only for frequencies less than 1600 Hz. The expected variability about any datum point in (a) is approximately 0.7 dB, while in (b) it is approximately 2°. Adapted from the data of Yost and Dye [1987, (a)] and Yost [1974, (b)] as shown in Figs. 3.9 and 3.10 of the chapter by Yost and Hafter (1987) in Yost and Gourevitch (1987).

tain primarily to localization of azimuth position (see Blauert, 1983).

Sound is transformed in a number of ways as it travels from its source to a listener's middle ear. These transformations can be determined by comparing the sound measured by small microphones placed in the outer ear to that originating at the source. "Head transfer functions" such as those shown in Fig. 21 can be established; they describe the magnitude (and phase) changes that a sound undergoes as it travels past the various parts of the head and torso.

When sounds are presented over headphones, they are not transformed by the head and body. When the magnitude and phase changes of the head transfer function are introduced back into the spectrum of a complex sound before being delivered to headphones, listeners usually report that the sounds are no longer internalized but are externalized at their real-world locations. Table 2 shows a comparison of localization judgments made when sounds were presented from loudspeakers in an anechoic room versus sounds presented over headphones after they were transformed by the inverse of the head transfer functions measured for the listener making the judgments. There is excellent correspondence for both azimuth and vertical judgments. These results suggest that for broadband stimuli, the transformations that sounds undergo while traveling to the ears are crucial for externalization and accurate localization of the sound source (see Wightman, Kistler, and Perkins, 1987).

7.3 Binaural Masking

The masking of one sound by another is reduced if the two sounds occupy different locations in space relative to conditions when the two sounds occupy the same location (see Blauert, 1983). Signals and maskers can also

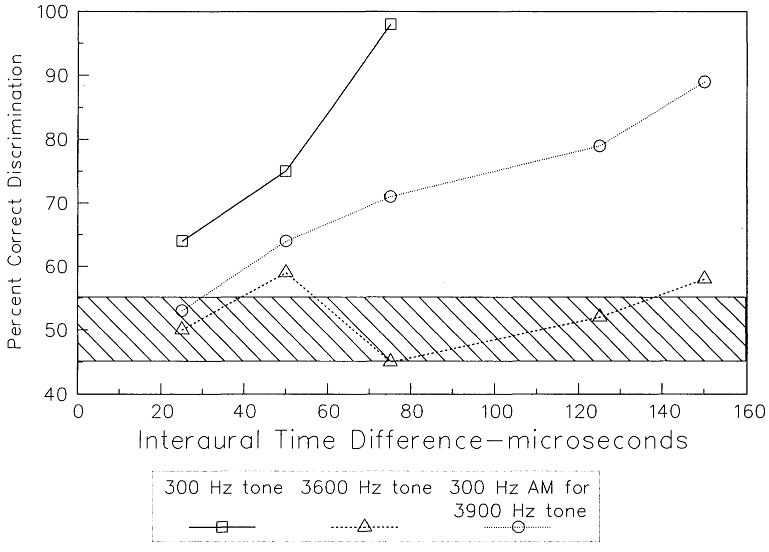

FIG. 20. The percentage correct discriminations of a change in interaural time differences as a function of the interaural time difference (in microseconds). Three stimuli were used: a 300-Hz tone, a 3600-Hz tone, and a 3900-Hz tone that was sinusoidally amplitude modulated (AM) at 300 Hz. As the interaural time difference increases, the listener's ability to discriminate a change in the interaural time difference for the 300-Hz tone and the 300-Hz AM 3900-Hz complex improves, but not for the 3600-Hz tone. The hatched area represents the region of chance performance indicating that the listener was unable to discriminate a change in the interaural time difference for the 3600-Hz tone. These data indicate that high-frequency [above approximately 1600 Hz, see Fig. 19(b)] sounds can be lateralized only when they contain a form of low-frequency temporal modulation. Adapted from the data of Henning (1977) as shown in Fig. 12.7 of Yost and Nielsen (1985).

be separated in lateral space when the sounds are presented over headphones. If the masking stimulus is presented with a different interaural difference than the signal, the signal is easier to detect (has a lower threshold) than when the masker and signal are presented with the same interaural difference. A nomenclature for defining the interaural differences of the masker (N, since the masker is usually a noise) and the signal (S) has been developed. Table 3 describes this nomenclature and shows the masked thresholds for a variety of binaural conditions. Whenever the signal and masker have different interaural values (e.g., the NoSπ condition) thresholds are lower than when the signal and masker have the same interaural values (e.g., the NoSo condition). This difference in masked threshold between a dichotic condition and a diotic condition is referred to as the binaural masking-level difference (BMLD). The BMLD has been used to describe the advantage in detection offered by spatially separating sound sources. This description is based on the observation that when the masker and signal with different interaural values are presented over headphones, they are perceived at different lateral positions within the head. Thus, binaural processing enables the auditory system to locate sounds and to detect one sound in the presence of another when the target sound is spatially separated from the interfering sound (see Durlach and Colburn, 1978).

Spatial localization is most often modeled by assuming that the nervous system performs a cross correlation between the neural information at each ear. A coincidence network has been suggested as a way in which cross correlation could be neurally implemented. The location of coincidence along the network indicates the location of sounds in space. It is usually assumed that such a coincidence network would occur at the output of each filter mechanism, as indicated in Fig. 1. Thus, the pattern of coincidences across the spectrally coded array of networks would form a type of neural spatial map for sound source location (see Colburn and Durlach, 1978).

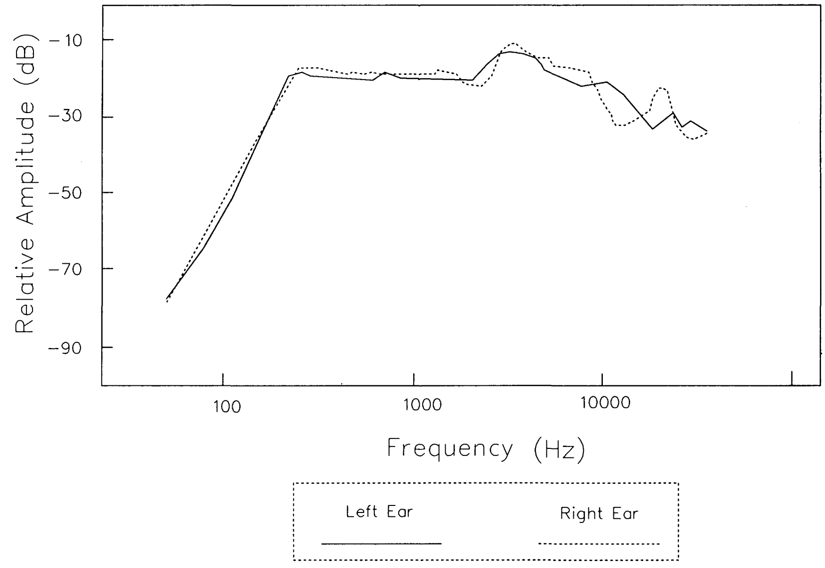

FIG. 21. The relative amplitude (in dB) measured in each outer ear of a listener as a function of frequency (in Hz). The sound source was located 2 m directly in front of the listener. These "head transfer functions" indicate the complex pattern (especially at high frequencies) that exist in the outer ears due to the filtering actions of the head and torso. The differences in the two functions are due to slight asymmetries in the head and torso of this listener. Adapted from the data of Wightman, Kistler, and Perkins (1987) as shown in Fig. 2.9 of Yost and Gourevitch (1987).

8. SUBJECTIVE ATTRIBUTES OF SOUND

The data discussed so far concern a listener's ability to detect stimuli in different stimulus contexts or to discriminate changes in stimulus events. The physical variables of sound—frequency, level, complexity, and time—have subjectively perceived counterparts: pitch, loudness, timbre, rhythm, etc. Subjective psychophysics is the study of the relationship between the physical variables of sound and their subjective attributes (see Stevens, 1975).

8.1 Loudness

Figure 22 shows equal-loudness contours for a range of tonal frequencies and sound levels. These data were obtained by asking listeners to adjust the sound level of a test tone until it is perceived equally loud to that of a comparison tone. The comparison tone is always 1000 Hz, but it is presented at different sound levels expressed in dB SPL. For each level of the comparison tone, the listener is presented test tones at a number of different frequencies and is asked to adjust the level of

Table 2. Correlation coefficients between absolute judgments of sound source location and actual sound source location for two listeners (S1 and S2). The listeners either judged the location of real sources (broad-band noise presented from one of 22 loudspeakers) in an anechoic chamber (free field) or over headphones when the spectra of the noise wave forms were transformed by the "head transfer functions" obtained from microphones in the outer ears of the listeners when they were in the free field (simulated free field). The correlations reflect judgments of both the azimuthal and vertical position of the 22 sound sources. The very high correlation coefficients indicate that listeners are very accurate in locating sound sources in both the free field and with headphones, if the headphone sounds are modified by the head transfer functions. Adapted from the data of Wightman, Kistler, and Perkins (1987).

Condition	Listener	Correlation[a]
Free field	S1	0.99
	S2	0.97
Simulated free field	S1	0.96
	S2	0.83

[a] Goodness-of-fit correlation coefficients ranging from −1.0 to 1.0, where 0 means there is no correlation.

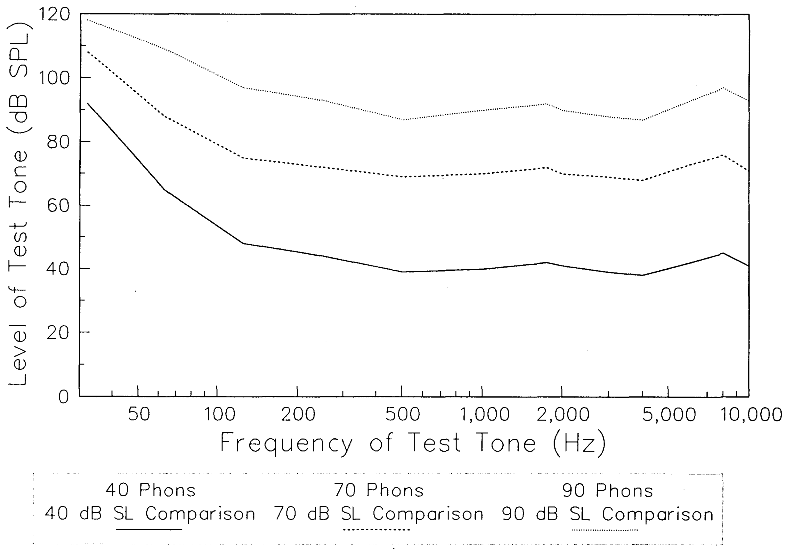

FIG. 22. The level of a test tone (in dB SPL) required to match the subjective loudness of a comparison, 1000-Hz tone, as a function of the frequency (in Hz) of the test tone. Data for three levels of the comparison tone are shown (40 dB SL, 70 dB SL, and 90 dB SL). All tones presented at the level and frequency along any one "equal loudness contour" are judged equally loud. These data are used to define a decibel scale of loudness, the "phon" scale. A tone has a level of *x* phons if it is judged equally loud as a 1000-Hz tone presented at *x* dB SPL. Hence, the three curves are the 40-, 70-, and 90-phon equal-loudness contours. Adapted from ISO Standard (1981) as shown in Fig. 13.1 of Yost and Nielsen (1985).

the test tone so that it appears "equally loud" to the 1000-Hz comparison tone presented at a particular level. The data shown along any one contour on Fig. 22 are, therefore, assumed to be equally loud, thus leading to the name of these curves as "equal loudness contours." All tones judged equally loud to the 1000-Hz comparison tone presented at 40 dB SPL are defined as having a loudness of 40 phons, those judged equally loud to the 1000-Hz comparison tone presented at 70 dB SPL are 70 phons loud, etc.

These data and the resulting phon scale of loudness have been standardized and have a number of practical uses. For instance, the 40-phon equal-loudness contour defines a frequency-weighting function used in sound level meters. That is, when making a sound level measurement that relates to human hearing, the sound needs to be filtered so that

Table 3. Masked thresholds in signal-to-noise ratios (dB) in a variety of binaural masking conditions. The difference in thresholds between a diotic or monotic condition and a dichotic condition is the binaural masking-level difference (BMLD).

Binaural condition	Description	Threshold (dB)	BMLD (dB)
NmSm (monotic)	Masker (N) at only one ear (m); signal (S) at only one ear (m)	13	Referent
NoSo (diotic)	Masker (N) the same at both ears (o); signal (S) the same at both ears (o)	13	0
NπSm (dichotic)	Masker (N) out of phase between ears (π); signal (S) at only one ear (m)	11	2
NoSm (dichotic)	Masker (N) the same at both ears (o); signal (S) at only one ear (m)	3	10
NπSo (dichotic)	Masker (N) out of phase between ears (π); signal (S) the same at both ears (o)	1	12
NoSπ (dichotic)	Masker (N) the same at both ears (o); signal (S) out of phase between ears (π)	−2	15

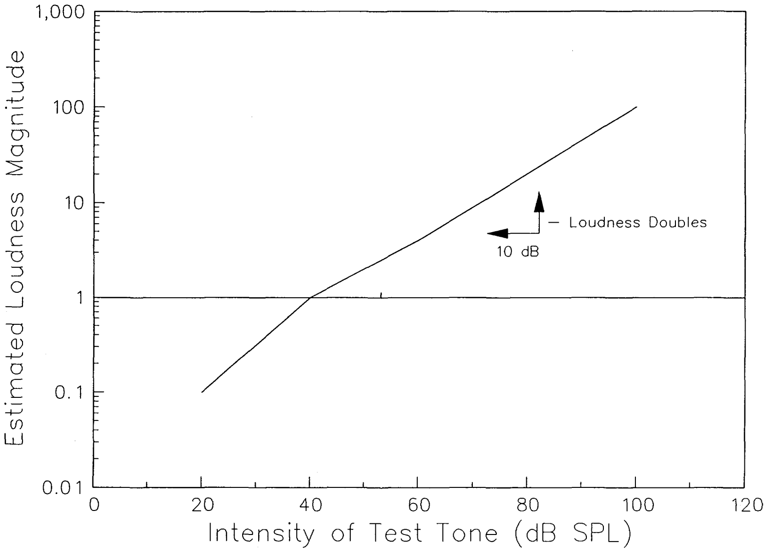

FIG. 23. The estimated magnitude of loudness for a 1000-Hz tone as a function of its level (in dB SPL). In a scaling procedure, the listener's task is to estimate the loudness of the tone by assigning a number proportional to the tone's subjective loudness, such that if the tone doubles in subjective loudness the estimated magnitude should also double. Most listeners indicate that a 10-dB increase in level is required for a doubling of loudness. A "sone" scale of loudness is derived from the scaling procedure such that a 40-dB SPL, 1000-Hz tone is 1 sone loud and any sound of *x* sones is judged to be *x* times as loud as 1 sone. Thus the ordinate is also loudness in sones. Adapted from Fig. 13.2a of Yost and Nielsen (1985).

only energy in the frequency region to which humans are sensitive is used in the sound level measurement. The 40-phon equal-loudness contour is used to define a weighting function that attenuates the levels of a sound at low and high frequencies. When the sound-pressure level has been measured based on the 40-phon weighting function, the sound-pressure level is expressed as dBA or A-weighted decibels. Most measurements of environmental sounds are based on dBA calculations.

The data of Fig. 23 show how the perceived loudness of sound changes when the sound level changes. These data were obtained by asking listeners to judge the loudness of a 1000-Hz tone. The listeners judged the loudness of the tone by using numbers to scale loudness such that if the listeners perceived the loudness to double, the value of the assigned number should double. This form of a "scaling procedure" indicates that the physical intensity of sound needs to be increased approximately 10 dB in order for the perceived loudness to double. Scaling has been used in a number of experiments to determine the relationship between the perceived subjective change in sound and the actual physical change in the sound, such as the "sone scale" explained in Fig. 23 caption.

8.2 Pitch

Pitch has also been measured with matching and scaling procedures. However, the scales or indicators of pitch most often used are those derived from music. Table 4 shows some of these scales.

Although the perceived pitch of a sound is highly correlated with the existence of spectral energy at frequencies equal to the reported pitch (i.e., the pitch of a 400-Hz tone is 400 Hz), many stimulus conditions can produce a pitch sensation when there is little or no energy in the frequency region of the sound that corresponds to the perceived pitch.

As stated previously, the transduction of sound into a neural code is nonlinear. Consequently, audible nonlinear distortion products are generated when sounds are presented, especially at high levels. Table 5 indicates the nonlinear distortion products that are audible when a two-tone complex is presented at a fairly high level. Under most circumstances the cubic difference tone is the

Table 4. The relationship among musical notes, cents, and fundamental frequency (in Hz) for three major ways of tuning for pitch. An octave is divided into 12 equal logarithmic intervals of 100 "cents" each, yielding 1200 cents per octave.

	Just intonation		Equal temperament		Pythagorean	
Musical note	Cents	Freq. (Hz)	Cents	Freq. (Hz)	Cents	Freq. (Hz)
C	0	264	0	264	0	264
D	204	297	200	296	204	297
E	386	329	400	332	408	334
F	498	352	500	353	498	352
G	702	396	700	395	702	396
A	884	440	900	444	906	445
B	1088	495	1100	498	1110	501
C (next octave)	1200	528	1200	528	1200	528

most audible of all of the distortion products. This indicates that the form of the nonlinearity is not a simple nonlinear transformation of the acoustic stimulus.

The existence of nonlinear distortion products has been known since the 18th century when musicians such as Tartini (1754) observed that a third tone (the difference tone) can be heard when two tones are played simultaneously. Tartini observed that the strength of the difference tone is most noticeable when the two generating tones had frequencies of simple ratios such as 2:3, 3:4, 4:5, and 5:6. Tartini and other 18th century composers wrote music based on the perception of the difference tones.

One procedure that indicates the existence of these nonlinear products is to present a slightly mistuned tone near the reported pitch of the suspected distortion tone. For instance, if a 1000-Hz tone is presented at a high level, then a listener may report hearing the aural harmonic pitch of 2000 Hz. If a 2003-Hz tone is added to the 1000-Hz original tone, then almost all listeners report that a faint sound with a pitch near 2000 Hz is beating in loudness three times per second. The 2000-Hz aural harmonic, produced by the auditory system's nonlinear response to the original 1000-Hz tone, and the 2003-Hz added tone are beating at a rate of 3 Hz. By adjusting the level of the 2003-Hz tone until the beating sensation is strongest, the level of the nonlinear aural harmonic at 2000 Hz can be estimated, since the strongest beating sensation occurs when two beating tones are equal in amplitude. This estimated level of the distortion tone can be confirmed and its phase estimated if a 2000-Hz tone is added to the 1000-Hz and 2003-Hz stimulus complex. Once the level of the 2003-Hz tone is adjusted until the listener perceives the strongest beat with the 2000-Hz aural harmonic, the listener then adjusts the level and phase of the 2000-Hz tone to cancel this beating sensation. That is, if the 2000-Hz tone is equal in level and out of phase with the 2000-Hz aural harmonic (produced by the original 1000-Hz tone), then the 2000-Hz aural harmonic and the 2000-Hz physical tone are cancelled. All the listener hears is the 1000-Hz tone and the 2003-Hz tone; there is no perception of a 2000-Hz tone

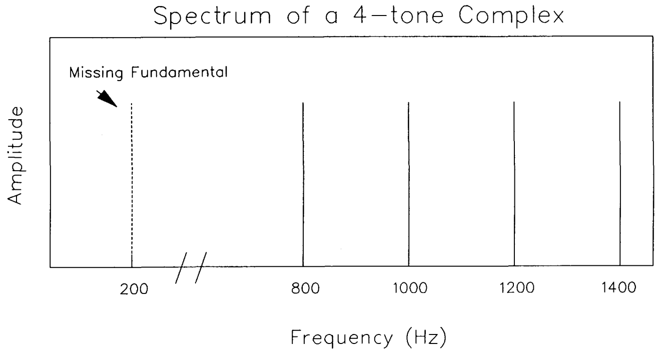

FIG. 24. A schematic drawing showing the amplitude spectrum of a complex sound consisting of the 4th, 5th, 6th, and 7th harmonics of 200 Hz. Despite the fact that 200 Hz is not in the stimulus, listeners assign a pitch of 200 Hz to this complex. The perceived pitch is at the "missing fundamental."

Table 5. Some of the audible pitches associated with the nonlinearity of the auditory system when two tones (f_1 and f_2) are presented. For the nonlinearity pitch column, $f_1 = 1000$ Hz and $f_2 = 1800$ Hz. In most situations, the cubic-difference tone is the easiest nonlinear pitch to detect.

Symbol	Nonlinearity pitch (Hz)	Label
$2f_1$	2000	Aural harmonic
$2f_2$	3600	Aural harmonic
$3f_1$	3000	Second aural harmonic
$3f_2$	5400	Second aural harmonic
f_2-f_1	800	Difference tone
$2f_1$-f_2	200	Cubic difference tone

(even though 2000 Hz is still in the stimulus) and there is no beating sensation. The fact that nonlinear distortion products, such as the 2000-Hz aural harmonic in the example above, can be manipulated as if the distortion products were actually in the stimulus, indicates that the nonlinearities occur early in the process of sound transduction. No simple description of the nonlinearity has been developed which can fully account for the estimates of the frequencies, levels, and phases of all the various distortion products (see Moore, 1982b).

The stimulus depicted in Fig. 24 indicates another stimulus condition for which listeners perceive a pitch when there are no frequency components in the stimulus corresponding to the reported pitch. The four-tone, complex stimulus consists of the 4th through 7th harmonics of 200 Hz. For this complex the listener reports a salient 200-Hz pitch; that is, the pitch of the sound is at the missing fundamental frequency of the complex. Listeners will match the pitch of this complex to that of a 200-Hz tone when the phases of the complex are randomized. Randomizing the phases of the four tones results in a time wave form with no apparent periodicity between the wave form peaks. Thus this "missing fundamental pitch" is not directly dependent on energy in the spectrum at 200 Hz or to any fundamental periodicity of 200 Hz between wave form peaks.

Figure 25 depicts another intriguing aspect of these complex pitch stimuli. For this condition listeners were asked to match the pitch of a tone to that of the four-tone complex when all the tones in the complex were shifted in frequency (e.g., 50 Hz as shown in Fig. 25). For instance, if the complex consists of tones at 750, 950, 1150, and 1350 Hz, the matched pitch is approximately 190 Hz. The frequency spacing is still 200 Hz, but the fundamental frequency is now 50 Hz, not 200 Hz. The pitch of this complex is neither 50 nor 200 Hz, but 190 Hz. A number of different models have been proposed to account for how the nervous system extracts the pitch of these complex stimuli. It is clear that mechanisms in addition to those that form the code for sound frequency are required to account for the pitch of many complex sounds such as the "missing fundamental pitch" described above (see Moore, 1982).

8.3 Other Subjective Sound Attributes

A number of subjective attributes have been measured with matching procedures similar to that used to obtain the equal loudness contours (Fig. 22). Measurements of sound volume, density, and annoyance are some of these attributes. Measures of volume and loudness have been used to calibrate sound level controls for radios and other audio and entertainment equipment. Annoyance measurements are used in dealing with

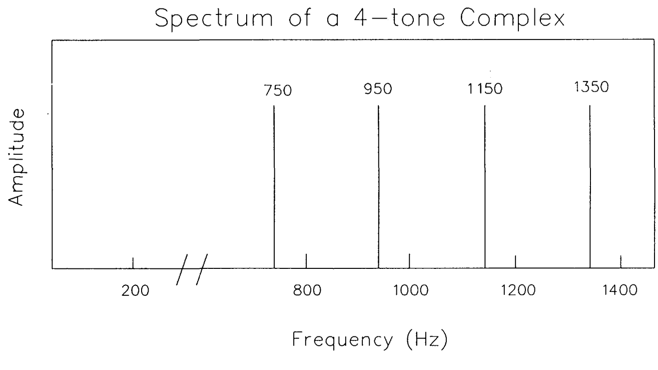

FIG. 25. This schematic amplitude spectrum is similar to that shown in Fig. 23, except the frequencies of the four tones have been shifted down 50 Hz relative to their frequencies in Fig. 23. The matched pitch is approximately 190 Hz for this complex, which is not equal to the missing fundamental (50 Hz).

indices of environmental noise pollution, especially in regard to airport noise (see Kryter, 1970).

The timbre of a sound is usually related to its spectral complexity, especially in the harmonic structure of periodic sounds. Thus, the difference in sound quality between a piano and a guitar playing the same pitch is referred to as a timbre difference. Each instrument will produce the same fundamental period of vibration if each produces the same pitch, but the amplitudes of the harmonics of this fundamental will differ between the two instruments resulting in the perceived timbre differences. No convenient metric has been developed to describe timbre.

Rhythm has been studied extensively in music and the musical notation of rhythm (i.e., specifying the relative durations of notes in terms of multiples of $\frac{1}{2}$, e.g., eighth notes, quarter notes) has proved to be among the most useful metrics for describing the subjective sense of rhythm (see Risset, 1978).

9. HEARING IMPAIRMENT

The data described so far relate to sound processing by the normal auditory system. For millions of people (approximately 20 million in the United States) auditory system disorders cause difficulties for functioning in everyday life. The primary means of determining the nature of a hearing disorder is by using psychoacoustic tasks similar to those described in this chapter.

9.1 Audiology and Otology

Two specialty areas deal with the diagnosis and treatment of hearing disorders: an otorhinolaryngologist (usually shortened to otolaryngologist or otologist and sometimes referred as ear, nose, throat or ENT specialist) is a surgical specialist of medicine, and an audiologist (or clinical audiologist) receives certification based on a master's degree and criteria set by the American Speech, Hearing, and Language Association, or in some special circumstances by state agencies. An audiologist often administers the hearing tests used for diagnosis and is usually responsible for rehabilitation following surgery or other corrective procedures such as the fitting of a hearing aid. An otolaryngologist is responsible for surgery or other medical treatments. For many patients, the two specialists form a team for treating hearing disorders.

9.2 Tests for Hearing Disorders

The neural site of a hearing disorder can be in the conductive pathways of the outer and middle ear, in the neural transduction mechanisms of the inner ear, or in the neural processes of the central nervous system. Many of the tests for detecting hearing disorders are designed to implicate one of these three sites as the location of the disorder.

The structures of the inner ear that signal the neural response to sound can be excited in two ways. The normal means is via the vibration of the middle ear bones by air-driven vibration of the eardrum, but the fluids and structures of the inner ear can be vibrated directly by the skull bone if the amplitude of bone vibration is great enough. Standard thresholds for both air-conducted (the thresholds shown in Fig. 2) and bone-conducted sound (by placing a vibrator on the mastoid or forehead) have been established (see Dirks, 1978). If a person has normal bone-conducted thresholds but abnormal air-conducted thresholds, it is assumed that the site of the impairment is in the conductive pathways of the outer and middle ears, most likely the middle ear bones. If both air-conducted and bone-conducted thresholds are abnormal, then the presumed site of the impairment is in the inner ear or the central nervous system.

This so-called "air-bone gap" has long been a standard hearing test. Another technique, frequently used to determine the integrity of the middle ear, is based on forming an acoustic impedance bridge, by reflecting sound off the eardrum and measuring the amount of reflected sound pressure as a function of changing the barometric pressure within the enclosed outer ear. The eardrum and bones of the middle ear are assumed to provide resistance and impedance to the reflected sound. Abnormal changes in the magnitude of the reflected sound with changes in the barometric pressure are interpreted as due to abnormal resistance or impedance changes, which can in turn implicate a middle ear structure as the cause of the abnormality. "Impedance audiometry" is a common test for deficiencies

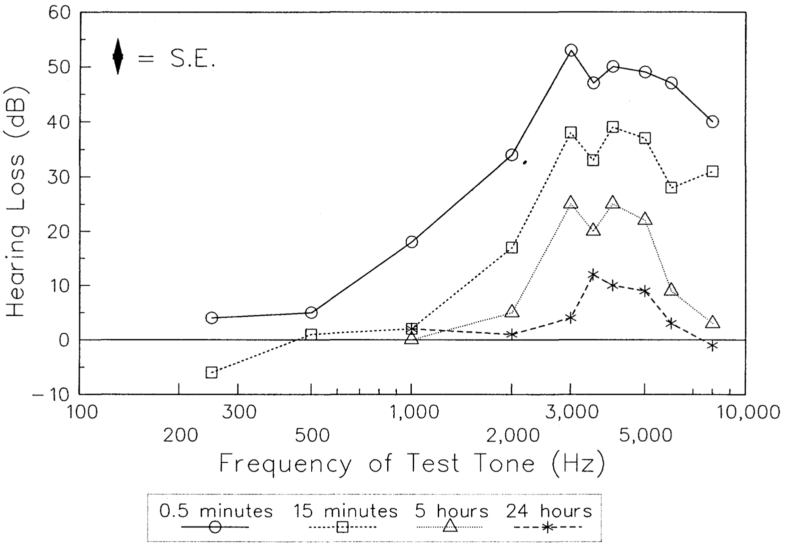

FIG. 26. The amount of hearing loss (in dB) for different tones as a function of the tonal frequency (in Hz) after the listener was presented a 115-dB SPL broadband noise for 20 min. Data are shown for four time intervals following the noise exposure (0.5 min, 15 min, 5 h, and 24 h). The amount of hearing loss (temporary threshold shift) was obtained by taking the difference between thresholds measured prior to the noise exposure and those measured at the various intervals after the noise exposure. The greatest temporary hearing loss is found in the region of 4000 Hz, and thresholds return to near normal 24 h after the exposure. The arrows labeled S.E. are an estimate of the standard error of measurement for these conditions and as such represent the expected variability about any data point. Adapted from the data of Postman and Egan (1949) as shown in Fig. 14.6 of Yost and Nielsen (1985).

in the conductive pathways for hearing (see Durrant and Lovrinic, 1977).

Tests for the neural sites of a hearing loss are more difficult to interpret. Psychophysical tests, often based on speech or binaural tasks (because binaural hearing and speech perception are assumed to depend on neural structures in the brain), are sometimes used to determine if a hearing disorder is due to abnormalities in the central nervous system. A variety of brain imaging techniques (e.g., measures of sound evoked electroencephalograms or PET) are also used if tumors or other such abnormalities are suspected as the cause of the hearing loss.

9.3 Hearing Loss and Noise Exposure

Hearing loss has many causes. The biological process of aging results in a progressive loss of hearing referred to as "presbycusis." Aging reduces sensitivity first to the highest frequencies, and then slowly, over time, the hearing loss progresses to lower and lower frequencies. Hearing abnormalities are due to genetic factors, diseases, infections, ototoxic drugs used in the treatment of some diseases and infections, damage to the nerves of the auditory system, or environmental factors, most notably exposure to intense sound.

Exposure to intense sound can produce a temporary hearing loss or a permanent hearing loss if the sound is very intense or the exposure is prolonged. Figure 26 shows data indicating the shift in thresholds of hearing following exposure to a 115-dB SPL noise presented for 20 min. The greatest loss occurs immediately after the noise is turned off and in the frequency region near 4000 Hz. Most temporary loss of hearing recovers to normal after a few hours following the exposure. However, repeated exposure to the intense sound may slow the recovery to the point that the loss is permanent. Table 6 shows the sound levels (expressed as dBA) and durations of exposure that will probably lead to a permanent loss of hearing if the exposure conditions are repeated. These "damage risk criteria" have been used in a number of laws and policies to limit the sound exposure that people can experience (see Miller, 1978).

9.4 Hearing Protection and Hearing Aids

In many job situations it is impossible to eliminate harmful exposure to intense sound levels. In these situations hearing protectors are used as a last resort for preventing a hearing loss. Most hearing protectors are passive, made of sound-attenuating material, and they fit into or over the outer ear. Some active noise-cancelling devices are also used to reduce noise, especially when speech communication is important (e.g., in the cockpit of a noisy airplane). These devices operate on a number of different principles, but generally attempt to cancel the noise background with an out-of-phase noise or to adaptively filter the unwanted noise, thus increasing the signal- to-noise ratio for the desired communication signal (see Lim, 1983).

Four general types of hearing aids or prosthetic devices are available to help a hearing-impaired listener: amplification aids, assisted listening devices, tactile aids, and cochlear prostheses. None of these aids restores hearing to a normal level, but each has its advantages and disadvantages (see Lutman and Haggard, 1983).

Amplification aids, made as small as possible for cosmetic purposes, act to amplify sound. They may amplify sound in particular frequency regions, limit the total amount of amplification to prevent discomfort by the listener, or provide some form of background-noise cancellation. Simply amplifying sound leads to two problems: (1) amplification causes all sounds to be increased in level, not just the signal the listener may want to hear, and (2) sounds can be increased only to a certain level before the listener experiences discomfort and the auditory system is jeopardized. Figure 27 shows the classic problem confronting an amplification aid. The abnormal increase in loudness for the hearing-impaired listener, sometimes called "recruitment," requires that the total output of the aid be limited. Many forms of compression are used to limit the sound level at high amplification. However, compression is a nonlinear operation that can distort the original sound. Many tricks of the trade are used to apply compression and reduce the distorting effects of the nonlinearity. Amplification aids are based on either analog or digital signal processes. Many digital amplification aids include a form of active noise cancellation, which often leads to a distorted signal requiring special circuitry to realize the noise cancellation while reducing distortion. The aid's small size and the close proximity of the microphone to the speaker also cause problems in providing a clear signal to the hearing-impaired listener. The battery life for aids is often very short, especially for digital aids that require a great deal of signal processing. Finally, properly fitting the aid to the ear of the individual listener is crucial both for comfort and to achieve the proper acoustic load for the hearing-aid speaker.

Table 6. Permissible noise exposure: sound levels (in dBA) and durations of exposures (in hours/day) that should not be exceeded. Repeated exposure to levels and durations greater than those of these damage-risk criteria could cause a measurable permanent hearing loss.

Duration (hours/day)	Sound level (dBA)
8	90
6	92
4	95
3	97
2	100
1.5	102
1	105
0.5	110
0.25 or less	115

Assisted listening devices enable sound to be fed directly to the listener. This can be accomplished over a cable, via FM broadcast, or by LED (light-emitting diode technology) transmission. These devices are found in classrooms, at theaters and churches, and in the home (e.g., connected to the television or as part of a telephone). Their main advantage is in magnifying the signal-to-noise ratio by carrying the signal directly to the listener with minimal amplification of the background noise. However, the talker as well as the listener must be fitted with a device.

Tactile aids provide vibration to the skin to translate various properties of sound to some part of the listener's skin surface (usually, the fingertip, forearm, back, or stomach). The devices usually divide sound into spectral bands through some form of bandpass filtering. The amount of energy in the various frequency bands may be coded according to different locations on the skin or by the rate or pattern of

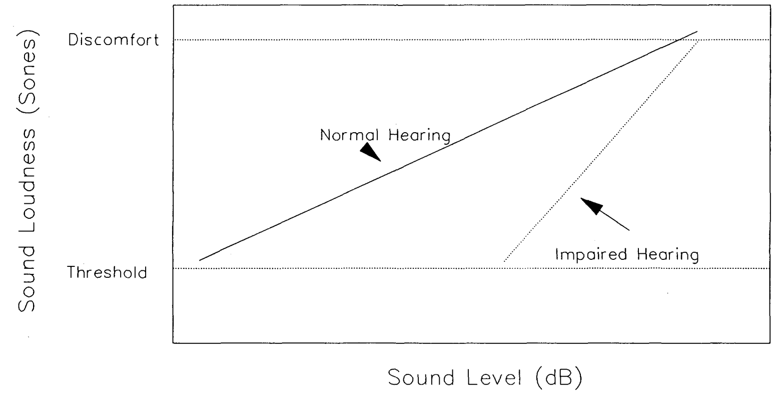

FIG. 27. A schematic loudness function represents the perceived change in loudness as a function of an increase in sound level (see also Fig. 23) for two types of listeners: a normal-hearing listener, and one with a hearing impairment. Both listeners judge very intense sounds to be approximately the same in loudness, especially near the sound level that is uncomfortable. However, because the hearing impaired listener has a hearing loss, the growth of his/her loudness function is steeper than for the normal hearing listener. Thus, the hearing impaired listener has a reduced dynamic range in which an amplification aid can operate in order to boost the level of sound without causing discomfort.

vibration. Tactile aids can assist the listener in lip reading and general sound awareness. For some users simple forms of speech can be transmitted through the skin, but usually only after considerable practice.

Cochlear prostheses are devices that deliver an electrical current directly to the nerves of the inner ear. Implanting the prosthesis is major microsurgery and is recommended only for patients with severe hearing loss. The aid consists of two main parts: a transducer which processes and translates sound into an electrical current, and an electrode(s) which delivers the current directly into the inner ear. The electrodes presumably stimulate neural tissue in the inner ear, triggering neural responses that mimic those that occur normally in neural sound transduction. For multiple-electrode devices, the transducer splits the sound into different frequency bands and delivers current to each electrode in proportion to the energy in each band. The electrodes are placed into different locations in the inner ear, such that those carrying information about the high frequencies are nearer the middle ear (the base of the inner ear) than those carrying low-frequency information (which are near the apex of the inner ear). In the normal inner ear, nerves near the base carry information to the brain about high frequencies while those near the apex carry lower-frequency information. Thus, the multiple-electrode devices attempt to mirror this form of neural coding. The success of cochlear prostheses is varied. Some users experience a range of sensations not dissimilar to those experienced by normal hearing listeners. However, the majority of the successful implants provide sensations useful for general sound awareness and aid in tasks such as lip reading (see Schindler and Merzenich, 1985).

GLOSSARY

All definitions are based on the American National Standards Institute's (ANSI) S3.20-1973(R 1986) Standard Terminology for Psychoacoustics. Terms not defined in the ANSI standard (and, therefore, not in this Glossary) but appearing in this chapter are defined within the chapter.

Aural Harmonic: An aural harmonic is a harmonic generated in the auditory mechanism.

Binaural Masking Level Difference (BMLD): Masking level difference is any decrease (improvement) in the masked threshold obtained when two ears are used instead of one. Masking level difference is expressed in decibels, as a function of the frequency of the masked tone.

Bone Conduction: Bone conduction is the process by which sound is conducted to the internal ear through the cranial bones.

Combination Tone: A combination tone is a (secondary) tone that can be perceived when two loud (primary) tones are presented simultaneously. The secondary tone may be a difference tone or a summation tone. Several combination tones may be produced from a single pair of primary tones. Combination tones can also be generated by aural harmonics. Combination tones are due to the nonlinear characteristics of the ear.

Coupler (6 cm^3): A coupler is a device for acoustic loading of earphones. It has a specified arrangement of acoustic elements, and is provided with a microphone for measurement of the sound pressure developed in a specified portion of the device.

Critical Band: The critical band for masking is that frequency band of sound, being a portion of a continuous-spectrum noise covering a wide band, that contains sound power equal to that of a pure tone centered in the critical band and just audible in the presence of the wide-band noise.

Dichotic: Dichotic refers to the condition in which the sound stimulus presented at one ear differs from the sound stimulus presented at the other ear.

Difference Tone: A difference tone is a combination tone with a frequency equal to the difference between the frequencies of two primary tones or of their harmonics.

Diotic: Diotic refers to the condition in which the sound stimuli presented at the two ears are identical.

Equal Loudness Contour: A loudness contour is a curve that shows the related values of sound pressure and frequency required to produce a given loudness sensation for the typical subject for a stated manner of listening to the sound.

Forward Masking: Forward masking describes the condition in which the masking sound appears before the masked sound.

Lateralization: Auditory lateralization is the determination by a subject that the apparent direction of a sound is either left or right of the frontal-medial plane within the head. Auditory lateralization is usually restricted to sounds presented by earphones or by bone-conduction vibrators.

Localization: Auditory localization is the determination by a subject of the apparent direction and/or distance of a sound source.

Loudness: Loudness is that attribute of auditory sensation in terms of which sounds may be ordered on a scale extending from soft to loud. Loudness depends primarily upon the sound pressure of the stimulus, but it also depends upon the frequency and wave form of the stimulus.

Masking: Masking is the process by which the threshold of audibility for one sound is raised by the presence of another (masking) sound. Masking is the amount by which the threshold of audibility of a sound is raised by the presence of another (masking) sound. The unit customarily used is the decibel.

Method of Magnitude Estimation: The method of magnitude estimation is a psychophysical method used primarily to scale sensations; in this procedure the subject assigns to a set of stimuli numbers that are proportional to some subjective dimension of the stimuli.

Minimal Audible Pressure (MAP): The minimum audible pressure is the sound pressure of a tone at the threshold of audibility that is presented by an earphone and measured or inferred at the tympanic membrane.

Minimal Audible Field (MAF): The minimum audible field is the sound pressure level of a tone at the threshold of audibility measured in a free sound field for a subject facing the sound source. The value of the sound pressure level is determined after the subject is removed from the field.

Monotic: Monotic refers to the condition in which a sound stimulus is presented at only one ear.

Phon: The (judged) loudness level of a sound, in phons, is numerically equal to the median sound pressure level, in decibels relative to 20 micropascals, of a 1000-Hz reference tone presented to subjects as a frontally incident free sound field, and judged by the subjects in a number of trials to be as loud as the sound under test.

Pitch: Pitch is that attribute of auditory sensation in terms of which sounds may be ordered on a scale extending from low to high. Pitch depends primarily upon the frequency of the sound stimulus, but it also depends upon the sound pressure and wave form of the stimulus. The pitch of a sound may be described by the frequency of that pure tone that is judged by subjects to produce the same pitch.

Precedence Effect: The precedence effect is the phenomenon that occurs during auditory fusion when two (primary) sounds of the same order of magnitude are presented dichotically and produce localization of the secondary sound toward the ear receiving the first (primary) sound stimulus. The precedence effect occurs for stimulus time delays varying from fractions of a millisecond to the upper time limit for auditory fusion, beyond which separate and independent sounds are heard.

Psychoacoustics: Psychoacoustics is the science that deals with the psychological correlates of the physical parameters of acoustics. Psychoacoustics is a branch of psychophysics.

Psychometric Function: A psychometric function is a mathematical relationship in which the independent variable is a measure of a stimulus and the dependent variable is a measure of response.

Psychophysics: Psychophysics is the science that deals with the quantitative relationship between physical and psychological events. Psychophysics is a branch of psychology.

Recruitment: Recruitment is the otological condition in which weak sounds are not heard while strong sounds are heard as loudly as by a normal ear. The function that relates loudness to sound pressure level is steeper than normal and is often nonlinear. In recruitment, the dynamic range of hearing is narrowed.

Sensation Level (SL): The sensation level of a sound is the pressure level of the sound in decibels above its threshold of audibility for the individual subject or for a specified group of subjects.

Sensory-Neural Hearing Loss: Sensory-neural hearing loss is the impairment of hearing that occurs when there is damage to the cochlea or the cochlear nerve.

Sone: The sone is a unit of loudness. One sone is the loudness of a sound for which the loudness level is 40 phons. The loudness of a sound that is judged by a subject to be *n* times that of a 1-sone tone is *n* sones.

Sound Pressure Level (SPL): Sound pressure level, in decibels, of a sound is 20 times the logarithm to the base 10 of the ratio of the pressure of this sound to the reference pressure of 20 micropascals.

Temporary Threshold Shift (TTS): Temporary threshold shift is a temporary increase in the threshold of audibility for an ear at a specified frequency. The amount of temporary threshold shift is customarily expressed in decibels.

Threshold of Audibility: The threshold of audibility for a specified signal is the minimum effective sound pressure level of the signal that is capable of evoking an auditory sensation in a specified fraction of the trials. The characteristics of the signal, the manner in which it is presented to the subject, and the point at which the sound pressure level is measured must be specified. Unless otherwise indicated, the ambient noise reaching the ears is assumed to be negligible. The threshold of audibility is usually given as a sound pressure level in decibels, relative to 20 micropascals.

Timbre: Timbre is that attribute of auditory sensation in terms of which a subject can judge that two sounds similarly presented and having the same loudness and pitch are dissimilar. Timbre depends primarily upon the spectrum of the stimulus, but it also depends upon the wave form, the sound pressure, the frequency location of the spectrum, and the temporal characteristics of the stimulus.

INTRODUCTION

Underwater acoustics is the science of sound in water (most commonly in the ocean) and encompasses not only the study of sound propagation, but also the masking of sound by interfering acoustic phenomena. Its origins date back centuries. For example, Leonardo da Vinci noted that sound travels to great distances in the sea and referred to interfering phenomena (in this case, self-noise) by suggesting the listener "...cause your ship to stop..." (Urick, 1983) before deploying a listening tube through the air-water interface. This listening tube was improved upon by Colladen and Sturm (Lasky, 1977) who, on Lake Geneva in 1827, employed a trumpetlike device as an underwater sound receiver together with a submerged bell ten miles away. By essentially a time of flight measurement, they determined the speed of sound to an accuracy of about two-tenths of one percent. In addition, "Colladen marvelled that so little energy at the source could be transmitted so great a distance through the water medium and could still be detected by the trumpet receiver." It is still believed that only sound will propagate signals to great distances in the sea.

The development of acoustics theory has followed a different historical path than optics and electromagnetic theory (Pierce, 1981). While there has been a long-running battle in optics between ray and wave theory, acoustics originally developed with wave and vibration concepts as far back as ancient Greek times. For example, musical sound is the result of air motion generated by a vibrating musical instrument. Thus sound is propagated in an analogous manner to water surface waves which propagate disturbances (signals), but not matter, long distances. The bending of sound around corners is then easily understood in the context of diffraction in the water surface wave analogy. In acoustics, the ray picture evolved as a mathematical approximation to wave theory. In underwater acoustics, in which the medium is inhomogeneous and bounded by complicated interfaces, ray theory has historically proved to be an indispensable tool for understanding and studying sound propagation. However, with the advent of computers and the recent developments of numerical physics, sound propagation in the ocean can now be studied and

quantitatively described in greater detail with the more exact wave theory. This latter trend is particularly important to the study of extracting signals from complex interfering fields in which quantitative understanding of the amplitude, phase, and higher order moments of all the relevant fields is necessary.

Research in the field of experimental underwater acoustics requires extensive equipment, with at least one ship and often an assortment of at-sea platforms equipped with sound projectors, receiving arrays, and sensors to measure the ocean environment. The requirements to measure the latter arise because the ocean is the medium which defines the acoustic index of refraction, and the ocean surface and bottom (and layers below) are the interfaces that define the boundary conditions of the partial differential equations descriptive of sound propagation in the ocean. Very often, the oceanographic and/or ocean geology measurements associated with an acoustic experiment rival or exceed the complexity of the acoustic measurements.

In this article the ocean environment will be introduced and described prior to the acoustics. Then we present underwater acoustics with minimum mathematics in a detailed, though descriptive, manner, associating various acoustic topics with the details of the previously discussed ocean environment. After completing the descriptive underwater acoustics part, more details are given on the theory of underwater acoustics and the models that have been developed to compute ocean acoustic phenomena. Since underwater acoustics cannot be divorced from the measurements of signals in complex media, some relevant array and signal processing ideas will also be reviewed together with a discussion of sonars and the sonar equation. We end by discussing the use of sonar technology for remote sensing of the ocean. We start by mentioning some relevant units and a brief discussion on underwater acoustic transducers.

Some Relevant Units

The decibel (dB) is the dominant unit in underwater acoustics and denotes a ratio of intensities (not pressures) expressed in terms of a logarithmic (base 10) scale. Two intensities, I_1 and I_2, have a ratio I_1/I_2 in decibels of 10 log I_1/I_2 dB. Absolute intensities can therefore be expressed by using a reference intensity. The presently accepted reference intensity is a micropascal (μPa): the intensity of a plane wave having an rms pressure equal to 10^{-5} dyn/cm^2. Therefore, taking 1 μPa as I_2, a sound wave having an intensity, of, say, one million times that of a plane wave of rms pressure 1 μPa has a level of $10 \log(10^6/1) \equiv 60$ dB re 1 μPa. Pressure (p) ratios are expressed in dB re 1 μPa by taking $20 \log p_1/p_2$, where it is understood that the reference originates from the intensity of a plane wave of pressure equal to 1 μPa.

The average intensity I of a plane wave with rms pressure p in a medium of density ρ and sound speed c is $I=p^2/\rho c$. In seawater, ρc is 1.5×10^5 g cm^{-2} s^{-1} so that a plane wave of rms pressure 1 dyn/cm^2 has an intensity of 0.67×10^{-12} W/cm^2. Substituting the value of a micropascal for the rms pressure in the plane wave intensity expression, we find that a plane wave pressure of 1 μPa corresponds to an intensity of 0.67×10^{-22} W/cm^2 (i.e., 0 dB re 1 μPa).

Acoustical Instrumentation

(See ACOUSTICAL INSTRUMENTATION in this volume.) A transducer converts some sort of energy to sound (source) or converts sound to energy (receiver), usually electric (Wilson, 1985). In underwater acoustics, piezoelectric and magnetostrictive transducers are commonly used. The piezoelectric effect, which occurs in certain crystals, such as quartz, involves electric polarization produced by mechanical strain and vice versa. There is also an electrostrictive effect which is common to all dielectrics but smaller than the piezoelectric effect: an electric field mechanically deforms the dielectric, independently of the direction of the electric field. The magnetostrictive effect is the change in dimensions of a ferromagnetic material when it is placed in a magnetic field and the change in magnetization when the material's dimensions change from an external force.

There are also electrodynamic transducers. For example, a receiver element operates by sound pressure oscillations moving a current-carrying conductor through a magnetic field causing a back emf. Electrostatic transducers operate on the principle that charged electrodes moving in a sound field change separation distance, thereby changing the capacitance of the system.

Explosive and airgun sources are high energy wideband types of sources. The technology is such that their signatures are fairly reproducible (Urick, 1983). Electric discharge and laser sources are also in use.

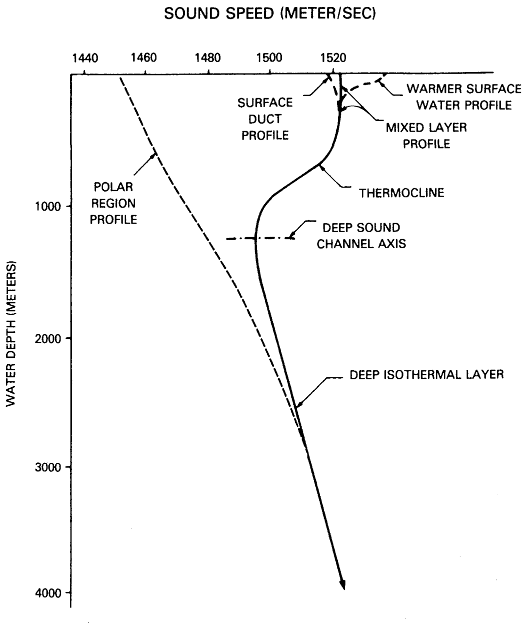

FIG. 1. Generic sound speed profiles.

1. THE OCEAN ENVIRONMENT

In underwater acoustics, the ocean is a waveguide and the speed of sound (c) plays the same role as the index of refraction does in optics. Sound speed is normally related to density and compressibility. In the ocean, density is related to static pressure (which increases with depth), salinity, and temperature (which varies significantly in the upper mixing layer). The sound speed in the ocean is an increasing function of temperature, salinity, and pressure. It is customary to express sound speed as an empirical function of three independent variables: temperature (T) in degrees centigrade, salinity (S) in parts per thousand, and depth (z) in meters. A simplified expression for this dependence is (Clay and Medwin, 1977)

$$c=1449.2+4.6T-0.055T^2+0.00029T^3 \\ +(1.34-0.10T)(S-35)+0.016z. \qquad (1)$$

For most cases, the above equation is sufficiently accurate; however, occasionally more accuracy may be required when distances are derived from travel time measurements.

Seasonal and diurnal changes affect the oceanographic parameters in the upper ocean. In addition, all of these parameters are functions of geography. Figure 1 illustrates a typical set of sound speed profiles indicating greatest variability near the surface as a function of season and time of day. In a warmer season (or warmer part of the day), the temperature increases near the surface and hence the sound speed decreases with depth. In nonpolar regions, the oceanographic properties of the water near the surface result from mixing activity originating from the air-sea interface. This near-surface mixed layer has a constant temperature (except in calm, warm surface conditions as described above). Hence, in this isothermal mixed layer, the sound speed profile can increase with depth due to the pressure gradient effect of the last term in Eq. (1). This is the "surface duct" region, and its existence depends on the near-surface oceanographic conditions. Note, the more agitated the upper layer, the deeper the mixed layer and the less likely there will be any departure from the mixed-layer part of the profile depicted in Fig. 1. Hence, an atmospheric storm passing over a region where a surface duct exists is likely to mix the surface waters and cause the duct to change.

Below the mixed layer is the thermocline in which the temperature decreases with depth and the sound speed decreases with depth. Below the thermocline, the temperature is constant (about 4 °C—a thermodynamic property of salt water at high pressure) and the sound speed increases because of increasing pressure. Therefore, a minimum sound speed which is often referred to as the axis of the deep sound channel exists between the deep isothermal region and the mixed layer. However, in polar regions, the water is coldest near the surface and hence the minimum sound speed is at the ocean/air (or ice) interface as indicated in Fig. 1. In continental shelf regions (shallow water) with water depths on the order of a few hundred meters, only the upper region of the sound speed profile in Fig. 1, which is dependent on season

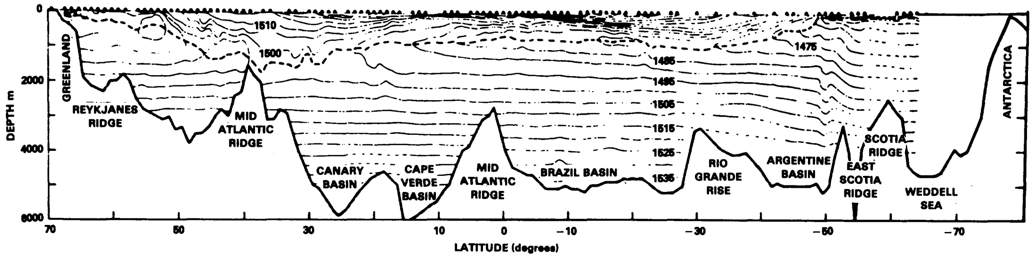

FIG. 2. Sound speed contours at 5 m/s intervals taken from North and South Atlantic along 30.50° W. Dashed line indicates axis of deep sound channel (from Northrup and Colburn, 1974).

and time of day, affects sound propagation in the water column.

Figure 2 is a contour display of the sound speed structure of the North and South Atlantic (Northrup and Colburn, 1974) with the deep sound channel indicated by the heavy dashed line. Note the geographic (and climatic) variability of the upper ocean sound speed structure and the stability of this structure in the deep isothermal layer. For example, as explained above, the axis of the deep sound channel becomes shallower toward both poles, eventually going to the surface.

2. SOUND PROPAGATION PATHS IN THE OCEAN

Figure 3 is a schematic of the basic types of propagation in the ocean resulting from the sound speed profiles (indicated by the dashed lines) discussed in the last section. These sound paths can be understood from a simplified statement of Snell's law: sound bends locally toward regions of low sound speed (or sound is "trapped" in regions of low sound speed). Simplest to explain are the paths about local sound speed minima: A, B, and C. Paths A and B correspond to surface duct propagation where the minimum sound speed is at the ocean surface (or at the bottom of the ice cover for the Arctic case). Path C, depicted by a ray leaving a deeper source at a shallow horizontal angle, propagates in the deep sound channel whose axis is at the shown sound speed minimum. As stated above, this local minimum tends to become more shallow towards polar latitudes converging to the Arctic surface minimum, path A. Hence for mild latitudes, sound in the deep channel can propagate long distances without interacting with lossy boundaries; propagation via this path has been observed over distances of thousands of kilometers. Also, from the above description of the geographical variation of the acoustic environment combined with Snell's law, we can expect that shallow sources coupling into the water column at polar latitudes will tend to propagate more horizontally around an axis which becomes deeper toward the mid latitudes. Path D, which is at slightly steeper angles than those associated with path C, is convergence zone propagation, a spatially periodic (~35–65 km) refocusing phenomenon producing zones of high intensity near the surface due to the upward refracting nature of the deep sound speed profile. Referring back

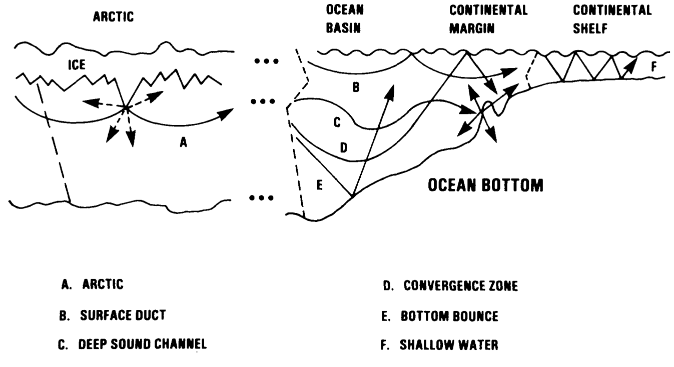

FIG. 3. Schematic representation of various types of sound propagation in the ocean.

to Fig. 1, there may be a depth in the deep isothermal layer at which the sound speed is the same as it is at the surface. This depth is called the "critical depth" and, in effect, is the lower limit of the deep sound channel. A "positive critical depth" specifies that the environment supports long distance propagation without bottom interaction, whereas "negative" implies that the bottom ocean boundary is the lower boundary of the deep sound channel. The bottom bounce path E, which interacts with the ocean bottom, is also a periodic phenomenon but with a shorter cycle distance and a shorter total propagation distance because of losses when sound is reflected from the ocean bottom. Finally, the right-hand side of Fig. 3 depicts propagation in a shallow water region such as a continental shelf. Here sound is channeled in a waveguide bounded above by the ocean surface and below by the ocean bottom. Because of the latter, negative critical depth environments exhibit much of the sound propagation physics descriptive of shallow water environments.

The modeling of sound propagation in the ocean is further complicated because the environment varies laterally (range dependence), and all environmental effects on sound propagation are dependent on acoustic frequency in a rather complicated way which often makes the ray type schematic of Fig. 3 misleading, particularly at low frequencies. Finally, a quantitative understanding of acoustic source mechanisms in the ocean is required for modeling sound propagation. These losses are, aside from geometric spreading: volume attenuation, bottom loss, and surface, volume (including fish), and bottom scattering loss.

2.1 Volume Attenuation

Volume attenuation increases with frequency. Returning to Fig. 3, the losses associated with path C, deep channel propagation, include volume attenuation and scattering because this path does not involve interaction with the boundaries. The volume scattering can be biological in origin or arise from the environmental condition that the upper boundary of the deep sound channel is typically the region of greatest internal wave activity in the ocean. Both of these effects are small for low frequencies, and hence deep sound propagation has been observed to distances of thousands of kilometers. This same internal wave region is also on the lower boundary of the surface duct, allowing scattering out of the surface duct, thereby constituting a loss mechanism for the surface duct. This mechanism also "leaks" sound into the Deep Sound Channel, a region which without scattering would be a "shadow zone" for a surface duct source. This type of volume scattering from internal waves is also thought to be a major source of fluctuation (Flatte, 1983).

Plane wave attenuation (α) is defined from a differential equation for a decay law as a function of distance:

$$\frac{dA}{dx}=-\alpha A \Rightarrow A=A_0 \exp(-\alpha x), \qquad (2)$$

where A_0 is the rms amplitude at $x=0$. The unit of α is nepers/distance. For example, a plane wave with wave number k that undergoes attenuation has the form $\exp(ikx-\alpha x)$. Attenuation is often expressed in decibels loss per unit distance, α', with units of dB/distance:

$$\text{Loss} \equiv 20 \log \frac{A_0}{A}=8.686\alpha x \Rightarrow \alpha'=8.686\alpha. \qquad (3)$$

The frequency dependence of attenuation can be roughly divided into four regimes of different physical origin as displayed in Fig. 4 (taken from Urick, 1979). The lowest frequency regime, Region I, is still not completely understood but it is conjectured that it is related to low-frequency propagation-duct cutoff, or, in other words, leakage out of the deep sound channel, as mentioned above. The main mechanisms associated with Regions II and III are boric acid and magnesium sulfate chemical relaxation. Region IV is dominated by the shear and bulk viscosity associated with freshwater. A summary of the approximate frequency dependence (f in kHz) of the attenuation (in units of dB/km) is (Urick, 1979; Fisher and Simmon, 1977; Thorpe, 1967)

$$\alpha'(\text{dB/km}) \approx 3.3\times 10^{-3}+\frac{0.11f^2}{1+f^2} + \frac{43f^2}{4100+f^2}+2.98\times 10^{-4}f^2, \qquad (4)$$

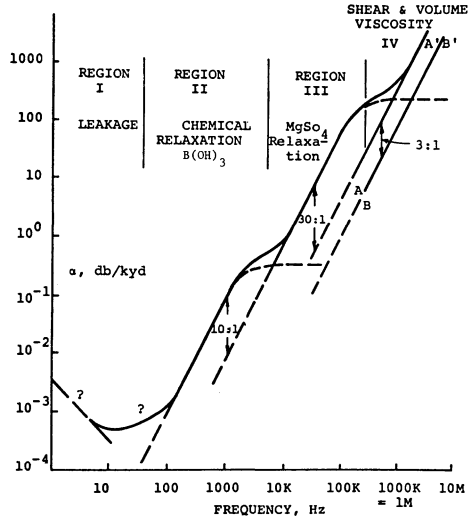

FIG. 4. Regions of different dominant processes of attenuation of sound in seawater (from Urick, 1979). The attenuation α is given in dB per kiloyard.

with the terms sequentially associated with Regions I–IV in Fig. 4.

2.2 Bottom Loss

When sound interacts with the ocean bottom, the structure of the ocean bottom becomes important. Ocean bottom sediments are often modeled as fluids, which support only one type of sound wave—the compressional wave. This is often a good approximation since the rigidity (and hence the shear speed) of the sediment is usually considerably less than that of a solid, such as rock. In the latter case, which applies to the "ocean basement," or the case where there is no sediment overlying the basement, the medium must be modeled as an elastic solid which means it supports both compressional and shear waves. In reality, the media are viscoelastic, as volume attenuation is important.

Reflectivity, the amplitude ratio of reflected and incident plane waves at an interface separating two media, is an important measure of the effect of the bottom on sound propagation. For an interface between two fluid semi-infinite half-spaces with density ρ_i and sound speed c_i, $i = 1, 2$, as shown in Fig. 5(a), the reflectivity is given by

$$\mathscr{R}(\theta) = \frac{\rho_2 k_{1z} - \rho_1 k_{2z}}{\rho_2 k_{1z} + \rho_1 k_{2z}}, \tag{5}$$

with

$$k_{iz} = (\omega / c_i) \sin\theta_i \equiv k_i \sin\theta_i; \quad i = 1, 2. \tag{6}$$

The incident and transmitted grazing angles are related by Snell's law,

$$k_\perp = k_1 \cos\theta_1 = k_2 \cos\theta_2, \tag{7}$$

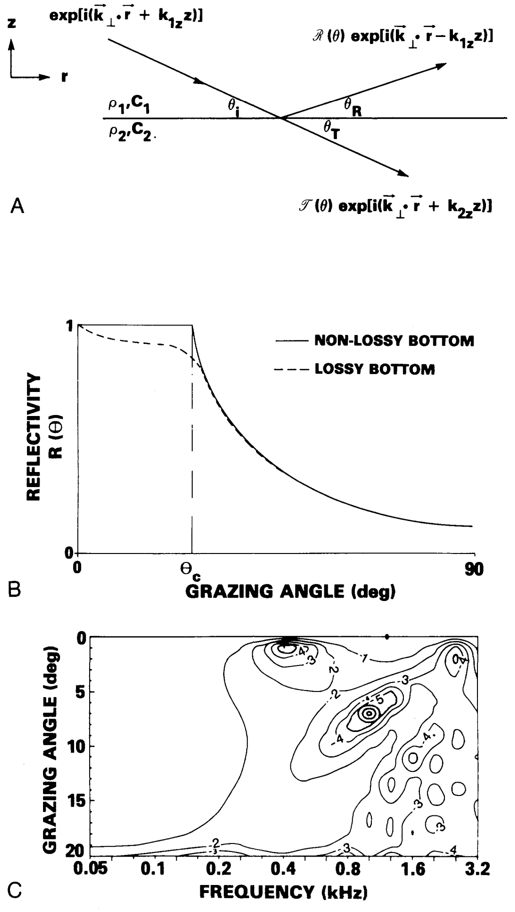

FIG. 5. The reflection and transmission process. Grazing angles are defined relative to the horizontal. (a) Plane wave impinges on interface separating two media with densities ρ_1, ρ_2 and sound speeds c_1, c_2. $\mathscr{R}(\theta)$ and $\mathscr{T}(\theta)$ are reflection and transmission coefficients. Snell's law is a statement that $k_\perp$ is the same for all three waves. (b) Rayleigh reflection curve indicating critical angle θ_c. The dashed curve shows that if the second medium is lossy, there is less than perfect reflection below the critical angle. (c) Contour of reflection loss for a layered bottom showing frequency and grazing angle dependence. Simpler Rayleigh reflection curve for each frequency is obtained from vertical slice.

where the incident grazing angle θ_1 is also equal to the angle of the reflected plane wave. $\mathscr{R}(\theta)$ is also referred to as the Rayleigh reflection coefficient and has unit magnitude (total internal reflection) when the numerator and denominator of Eq. (5) are complex conjugates. This occurs when k_{2z} is purely imaginary, and using Snell's law for determining θ_2 in terms of the incident grazing angle, we obtain the critical grazing angle, below which there is perfect reflection,

$$\cos\theta_c = c_1/c_2, \tag{8}$$

so that a critical angle can exist only when the speed in the second medium is higher than that of the first.

Using Eq. (6), Eq. (5) can be rewritten as

$$\mathscr{R}(\theta) = \frac{\rho_2 c_2/\sin\theta_2 - \rho_1 c_1/\sin\theta_1}{\rho_2 c_2/\sin\theta_2 + \rho_1 c_1/\sin\theta_1} = \frac{Z_2 - Z_1}{Z_2 + Z_1}, \tag{9}$$

where the right-hand side is in the form of impedances, $Z_i(\theta_i) = \rho_i c_i/\sin\theta_i$, which are the ratios of the pressure to the vertical particle velocity at the interface in the ith medium (Brekhovskikh, 1980). Written in this form, more complicated reflection coefficients become intuitively plausible. Consider the case in Fig. 5(a) where the second medium is elastic and thus supports shear as well as compressional waves with sound speeds c_{2s} and c_{2p}, respectively. The Rayleigh reflection coefficient is then given by

$$\mathscr{R}(\theta) = \frac{Z_{2\mathrm{tot}} - Z_1}{Z_{2\mathrm{tot}} + Z_1}, \tag{10}$$

with the total impedance of the second medium being

$$Z_{2\mathrm{tot}} \equiv Z_{2s} \sin^2 2\theta_{2s} + Z_{2p} \sin^2 2\theta_{2p}. \tag{11}$$

Snell's law for this case is

$$k_1 \cos\theta_1 = k_{2s} \cos\theta_{2s} = k_{2p} \cos\theta_{2p}. \tag{12}$$

It can be shown that the total impedance of the elastic medium is less than that of a liquid layer with the same compressional speed. Hence, the elastic interface appears to be "softer" than the equivalent liquid layer, which can be thought to arise from the fact that the shear wave provides an additional degree of freedom for the acoustic wave to penetrate into the second medium. A good approximation (neglecting interface waves) for a second medium, whose shear wave velocity is greater than the compressional wave velocity of the first medium, is to replace the elastic reflection coefficient with the two-fluid reflection coefficient using the shear wave of the second medium as the compressional wave of an "effective" second fluid medium.

In lossy media, attenuation can be included in the reflectivity formula by taking the sound speed as complex so that the wave numbers are, consequently, also complex, $k_i \to k_i + \alpha_i$. Then, a plane wave has the form exp $(ikx - \alpha x)$, just as in the volume attenuation case above. The acoustic properties of ocean bottom media have been estimated from measurements (see, for example, Hamilton and Bachman, 1982) and are given in Table 1 (as compiled in Jensen and Kuperman, 1983).

Figure 5(b) depicts a simple bottom loss curve derived from the Rayleigh reflection co-

Table 1. Geoacoustic properties of some ocean bottom types.

Bottom type	Porosity P(%)	Relative density $\frac{\rho_B}{\rho_W}$	Relative speed $\frac{C_P}{C_W}$	Compressional speed C_P (m/s)	Shear speed C_S (m/s)	Compressional attenuation β_ρ (dB/λ)	Shear attenuation β_ρ (dB/λ)

Basalt	···	2.6	3.5	5250	2500	0.2	0.5

efficient formula, where both the densities and sound speed of the second medium are larger than those in the first medium with unit reflectivity indicating perfect reflection. For loss in dB, 0 dB is perfect reflecting, 6 dB loss is an amplitude factor of one-half, 12 dB loss is one-fourth, etc. For a lossless bottom, severe loss occurs above the critical angle in the water column due to transmission into the bottom. For the lossy (more realistic) bottoms, only partial reflection occurs at all angles. With paths involving many bottom bounces (shallow water propagation), bottom losses as small as a few tenths of a dB per bounce accumulate and become significant because the propagation path may involve many tens of bounces.

Path E in Fig. 3, the bottom bounce path, often involves paths which correspond to angles near or above the critical angle; therefore, after a few bounces, the sound level is highly attenuated. On the other hand, for shallow angles, many bounces are possible. Hence, in shallow water, path F, most of the energy that propagates is close to the horizontal and this type of propagation is most analogous to waveguide propagation. In fact, as shown in Fig. 6, there exists a small cone from which energy propagates long distances (θ_c is typically 10°–20°). Energy outside the cone is referred to as the near field (or continuous spectrum), which eventually escapes the waveguide. The trapped field originating from within the cone is referred to as the normal mode field (or discrete spectrum) because there are a set of angles corresponding to discrete paths which constructively interfere and make up the normal (natural) modes of the shallow water environment. The modes within the cone are discrete because the nearly perfect reflectivity permits the existence of a set of discrete vertical standing waves analogous to those of a vibrating string or an organ pipe.

Very often, the ocean is more complicated than that described by the frequency independent reflection loss of Fig. 5(b). For example, the ocean may be a complex layered structure. For this bottom type, the reflectivity will be a complicated function of frequency and incident grazing angle with respect to the horizontal. Figure 5(c) displays some model results of loss contours of such a layered bottom. The more familiar curve of reflectivity versus grazing angle, such as depicted in Fig. 5(b), is obtained from a vertical cut through the loss contours (the loss contours are expressed in decibels). For example, at low fre-

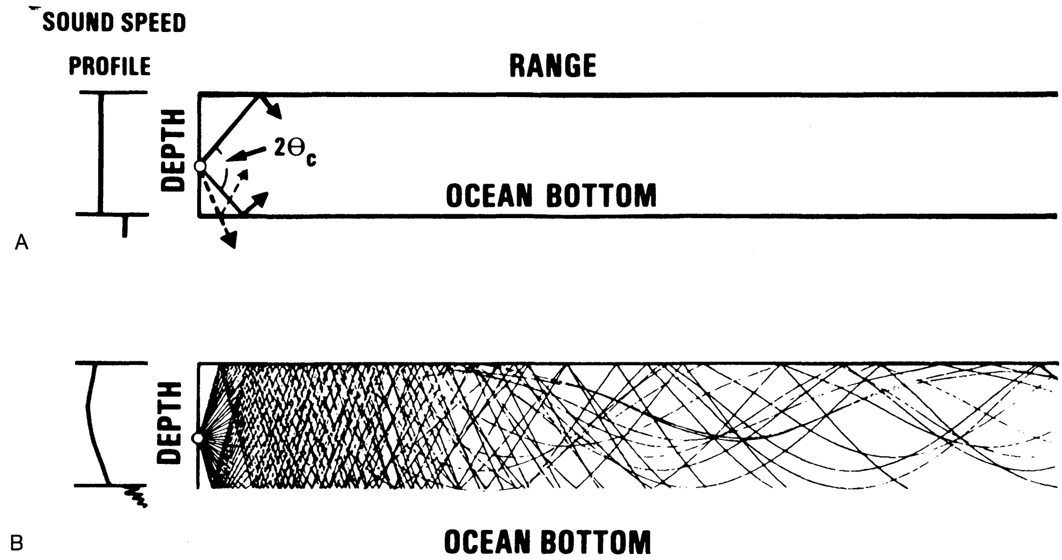

FIG. 6. Ocean waveguide propagation. (a) Long distance propagation occurs within a cone of $2\theta_c$. For angles greater than the critical angle θ_c, acoustic energy is partially transmitted into the ocean bottom at each bounce resulting in severe decay of the acoustic field in the water column with range. (b) The same as (a) but with a nonisovelocity water column showing refraction. Even below critical angle, higher angle paths have greater loss per bounce, as shown in Fig. 5(a).

quencies, Fig. 5(c) indicates a critical angle of about 18°, whereas at high frequencies we do not see a critical angle.

2.3 Surface, Bottom, and Volume Scattering

Scattering is a mechanism for loss, interference, and fluctuation phenomena. Ocean surface and bottom roughness attenuate the mean acoustic field. This attenuation increases with frequency. The field scattered away from the specular direction (reverberation) acts as interference for active sonar systems. Because the ocean surface moves, it generates acoustic fluctuations. Bottom roughness can also generate fluctuations when the sound source and/or receiver is moving. The effect of the roughness depends on the sound speed profile which determines the degree of interaction of sound with the rough surface.

The scattering theory literature is massive (see Ogilvy, 1987 for a review). Very often the effect of scattering from a rough surface is thought of in terms of a loss of a specularly reflected (coherent) component which results from scattering out of the coherent or specular field. The ocean bottom or surface can often be modeled as a randomly rough surface; if the roughness is small, relative to a wavelength, the scattering process can be modeled as a reduced reflection coefficient. A formula often used (Urick, 1979) for reflection from a rough interface is

$$\mathscr{R}'(\theta)=\mathscr{R}(\theta)e^{-2\Gamma^2}, \tag{13}$$

where $\mathscr{R}'(\theta)$ is the reduced reflection coefficient and Γ is the Rayleigh roughness parameter:

$$\Gamma=K\sigma\sin\theta. \tag{14}$$

In particular, the rough coherent sea surface reflection coefficient for the coherent field is

$$\mathscr{R}'(\theta)=-e^{-2\Gamma^2}. \tag{15}$$

For the ocean bottom, the appropriate parameters such as those from Table 1 are inserted into the expression for $\mathscr{R}$.

The coherent field is attenuated because of the generation of a scattered incoherent field, which is referred to as reverberation and can cause interference in the signal processing of the coherent waves. The excitation of this scattered field is characterized by a scattering cross section, which is defined as the ratio of the scattered power measured at a unit distance from a specified point to the intensity incident on a specified unit area (or unit volume in the case of volume scattering). Since power is the product of intensity and area, cross section is an effective area which multiplies the intensity of an incident field to give the scattered power. In underwater acoustics, the surface (area) and volume scattering strength $S_{s,v}$ (see Sec. 6.2) has become the more conventional parameter of reverberation and it is defined as the ratio (in dB units) of the intensity of the sound scattered by a unit surface area or volume, referenced to a unit distance (normally a yard), I_{scat} to the incident plane wave intensity I_{inc}:

$$S_{s,v}=10\log\frac{I_{\text{scat}}}{I_{\text{inc}}}. \tag{16}$$

Below we give empirical expressions for surface and bottom backscattering strengths $S_{S,B}$, which have been employed with some success.

At the ocean surface, the Chapman–Harris curves (Chapman and Harris, 1962) derived from measurements over the frequency range of 400 to 6400 Hz and wind speed up to 30 kn give a backscattering strength dependent on grazing angle θ in degrees, windspeed w in kn, frequency f in Hz, but independent of scattering angle:

$$S_S=3.3\,\beta\log\frac{\theta}{30}-42.4\log\beta+2.6;$$

$$\beta=158(wf^{1/3})^{-0.58}, \tag{17}$$

where the units are dB referenced to 1 yard.

At the ocean bottom, diffuse scattering described by Lambert's law together with an empirical scattering coefficient is used to estimate bottom scattering strengths from very rough ocean bottoms. Lambert's law states that the scattered power from a rough surface is proportional to the sine of the scattering angle ϕ. The incident power intercepted by the surface δA is proportional to the intensity $I_{\text{inc}}\times\sin\theta\delta A$. With Eq. (16) (per unit area) in the backscattered direction $\phi=\pi-\theta$, Lambert's law gives bottom scattering strength

$$S_B=-5+10\log\sin^2\theta, \tag{18}$$

where the first term is the proportionality constant arising from an assumption that all the incident energy is scattered and redistributed into the water column with no transmission into the bottom (Urick, 1983). Often, the first term of Eq. (18) is empirically adjusted according to a measured scattering strength.

In Sec. 2.1 we quantitatively summarized volume attenuation, part of which is caused by scattering. This scattering also produces a backscattered or reverberant acoustic field. However, most volume reverberation is thought to arise from biological organisms. A quantity often used to describe volume scattering is column strength. Returning to the discussion above Eq. (16), a surface (area) scattering strength can be related to a local volume scattering strength at depth h, $s_v(h)$:

$$S_s = 10 \log \int_0^H s_v(h)dh = S_v + 10 \log H, \qquad (19)$$

where S_v is an average volume scattering strength and H is a layer thickness in consistent units. When H is the entire water depth, $S_s \equiv S_c$ is called the column or integrated scattering strength.

In general, volume scattering decreases with increasing depth (about 5 dB per 300 m) with the exception of the deep scattering layer discussed below. For the lower frequencies (< 10 kHz), fish with air-filled swim bladders are the main scatterers. Above 20 kHz, zooplankton or smaller animals that feed upon the phyloplankton and the associated biological chain are the scatterers. The depth of the deep scattering layer varies throughout the day, being deeper in the day than in the night and changing most rapidly during sunset and sunrise. This layer produces a strong scattering increase of 5–15 dB within 100 m of the surface at night, and virtually no scattering in the daytime at the surface since it can migrate down to a depth of about 180 to 900 m at midlatitudes. Typical scattering results for the integral in Eq. (19) ($M_z \equiv s_v$) are shown in Fig. 7 (Chapman and Marshall, 1966) where the difference in day and night spectra of column scattering strength is thought to arise from the lower hydrostatic pressure nearer the ocean surface. This tends to lower the resonance frequency of the swim bladders, and the peak is lower in the night.

Finally, scattering off bubbles near the surface is sometimes referred to as either a volume or a surface scattering mechanism. These bubbles arise not only from sea surface action, but also from biological origins and ship wakes. Further, bubbles are not only a scattering mechanism, but bubble clouds may significantly alter local sound speed conditions. At the sea surface, the relative importance of roughness versus bubble effects is not yet resolved.

2.4 Ambient Noise

In underwater acoustics, ambient noise is an issue when it masks a signal of interest. Ocean acoustic signal processing (see Sec. 8) is a procedure for extracting a signal embed-

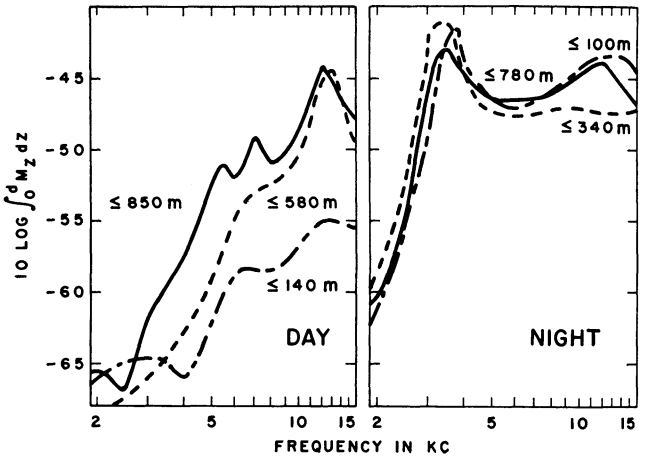

FIG. 7. Day and night scattering strength measurements using an explosive source, as a function of frequency (from Chapman and Marshall, 1966). The spectra measured at various times after the explosion are labeled with the depth of the nearest scatterer that could have contributed to the reverberation. The variable M_z corresponds to s_v in the text.

ded in noise. The noise is irrelevant if the signal is very strong. However, the more interesting case is the marginal situation of low signal to noise ratio. We would like to exploit the difference in the properties of the signal of interest and the noise to be rejected. Simple examples of this procedure are: omnidirectional noise can be reduced by a directional receiver with narrow look directions (beams); directional noise can be avoided by not looking in the direction of the noise. The more general case of achieving noise gain (i.e., enhancement of signal over noise) is to factor into the design of a receiving system knowledge of the general distribution of the ambient noise including its coherence properties. In this section we describe some of the properties of ocean ambient noise. In particular, we summarize the spectral character of noise. In Sec. 5 we discuss the relevant acoustic theory which explains the spatial distribution of noise.

There are essentially two types of noise: man-made and natural. Generally, shipping is the most important source of man-made noise, though noise from offshore rigs is becoming more prevalent. Usually, natural noise dominates at low frequencies (below 10 Hz) and at high frequencies (above a few hundred Hz). The field of ambient noise is reviewed rather extensively by Ross (1976), Urick (1984), and Kerman (1988), the last being a series of reviews and research papers on natural mechanisms of sea noise. Shipping noise fills in the region between ten and a few hundred Hz. A summary of the spectrum of noise is shown in Fig. 8 (Wenz, 1962). The higher frequency wind noise is usually parametrized according to sea state (also Beaufort number) and/or wind. Table 2 (Wenz, 1962) summarizes the relationship between sea state, wind, and wave height. The discussion of the spatial distribution of noise ap-

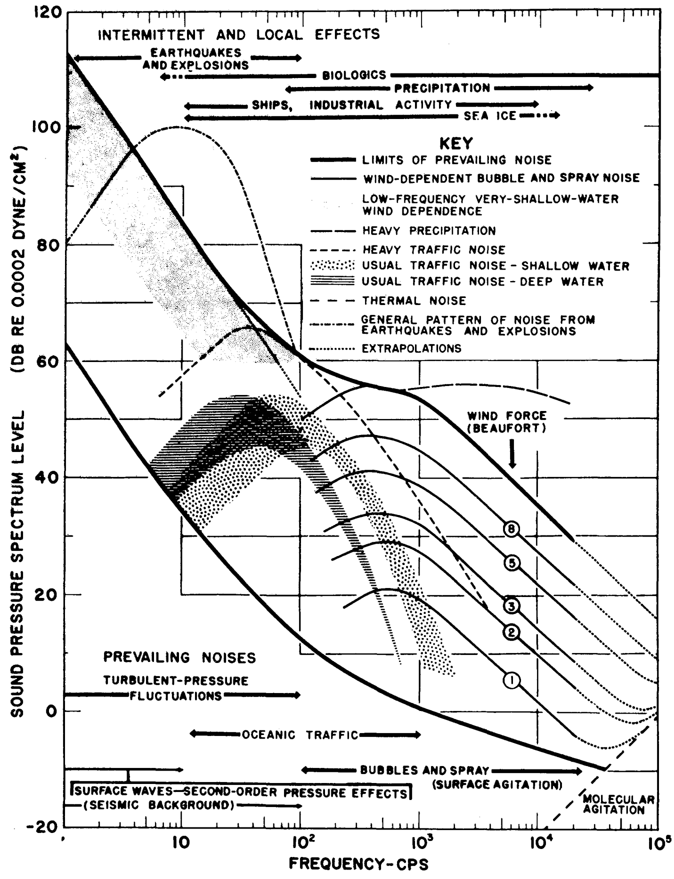

FIG. 8. Composite of ambient noise spectra (from Wenz, 1962).

Table 2. Descriptions of the ocean sea surface (from Wenz, 1962). Approximate relation between scales of wind speed, wave height, and sea state.

	Wind speed			12-h wind	Fully arisen sea			
Sea criteria	Beaufort scale	Range knots (m/s)	Mean knots (m/s)	Wave height[a,b] ft (m)	Wave height[a,b] ft (m)	Duration[b,c] h	Fetch[b,c] naut. miles (km)	Seastate scale
Mirrorlike	0	<1 (<0.5)						0
Ripples	1	1–3 (0.5–1.7)	2 (1.1)					$\frac{1}{2}$

pears in a following section after propagation models are described.

3. SOUND PROPAGATION MODELS

Sound propagation in the ocean is mathematically described by the wave equation whose parameters and boundary conditions are descriptive of the ocean environment. There are essentially four types of models (computer solutions to the wave equation) to describe sound propagation in the sea: ray theory, fast field program (FFP), normal mode (NM), and parabolic equation (PE). All of these models allow for the fact that the ocean environment varies with depth. A model that also takes into account horizontal variations in the environment (i.e., sloping bottom or spatially variable oceanography) is termed range dependent. For high frequencies (a few kHz or above), ray theory is the most practical. The other three model types are more applicable and usable at lower frequencies (below 1 kHz). The hierarchy of underwater acoustics models is shown in schematic form in Fig. 9 (modified from Kuperman and McDonald, 1986, which also includes a list of references to the specific models).

3.1 The Wave Equation and Boundary Conditions

The wave equation together with the appropriate boundary conditions describes acoustic fields in various media. It is typically written and solved in terms of pressure, displacement, or velocity potentials. This choice is not critical for fluid media but it is convenient, though not necessary, to formulate the elastic or shear-supporting medium problem in terms of displacement potentials. For a velocity potential φ, the wave equation in cylindrical coordinates with the range coordinates denoted by $\mathbf{r}=(x,y)$ and the depth coordinate denoted by z (and taken positive downward) for a source free region is

$$\nabla^2\varphi(\mathbf{r}, z, t)-\frac{1}{c^2}\frac{\partial^2\varphi(\mathbf{r}, z, t)}{\partial t^2}=0, \tag{20}$$

where c is the sound speed in the wave propagating medium and appears in the wave equation because its derivation involves the linearized equations of hydrodynamics and a linear adiabatic equation of state relating pressure changes to density changes, and c is related to the compressibility of the medium. [Nonlinear acoustics theory retains the convection term in the hydrodynamics equations as well as higher order terms in the equation of state (Kuperman and McDonald, 1986).] With respect to the velocity potential, the velocity v and pressure p are given by

$$\mathbf{v}=\nabla\varphi, \quad p=-\rho\frac{\partial\varphi}{\partial t}, \tag{21}$$

where ρ is the density of the medium. The wave equation is most often solved in the frequency domain; that is, a frequency dependence of $\exp(-i\omega t)$ is assumed to obtain the Helmholtz equation,

$$\nabla^2\varphi(\mathbf{r}, z)+K^2\varphi(\mathbf{r}, z)=0, \tag{22}$$

where $K\equiv\omega/c$.

In underwater acoustics both fluid and elastic (shear supporting) media are of interest. In elastic media the field can be expressed in terms of three scalar displacement potentials, $\phi(\mathbf{r}, z)$, $\psi(\mathbf{r}, z)$, and $\Lambda(\mathbf{r}, z)$, corresponding to compressional (P), vertically polarized (SV), and horizontally polarized shear waves (SH), respectively. For brevity, we write

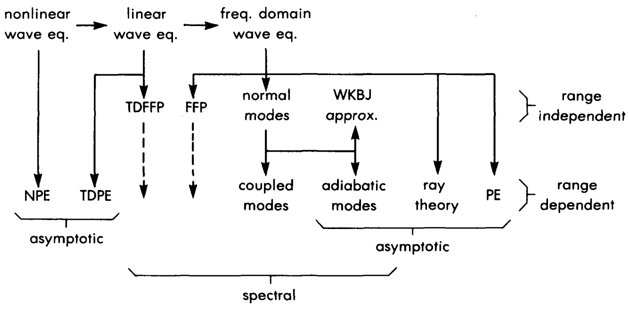

FIG. 9. Hierarchy of underwater acoustics models. (Note: TD refers to time domain.)

$$\Phi(\mathbf{r}, z)=\begin{cases}\phi(\mathbf{r}, z), & \text{P waves}\\ \psi(\mathbf{r}, z), & \text{SV waves}\\ \Lambda(\mathbf{r}, z), & \text{SH waves.}\end{cases} \tag{23}$$

In the limiting case of a fluid medium, where shear waves do not exist, $\Phi(\mathbf{r}, z)$ represents the compressional potential $\phi(\mathbf{r}, z)$. Most underwater acoustic applications involve only compressional sources which only excite the P and SV potentials, eliminating the SH potential $\Lambda(\mathbf{r}, z)$. The displacement potentials satisfy the Helmholtz equation with the appropriate compressional or shear sound speed, c_p or c_s, respectively,

$$c_p=\left[\frac{\lambda+2\mu}{\rho}\right]^{1/2}, \quad c_s=\left[\frac{\mu}{\rho}\right]^{1/2}, \tag{24}$$

where λ and μ are the Lamé constants. For the above defined fields, we can now write down the most common plane interface boundary conditions encountered in underwater acoustics. For the ocean surface, the pressure (normal stress) vanishes. This is often referred to as the pressure release condition equation involving the appropriate solution of the Helmholtz equation:

$$p=0, \quad \varphi=0, \quad \text{or} \quad \phi=0. \tag{25}$$

The interface between the water column (layer 1) and an ocean bottom (layer 2) is often characterized as a fluid-fluid interface. The continuity of pressure and vertical particle velocity, respectively, across a horizontal interface separating the layers yields the following boundary conditions for the Helmholtz equation in terms of pressure:

$$p_1=p_2, \quad \frac{1}{\rho_1}\frac{\partial p_1}{\partial z}=\frac{1}{\rho_2}\frac{\partial p_2}{\partial z}, \tag{26}$$

or velocity potential:

$$\rho_1\varphi_1=\rho_2\varphi_2, \quad \frac{\partial \varphi_1}{\partial z}=\frac{\partial \varphi_2}{\partial z}. \tag{27}$$

The boundary conditions applied to the plane wave fields in Fig. 5(a) yield the Rayleigh reflection coefficient given by Eq. (5).

For an interface separating two solid layers, the boundary conditions are continuity of vertical displacement $w(\mathbf{r}, z_i)$, tangential displacements $\mathbf{u}(\mathbf{r}, z_i) = (u_x, u_y)$, normal stress $n = \sigma_{zz}$, and tangential stresses $\mathbf{t} = (\sigma_{xx}, \sigma_{yz})$. (Note that the equations normal to the interface are scalar, whereas the tangential equations are vector equations.) In cylindrical coordinates with azimuthal symmetry, the radial and vertical components of displacements (in homogeneous media), u and w, respectively, are

$$u(r, z)=\frac{\partial \phi}{\partial r}+\frac{\partial^2 \psi}{\partial z^2}, \tag{28}$$

$$w(r, z)=\frac{\partial \phi}{\partial z}-\frac{1}{r}\frac{\partial}{\partial r} r \frac{\partial \psi}{\partial r}, \tag{29}$$

and the normal and tangential stresses are

$$\sigma_{zz}(r, z)=(\lambda+2\mu)\frac{\partial w}{\partial z}+\lambda\frac{\partial u}{\partial r}, \tag{30}$$

$$\sigma_{rz}(r, z)=\mu\left[\frac{\partial u}{\partial z}+\frac{\partial w}{\partial r}\right]. \tag{31}$$

Continuity of these quantities at the interface between two solids are the boundary conditions. For a fluid-solid interface, the rigidity μ vanishes in the fluid layers and the tangential stress in the solid layer vanishes at the boundary.

The Helmholtz equation for an acoustic field from a point source with angular frequency ω is

$$\nabla^2 G(\mathbf{r}, z)+K^2(\mathbf{r}, z)G(\mathbf{r}, z) = -\delta^2(\mathbf{r}-\mathbf{r}_s)\delta(z-z_s);$$

$$K^2(\mathbf{r}, z)=\frac{\omega^2}{c^2(\mathbf{r}, z)}, \tag{32}$$

where the subscript s denotes the source coordinates. The range dependent environment manifests itself as the coefficient $K^2(\mathbf{r}, z)$ of the partial differential equation for the appropriate sound speed profile. The range dependent bottom type and topography appears as boundary conditions on scalars and tangential and normal quantities as discussed above.

3.2 Ray Theory

Ray theory (Keller and Papadakis, 1977), a geometrical approximation, in its simplest form is just an application of Snell's law. It is a high frequency approximation to Eq. (22) and assumes a solution of the form

$$G(\mathbf{R})=A(\mathbf{R}) \exp[iS(\mathbf{R})], \tag{33}$$

where the exponential term allows for rapid variations as a function of range and $A(\mathbf{R})$ is a more slowly varying "envelope" which incorporates both geometrical spreading and loss mechanisms. Substituting Eq. (33) into Eq. (22) in a source free space, we obtain from real and imaginary parts

$$\frac{1}{A}\nabla^2 A-(\nabla S)^2+K^2=0;$$

$$\nabla A\cdot\nabla S+\frac{1}{2}A\nabla^2 S=0. \tag{34}$$

The geometrical approximation is that the amplitude varies slowly with range [i.e., $(1/A)\nabla^2 A \ll K^2$] so that the first part of Eq. (34) is approximated by the eikonal equation

$$(\nabla S)^2=K^2. \tag{35}$$

The ray trajectories are perpendicular to surfaces of constant phase (wave fronts) S and may be expressed mathematically as follows:

$$\frac{d}{dl}\left[K\frac{d\mathbf{R}}{dl}\right]=\nabla K, \tag{36}$$

where l is the arc length along the direction of the ray and $\mathbf{R}$ is the displacement vector. One can show that the direction of average flux (energy) follows that of the trajectories, and the amplitude of the field at any point can be obtained from the density of rays. Once S is obtained, the second part of Eq. (34) yields the amplitude. We mention here, also, that "corrected" ray theory assumes that A can be expanded in powers of inverse frequency—the leading term is the infinite-frequency result with the additional terms being frequency corrections.

The ray theory method is computationally rapid and extends to range dependent problems. Furthermore, the ray traces give a physical picture of the acoustic paths. It is helpful in describing how noise redistributes itself when propagating long distances over paths that include shallow and deep environments and/or midlatitude to polar regions. The disadvantage of ray theory is that it does not include diffraction and such effects that describe the low-frequency dependence ("degree of trapping") of ducted propagation. An example is given at the end of this section.

3.3 Full Field Solution or "Fast Field Program" (FFP)

The wave equation can be solved efficiently with spectral methods when the ocean environment does not vary with range. The term "Fast Field Program" is used because the spectral methods became practical with the advent of the fast Fourier transform (FFT). One of the possible derivations of the solution of Eq. (32) is to Fourier decompose the acoustic field into an infinite set of horizontal waves:

$$G(\mathbf{r},z)=\frac{1}{2\pi}\int_{-\infty}^{\infty} d^2k\, g(\mathbf{k},z,z_s) \times\exp[i\mathbf{k}\cdot(\mathbf{r}-\mathbf{r}_s)], \tag{37}$$

and from Eq. (22), the depth dependent Green's function $g(\mathbf{k},z,z_s)$ satisfies

$$\frac{d^2g}{dz^2}+[K^2(z)-k^2]g=-\frac{1}{2\pi}\,\delta(z-z_s). \tag{38}$$

Assuming azimuthal symmetry, we can integrate Eq. (37) over the angular variable obtaining Hankel functions; using their asymptotic form reduces Eq. (37) to (for simplicity, we take $\mathbf{r}_s=0$)

$$G(r,z)=\frac{\exp(-i\pi/4)}{(2\pi r)^{1/2}}\int_{-\infty}^{\infty} dk\,k^{1/2} \times g(k,z,z_s)\exp(ikr). \tag{39}$$

Note that the factor $r^{-1/2}$ arises from cylindrical spreading. We now discretize the above integral and transform to a form amenable to the FFT technique by setting $k_m = k_0 + m\Delta k$; $r_n = r_0 + n\Delta r$, where $n, m = 0,1,\ldots,N-1$ with the additional condition $\Delta r\Delta k = 2\pi/N$ and N is an integral power of 2. The discretization scheme limits the solution to outgoing waves and Eq. (39) becomes

$$G(\mathbf{r}_n,z)=\frac{\Delta k\,\exp[i(k_0r_n-\pi/4)]}{(2\pi r)^{1/2}}\sum_{m=0}^{N-1}X_m \times\exp(2\pi imn/N), \tag{40}$$

$$X_m=(k_m)^{1/2}g(k_m,z,z_s)\,\exp(imr_0\Delta k).$$

The above equation is now easily evaluated using the FFT algorithm with the bulk of the effort going into evaluating the Green's function by solving Eq. (38). Although the method is labeled "fast field" it is fairly slow because of the time required to calculate the Green's functions. However, it has advantages when one wishes to calculate the "near field" region or to include shear wave effects in elastic media (Schmidt and Jensen, 1985); it is also often used as a benchmark for other less exact techniques (Kuperman and Jensen, 1980). One such technique, not applicable to the near field but essentially exact for a large class of range independent far-field problems, is the computationally faster normal mode method.

3.4 Normal Mode Model (NM)

Rather than evaluate Eq. (38) for each g for the complete set of k's [typically solving Eq. (38) 1024 to 8196 times], one can utilize a normal mode expansion of the form

$$g(\mathbf{k},z)=\sum a_n(\mathbf{k})u_n(z), \tag{41}$$

where the quantities u_n are eigenfunctions of the following eigenvalue problem:

$$\frac{d^2u_n}{dz^2}+[K^2(z)-k_n^2]u_n(z)=0. \tag{42}$$

The eigenfunctions u_n are zero at $z=0$, satisfy the local boundary conditions descriptive of the ocean bottom properties, and satisfy a radiation condition for $z\rightarrow\infty$. They form an orthonormal set in a Hilbert space with weighting function $\rho(z)$, the local density. The range of discrete eigenvalues is given by the condition

$$\min[K(z)]<k_n<\max[K(z)]. \tag{43}$$

These discrete eigenvalues correspond to discrete angles within the critical angle cone in Fig. 6, such that specific waves constructively interfere. The eigenvalues k_n typically have a small imaginary part α_n, which serves as modal attenuation representative of all the losses in the ocean environment (see Kuperman and Ingenito, 1977, for the formulation of normal mode attenuation coefficients and other references on the subject).

We now substitute the normal mode expansion of g given by Eq. (41) into Eq. (37) (we take the source at the origin for simplicity) and multiply both sides by $\rho(z)u_n(z)$ and integrate over all z space to obtain, with the Hilbert space orthonormality conditions,

$$G(r,z)=\frac{\rho(z_s\,z)}{(2\pi)^2}\int_{-\infty}^{\infty}dk_x\int_{-\infty}^{\infty}dk_y \times\sum_n\frac{u_n(z_s)u_n(z)}{k^2-k_n^2}\exp(i\mathbf{k}\cdot\mathbf{r}). \tag{44}$$

We choose a contour about the poles which leads to a solution with outgoing waves from the point source. Each integral in Eq. (44) is proportional to the two-dimensional plane wave representation of the zero-order Hankel function of the first kind, and G can be expressed as

$$G(r,z)=\frac{i}{4}\rho(z_s)\sum_n u_n(z_s)u_n(z)H_0^1(k_nr). \tag{45}$$

The asymptotic form of the Hankel function can be used in the above equation to obtain the well known normal mode representation of a cylindrical (axis is depth) waveguide:

$$G(r,z)=\frac{i\rho(z_s)}{(8\pi r)^{1/2}}\exp(-i\pi/4) \times\sum_n\frac{u_n(z_s)u_n(z)}{k_n^{1/2}}\exp(ik_nr). \tag{46}$$

Equation (46) is a far field solution of the wave equation and neglects the continuous spectrum $\{k_n<\min[K(z)]\}$ of modes. For purposes of illustrating the various portions of the acoustic field, we note that k_n is a horizontal wave number so that a "ray angle" associated with a mode with respect to the horizontal can be taken to be $\theta=\cos^{-1}[k_n/K(z)]$. For a simple waveguide the maximum sound speed is the bottom sound speed corresponding to min $[K(z)]$. At this value of $K(z)$, we have from Snell's law $\theta=\theta_c$, the bottom critical angle. In effect, if we look at a ray picture of the modes, the continuous portion of the mode spectrum corresponds to rays with grazing angles greater than the bottom critical angle of Fig. 5(b) and therefore outside the cone of Fig. 6. This portion, as explained in Sec. 3.2, undergoes severe loss. Hence, we note that the continuous spectrum is the near (vertical) field and the discrete spectrum is the (more horizontal, profile dependent) far field (falling within the cone in Fig. 6). Note also that, in describing the acoustic paths in these two regimes, we use the result from Snell's law that, for a medium with a vertical variability in index of refraction like the horizontally stratified ocean, rays that start close to the horizontal are "more confined within their ducts" than the more vertical rays. Hence, we conclude that the continuous, more vertical portion of the sound field is less profile dependent than the discrete, more horizontal part.

The advantages of the NM procedure are that the solution is available for all source and receiver configurations once the eigenvalue problem is solved; it is easily extended to moderately range-dependent conditions using the adiabatic approximation; and it can be applied (with more effort) to extremely range-dependent environments using coupled mode theory.

3.5 Adiabatic Mode Theory

All of the range independent normal mode "machinery" developed for environmental ocean acoustic modeling applications can be adapted to mildly range dependent conditions using adiabatic mode theory. The underlying assumption (Brekhovskikh and Lysanov, 1982) is that individual propagating normal modes adapt (but do not scatter or "couple" into each other) to the local environment. The coefficients of the mode expansion, a in Eq. (41), now become mild functions of range, i.e., $a_n(k) \rightarrow a_n(k,\mathbf{r})$. This modifies Eq. (46) as follows:

$$G(r,z)=\frac{ip(z_s)}{(8\pi r)^{1/2}}\exp(-i\pi/4)$$

$$\times\sum_n \frac{u_n(z_s)v_n(z)}{\overline{k}_n^{\,1/2}}\exp(i\overline{k}_n r), \tag{47}$$

where the range-averaged wave number (eigenvalue) is

$$\overline{k}_n=\frac{1}{r}\int_0^{\mathrm{r}} k_n(r')dr', \tag{48}$$

and the $k_n(r')$ are obtained at each range segment from the eigenvalue problem Eq. (42) evaluated at the environment at that particular range along the path. The quantities u_n and v_n are the sets of modes at the source and the field positions, respectively.

Simply stated, the adiabatic mode theory leads to a description of sound propagation such that the acoustic field is a function of the modal structure at both the source and the receiver and some average propagation conditions between the two. Thus, for example, when sound emanates from a shallow region where only two discrete modes exist and propagates into a deeper region with the same bottom (same critical angle), the two modes from the shallow region adapt to the form of the first two modes in the deep region. However, the deep region can support many more modes; intuitively, we therefore expect the resulting two modes in the deep region will take up a smaller, more horizontal part of the cone of Fig. 6 than they take up in the shallow region. This means that sound rays going from shallow to deep tend to become more horizontal which is consistent with a ray picture of downslope propagation.

Fully coupled mode theory for range dependent environments has been developed (Evans, 1983). Numerical methods to evaluate coupled mode theories efficiently are under development.

3.6 Parabolic Equation Model (PE)

The PE method is presently the most practical and encompassing wave-theoretic range-dependent propagation model. In its simplest form, it is a far-field narrow-angle (~ ±20° with respect to the horizontal—adequate for many underwater propagation problems) approximation to the wave equation. Assuming azimuthal symmetry about a source, we express the solution of Eq. (32) in cylindrical coordinates in a source free region in the form

$$G(r,z)=\psi(r,z)\cdot J(r), \tag{49}$$

and we define $K^2(r,z)\equiv K_0^2 n^2$, n therefore being an "index of refraction" c_0/c, where c_0 is a reference sound speed. Substituting Eq. (49) into Eq. (32) in a source free region and taking K_0^2 as the separation constant, J and ψ satisfy the following two equations:

$$\frac{d^2J}{dr^2}+\frac{1}{r}\frac{dJ}{dr}+K_0^2\,J=0; \tag{50}$$

$$\frac{\partial^2\psi}{\partial r^2}+\frac{\partial^2\psi}{\partial z^2}+\left(\frac{1}{r}+\frac{2}{J}\frac{\partial J}{\partial r}\right)\frac{\partial\psi}{\partial r}+K_0^2n^2\psi-K_0^2\psi=0. \tag{51}$$

Equation (50) is a Bessel equation and we take the outgoing solution, a Hankel function $H_0^1(K_0r)$, in its asymptotic form and substitute it into Eq. (51), together with the "paraxial" (narrow angle) approximation:

$$\left|\frac{\partial^2\psi}{\partial r^2}\right| \ll \left|2iK_0\frac{\partial\psi}{\partial r}\right|, \tag{52}$$

to obtain the parabolic equation (in r),

$$\frac{\partial^2\psi}{\partial z^2}+2iK_0\frac{\partial\psi}{\partial r}+K_0^2(n^2-1)\psi=0, \tag{53}$$

where we note that n is a function of range and depth. We use a marching solution to solve the parabolic equation. There has been an assortment of numerical solutions but the one that still remains the most efficient is the so-called "split step algorithm" (Tappert, 1977), which we briefly describe below.

For this derivation, we take n to be a constant; the error this introduces can be made arbitrarily small by the appropriate numerical gridding. The Fourier transform of ψ with respect to z can then be written as

$$\chi(r,s)=\frac{1}{2\pi}\int_{-\infty}^{\infty}\psi(r,z)\exp(-isz)dz, \tag{54}$$

which together with Eq. (53) gives

$$-s^2\chi+2iK_0\frac{\partial\chi}{\partial r}+K_0^2(n^2-1)\chi=0. \tag{55}$$

The solution of Eq. (55) is simply

$$\chi(r,s)=\chi(r_0,s)\exp\left[-\frac{K_0^2(n^2-1)-s^2}{2iK_0}\times(r-r_0)\right], \tag{56}$$

where the initial condition at r_0 must be specified. The inverse transform then gives the field as a function of depth:

$$\psi(r,z)=\int_{-\infty}^{\infty}\chi(r_0,s)\exp\left[\frac{iK_0}{2}(n^2-1)\Delta r\right]\times\exp\left[-\frac{i\Delta r}{2K_0}s^2\right]\exp(isz)ds, \tag{57}$$

where $\Delta r = r - r_0$. Introducing the symbol $\mathscr{F}$ for the Fourier transform operation from the z domain [as performed in Eq. (54)] and $\mathscr{F}^{-1}$ as the inverse transform, Eq. (57) can be summarized by the range-stepping algorithm:

$$\psi(r+\Delta r,z)=\exp\left[\frac{iK_0}{2}(n^2-1)\Delta r\right]\times\mathscr{F}^{-1}\left\{\left[\exp\left(-\frac{i\Delta r}{2K_0}s^2\right)\right]\times\mathscr{F}[\psi(r,z)]\right\}, \tag{58}$$

which is often referred to as the "split step" marching solution to the PE. The Fourier transforms are performed using FFTs. Equation (58) is the solution for n constant, but the error introduced when n (profile or bathymetry) varies with range and depth can be made arbitrarily small by increasing the transform size and decreasing the range-step size.

Methods of solving the parabolic equation, including extensions of it to higher angle propagation, elastic media, and direct time domain solutions including nonlinear effects, have recently appeared (see Kuperman and McDonald, 1986; Lee and McDaniel, 1988; Collins, 1989, from which an extensive set of appropriate references can be obtained).

3.7 Model Consistency

All of the models described above attempt to solve in one way or another, with and without assorted approximations, the Helmholtz equation. They therefore should be consistent and there is much insight to be gained from understanding this consistency (Kuperman and Jensen, 1980).

Figure 10 shows convergence zone type propagation for a simplified profile. The ray trace in Fig. 10(b) shows the cyclic focusing discussed in Sec. 3. The same profile is used to calculate normal modes as shown in Fig. 10(c), which, when summed according to Eq. (46), exhibits the same cyclic pattern as the ray picture. Figure 10(d) shows both the normal mode (wave theory) and ray theory result. Ray theory exhibits sharply bounded shadow regions as expected whereas the normal mode theory, which includes diffraction, shows that the acoustic field does exist in the shadow regions, and the convergence zones have structure.

Normal mode models sum the discrete modes which roughly correspond to angles of propagation within the cone of Fig. 6. The FFP solution can include the full field, dis-

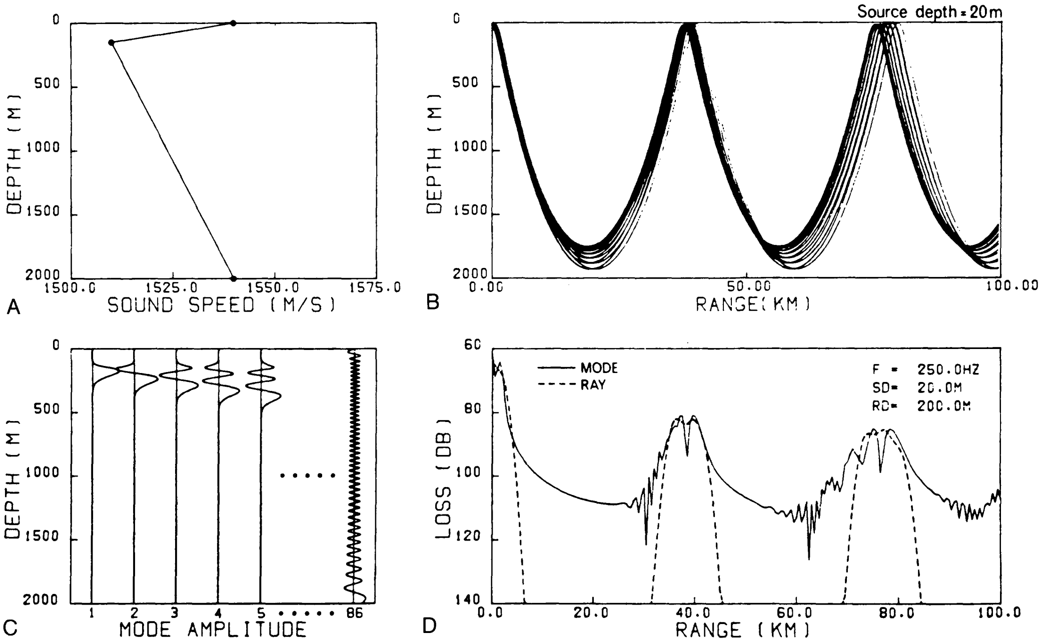

FIG. 10. Consistency between ray theory and normal mode theory. (a) Sound speed profile. (b) Ray trace plot. (c) The normal modes for this profile. Note that the lowest order modes are trapped in the duct around the sound speed minimum. (d) Normal mode and ray theory propagation calculations.

crete plus continuous, the latter corresponding to larger angles. The discussion below Eq. (46) defines these angles in terms of horizontal wave numbers, and the eigenvalues of the normal mode problem are a discrete set of horizontal wave numbers. Hence the integrand (Green's function) of the FFP method has peaks at the eigenvalues associated with the normal modes. These peaks are shown on the right of Fig. 11(a). The smoother portion of the spectrum is the continuous part corresponding to the larger angles. Therefore, the consistency we expect between normal mode and FFP and the physics of Fig. 6 is that the continuous portion of the FFP decays with range so that there should be complete agreement at long ranges between normal mode and FFP. The Lloyd's mirror effect, a near field effect, should also be exhibited in the FFP solution but not the normal mode solution. These aspects are apparent in Fig. 11(b). The PE solution appears in Fig. 11(b) and is in good agreement with the other solutions but with some phase error associated with the average wave number that must be chosen in

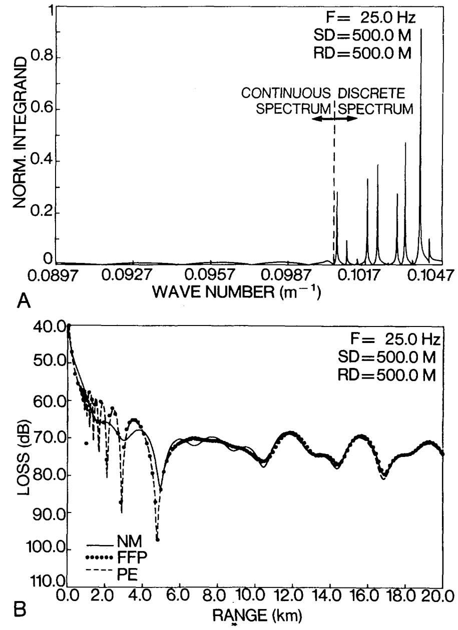

FIG. 11. Relation between full field (FFP), normal mode (NM), and parabolic equation (PE) computations. (a) A Green's function (integrand) of the FFP method. (b) Normal mode, parabolic equation and FFP propagation results showing some partial agreement of the latter two in the near field and agreement between all three in the far field.

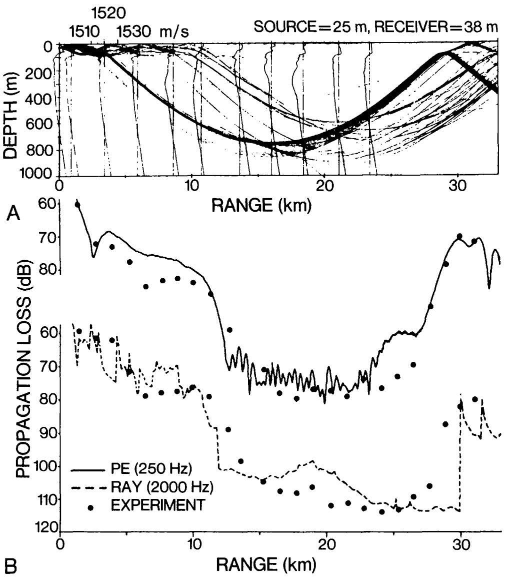

FIG. 12. Model and data comparison for a range-dependent deep water case (Kuperman and Jensen, 1980). (a) Sound speed profiles as a function of range and ray trace for the case of a surface duct disappearing. (b) PE comparison with data at 250 Hz and ray theory comparison with data at 2 kHz.

the split step method. The PE solution, which contains part of the continuous spectrum including the Lloyd's mirror beams, is more accurate than the normal mode solution at short range.

Range dependent results are shown in Fig. 12. A ray trace, a ray trace field result, a PE result, and data are plotted together for a range dependent sound speed profile environment. The models agree with the data in general with the exception that the ray results predict too sharp a leading edge of the convergence zone.

Upslope propagation is modeled with the PE (Jensen and Kuperman, 1980) in Fig. 13. As the field propagates upslope, sound is dumped into the bottom in what appears to be discrete beams. The flat region has three modes, and each is cut off successively as sound propagates into shallower water. The ray picture also has a consistent explanation of this phenomenon. The rays for each mode become steeper as they propagate upslope. When the ray angle exceeds the critical angle,

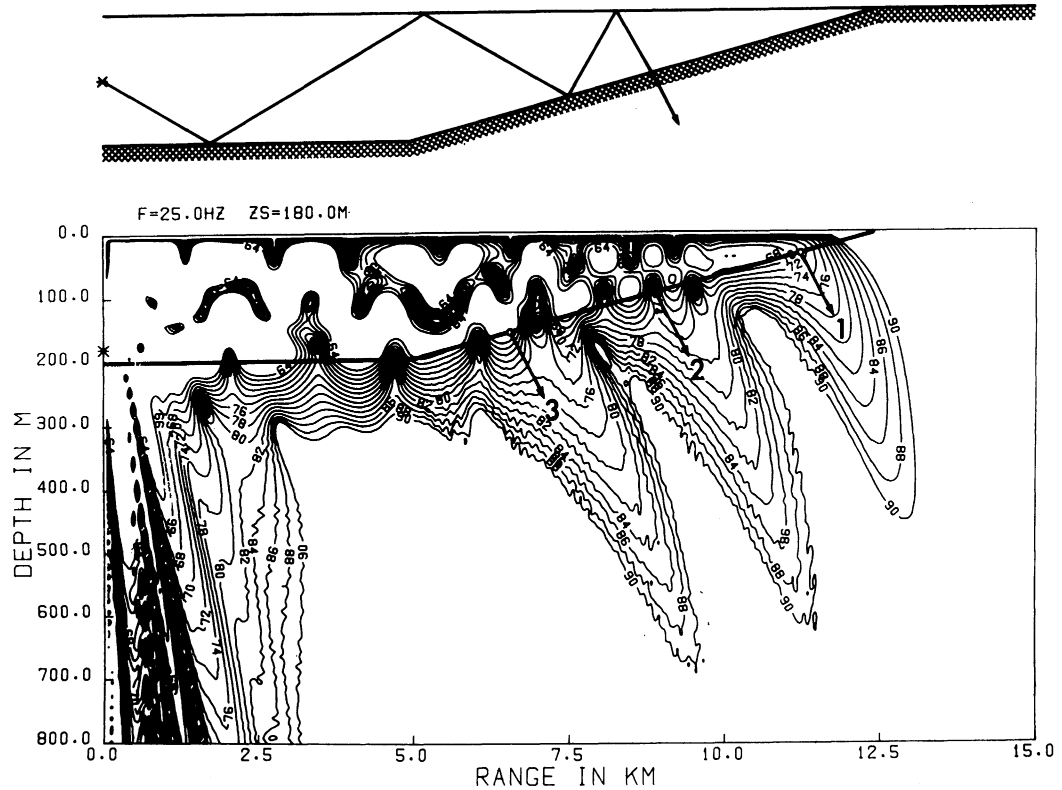

FIG. 13. Relation between upslope propagation (as calculated with the PE), showing individual mode cutoff and energy dumping in the bottom, and a corresponding ray picture.

the sound is significantly transmitted into the bottom. The locations where this takes place for each of the modes are identified by the three arrows.

4. SPATIAL PROPERTIES OF SURFACE GENERATED NOISE

The distribution of sound from surface noise sources can be calculated by coupling these noise sources into the water column using any of the above mentioned propagation models together with Green's theorem. We then would include both the physics of the noise sources and the environmental propagation effects. Figure 14 shows the geometry for such a model. The distribution of the field is characterized by the two-point "cross-spectral density," which reduces to the local sound intensity when the two field points are at the same position. Otherwise, this quantity is representative of the directional/spatial properties of the noise field (Kuperman and Ingenito, 1977) which would be measured by a distributed acoustic receiving array. The cross-spectral density is (⟨ ⟩ is the "expected value" symbol)

$$\langle \phi(\mathbf{r}_1, z_1)\phi^*(\mathbf{r}_2, z_2)\rangle$$

$$= \int\int d^2\mathbf{r}' d^2\mathbf{r}'' \langle S(\mathbf{r}')S^*(\mathbf{r}'')\rangle \times G(\mathbf{r}_1, \mathbf{r}', z_1, z')G^*(\mathbf{r}_2, \mathbf{r}'', z_1, z''), \qquad (59)$$

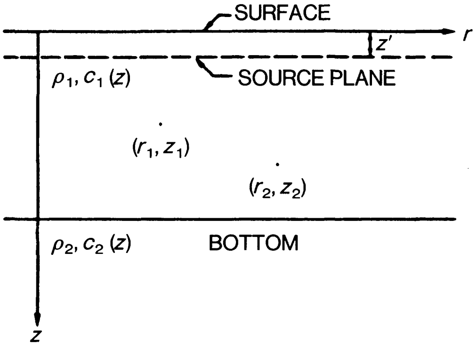

FIG. 14. Surface noise model geometry showing the noise source plane, at depth z′, below the surface, and the two field points.

where S is the surface noise source function and z'' is at the same depth as z'. The correlation function of the surface noise sources, which is the expectation quantity in the integrand of Eq. (50), is taken to be spatially dependent only on the separation ($\mathbf{s} \equiv \mathbf{r}' - \mathbf{r}''$) between sources. We denote this correlation function as $\langle S(\mathbf{r}')S^*(\mathbf{r}'')\rangle \equiv q^2 N(s)$, with q being surface source strength. We also express the noise field points through the difference of displacement vectors, $\mathbf{R} \equiv \mathbf{r}_1 - \mathbf{r}_2$, and denote the cross-spectral density given by Eq. (59) for angular frequency ω as $C_\omega(\mathbf{R}, z_1, z_2)$. Substitution in the full field representation of G given by Eqs. (37) and (38) into Eq. (59) and integration over the azimuth angle associated with k gives

$$C_\omega(\mathbf{R}, z_1, z_2)$$

$$= 2\pi q^2 \int ds\, N(s) \int k\, dk\, g(k, z_1, z') \times g^*(k, z_2, z') J_0(k|\mathbf{R} - \mathbf{s}|), \qquad (60)$$

where J_0 is the Bessel function of zero order. An alternative form to Eq. (60), which is particularly useful because it can directly call upon the algorithms associated with the FFP approach presented above, involves expressing the correlation function of the surface noise sources in terms of its spatial spectral representation $P(\mathbf{k})$. Then, if we substitute into Eq. (60) for N its Fourier transform,

$$N(\mathbf{s}) = \frac{1}{2\pi} \int d^3k\, P(\mathbf{k}) \exp(i\mathbf{k}\cdot\mathbf{s}), \qquad (61)$$

together with the other substitutions used to get Eq. (60), we obtain

$$C_\omega(\mathbf{R}, z_1, z_2)$$

$$= 2\pi q^2 \int d^3k\, P(\mathbf{k}) \exp(i\mathbf{k}\cdot\mathbf{R}) \times g(\mathbf{k}, z_1, z') g^*(\mathbf{k}, z_2, z'). \qquad (62)$$

Depending on the type of numerics being applied to a specific problem, Eqs. (60) and (62) are suitable for model computations. Note that the noise cross-spectral density evaluated at the same field points, $C_\omega(0, z, z)$, is the intensity of the noise at depth z for this range-independent formulation of the distribution of noise.

It has been shown (Liggett and Jacobsen, 1965) that the correlation function of surface sources which produces a far field radiation (of multipole order m) pattern $\cos^m\theta$ with respect to the vertical is given by

$$N(s)=\begin{cases}\dfrac{2\delta[K(z')s]}{[K^2(z')s]}, & m=1,\\[2ex] 2^m m!\,\dfrac{J_m[K(z')s]}{[K(z')s]^m}, & m>1.\end{cases} \tag{63}$$

In simple general terms, we know from the literature that many of the noise sources can be categorized as and are associated with (Ross, 1976):

1. monopole: mass addition, heat addition, volume change, compression—e.g., bubbles, rain droplet impact, etc.;
2. dipole: force, translation, acceleration (sloshing)—e.g., vibration of unbaffled rigid bodies;
3. quadrupole: moment, shear, distortion, rotation, turbulence.

These noise sources are then taken to be on the source plane in Fig. 14, where the surface is pressure released so that the radiation couples into the water column as a higher order pole radiator; for example, monopole sources near the surface couple as dipoles just by using the ocean sound propagation Green's function, which satisfies the pressure release condition. For this case we then use $m=1$ in Eq. (63), a dipole sheet at the surface corresponding to a monopole plane below the surface, which gives the $\cos^m\theta=\cos\theta$ radiation pattern with respect to the vertical. Then, the noise distribution of sound in the ocean from surface sources can be constructed from the above expressions using the propagation models described in Sec. 4 for G and the noise source distributions expressed in the multipole form of Eq. (63).

Of interest is a particular simplification when the noise can be modeled in a range independent environment and an expression for the distribution of noise is sought in terms of normal modes. Then, that part of the noise that corresponds to discrete propagation from mainly far away sources and corresponds to the inner cone of Fig. 6 and the inequality of Eq. (43) can be derived from Eqs. (60) and (46). A simple result can be obtained for this important case, with $m=1$ as given by Eq. (63). After a complex integration, we get the result for the discrete portion of the noise field (suppressing the subscript ω):

$$C_{\text{disc}}(\mathbf{R}, z_1, z_2)\approx\frac{\pi q^2\rho^2(z')}{2K^2(z')}\times\sum_n\frac{u_n^2(z')u_n(z_1)u_n(z_2)}{\alpha_n k_n}\times J_0(k_nR), \tag{64}$$

where α_n is the attenuation coefficient of the nth mode and, as described in Sec. 4, is the imaginary part of the eigenvalues resulting from the existence of loss in the system. It is clear from the physics of this problem that contributions from noise sources long distances away in a waveguide with only cylindrical spreading are unbounded if there is no loss in the system; hence, the attenuation coefficients in the denominator of Eq. (64) are essential.

As discussed in Sec. 3, the ocean is a waveguide. We can therefore draw some general conclusions about how sound sources at the upper boundary of a waveguide will couple into the waveguide. As mentioned earlier, the ray and mode pictures provide the most straightforward physical insight into the actual coupling process. First, for reference, let us consider the noise field in an unbounded semi-infinite isovelocity medium with constant distribution of monopole sources radiating into the medium from the upper boundary. Summing all the sources over an infinite area and noting that in this situation we have spherical spreading, it is easy to show that the resulting sound field will be finite and its directional properties will be isotropic in the upward direction (the only direction from which sound is coming) and the intensity of the sound will be independent of position. All these characteristics come from three simple considerations:

1. the sources are spherically symmetric;
2. the contributing source area goes up as the square of the radius;
3. the field of the sources decays, by spherical spreading.

However, cylindrical spreading occurs in the ocean and large areas from very long distances will contribute significantly to local noise [even for the real, lossy ocean, as discussed below Eq. (64)]. In a waveguide it makes sense that noise coming directly from above looks like the semi-infinite unbounded case discussed in the last paragraph whereas noise from long distances has the ocean channel properties discussed in Secs. 3 and 4.

With this background of sound propagation in the ocean and some intuition of how sources on a surface plane couple either into a semi-infinite space (spherical spreading) or into a waveguide (cylindrical spreading), we can understand much of how ambient noise is distributed in the ocean. Figure 15 depicts the possible propagation regimes by which surface generated noise can arrive at a receiver near the ocean bottom (where seismic paths might also be important). The continuous part is the vertical structured noise that is weakly affected by the sound speed profile. The discrete (or channeled) part corresponds to noise arriving horizontally from, typically, distant sources. We can write the continuous portion of the noise field as the right-hand side of Eq. (62), where the limit on the integration is $|k| < \min[K(z)]$ [see discussion below Eq. (46)]; we define this quantity to be C_{cont}. The total cross-spectral density of the noise field, which is also referred to as the spatial correlation or spatial coherence of the noise field, is given by

$$C_\omega(\mathbf{R}, z_1, z_2) = C_{\text{cont}}(\mathbf{R}, z_1, z_2) + C_{\text{disc}}(\mathbf{R}, z_1, z_2). \tag{65}$$

Equations (60) and (64) (which is in the discrete part of C) indicate that the noise field varies with depth; the cross-spectral density of the noise is a function of both the mean depth of the field points and the absolute depth location of the field points (i.e., noise is not homogeneous in depth). The cross-spectral density of the noise is homogeneous in range for a range-independent environment since there is no reference range. These conclusions are particularly true for horizontally stratified continental shelf areas in which waveguide theory is most applicable.

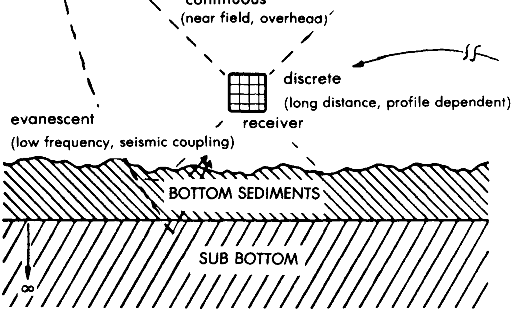

FIG. 15. Surface generated noise propagation paths to an acoustic receiver.

Figure 16(a) shows the above mentioned vertical inhomogeneity in a waveguide type environment by plotting the cross-spectral density of the noise related to receivers located at two different depths. The noise at receivers R_1 and R_2 is correlated with the noise at all other field points of the water column. We see that the two correlation functions appear different indicating the spatial inhomogeneity.

Also contrary to simplified noise models more applicable to high frequency, deep water environments (Cron and Sherman, 1962), the cross-spectral density of noise in a stratified waveguide should have a different structure than noise in a homogeneous semi-infinite medium. Figure 16(b) shows the modeled vertical spatial correlation (cross-spectral density for a receiver at the same horizontal location but different vertical positions) between a receiver located at 10 m depth and another receiver separated by distance D in units of wavelength λ. The particular environment for this case involves a 50 m water depth and an upward refracting sound speed profile. Here we see that the vertical correlation of the noise versus separation in units of wavelength is a function of frequency, in contrast to the simpler model for a semi-infinite medium where the spatial correlation scales with wavelength. This difference arises from the additional scales that are introduced when considering the stratified environment. Note also that the noise is more correlated over the water column than the simple case (the solid curve) because a few lower-order modes dominate the propagation due to upward refraction, and therefore there is very little interaction with the lossy bottom for the horizontal long distance contribution as opposed to the more vertical lossy propagation. That is, the noise tends to come from the horizontal rather than from all directions thereby increasing the spatial correlation.

Figure 16(c) shows the results for the horizontal correlation for the same kind of environment as for the case in Fig. 16(b) except

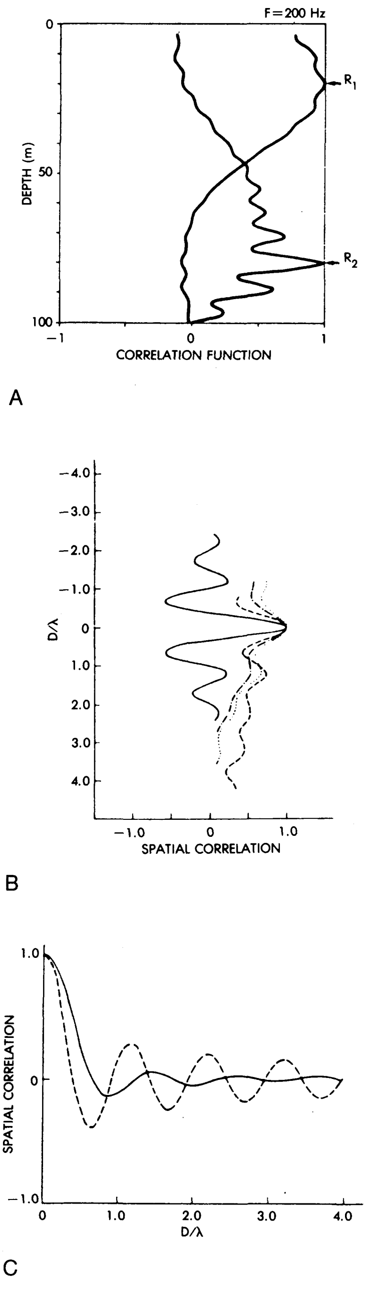

FIG. 16. Spatial distribution of noise (Kuperman and Ingenito, 1980). (a) Normalized spatial correlation in a waveguide environment for two different receiver depths. (b) Normalized vertical spatial correlation functions for an upward refracting environment with one receiver fixed at 10 m depth in a 50 m deep water column. Three frequencies are 200 (---), 400 (···), and 800 Hz (-·-·-). The solid line is the semi-infinite homogeneous result (Cron and Sherman, 1962). (c) Horizontal correlation. The solid line is the continuous contribution and the dashed line is the discrete contribution.

that the sound speed is constant in the water column. Here, we plot the discrete and continuous contributions separately. The continuous (vertical) part is more coherent for small receiver separations but quickly becomes less coherent (and looks like the simpler semi-infinite case) than the discrete part. Again, the physics of the propagation environment indicates the relative importance of the discrete and continuous parts. For low loss, the discrete modes dominate as they propagate very large distances from a very large area [see discussion below Eq. (64)]. In high loss cases, the continuous modes tend to dominate since they are important near the surface; the long range contributions of the discrete are severely attenuated. Therefore, a more vertical structure is expected for noise in a lossy environment.

In Secs. 2 and 3 we discussed the impact of the deep water sound speed structure on propagation. In particular, we mentioned in Sec. 3 the existence of a critical depth in the deep isothermal layer. For such a case we expect from the above discussion that, when there is a positive critical depth, sound from surface sources can travel long distances without interacting with the ocean bottom but that a receiver below this critical depth should sense less surface noise because any propagation from distant shallow sources to these depths involves interaction with the lossy boundaries, surface, and/or bottom. Indeed, Fig. 17 illustrates this effect using data from the Northeast Pacific (Morris, 1978). The noise in this figure comes from a combination of natural sources and shipping, but the propagation effects for these surface sources are the same. We should note here, also, that higher frequency noise (especially the multi-kHz region and above) diminishes with depth simply because volume attenuation increases with frequency.

The vertical directionality of deep water noise should also vary with depth as discussed above. Figure 18 shows some depth dependence of the directionality of low frequency noise in the Pacific (Anderson, 1979). The shallower depth is at the axis of the deep sound channel while the other is at the critical depth. We see, as expected, that the pattern is narrower at the critical depth where the sound paths tend to be horizontal since the rays are turning around at the lower boundary of the deep sound channel.

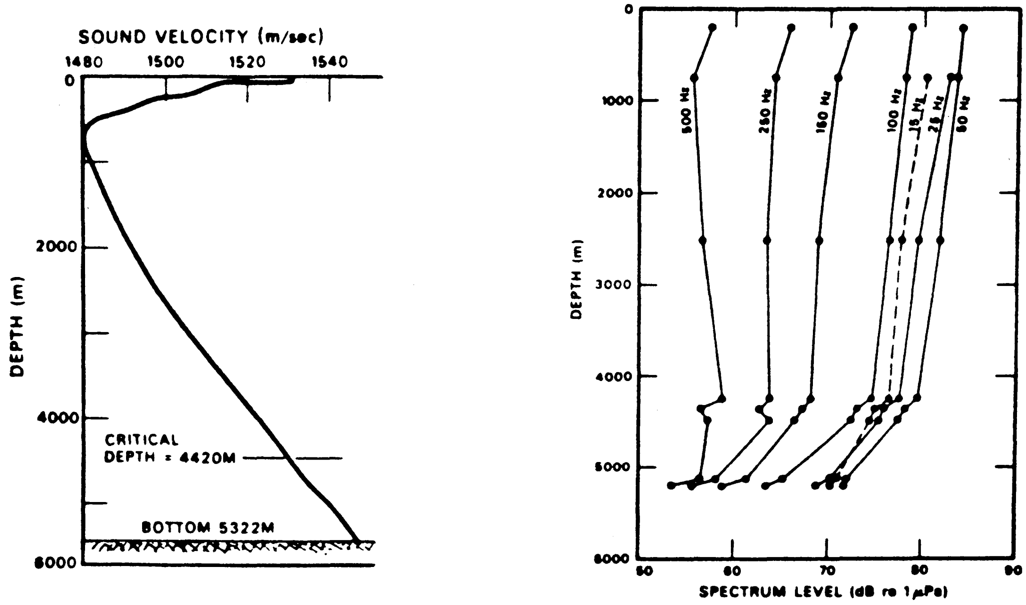

FIG. 17. Sound speed profile and noise level as a function of depth in the Pacific (from Morris, 1978).

In deep water, sound from surface sources would arrive, on the average, off the horizontal (~ ±12° to ±15°) if the ocean did not have a range varying environment. But, as explained in Sec. 4.4, noise from continental shelf areas tends to have paths which become more horizontal as the sound propagates to deeper water; an analogous effect is that polar latitudes have shallow sound channels so that sound propagating from polar latitudes will go deep and horizontal in the midlatitude regions. Hence, the accurate modeling of this horizontal component of the noise (Wagstaff, 1981) requires the use of range-dependent models. Adiabatic mode theory includes this effect.

Finally, we mention seismic noise. Very low frequency sound will couple directly into the ocean bottom. The surface generated "microseismic" noise (Akal *et al.*, 1988; Kibblewhite and Ewans, 1985) also obeys the basic physics of waveguide propagation we have discussed. Briefly, when the ocean surface sources are close (in terms of wavelength) to the ocean bottom, their evanescent field will couple into seismic waves. This coupling occurs below the acoustic cutoff frequency of the waveguide (Schmidt and Kuperman, 1988). Seismic noise shows a spectral peak around 0.25 Hz which is thought to originate from nonlinear surface wave-wave interactions corresponding to the surface wave peak of about 0.12 Hz.

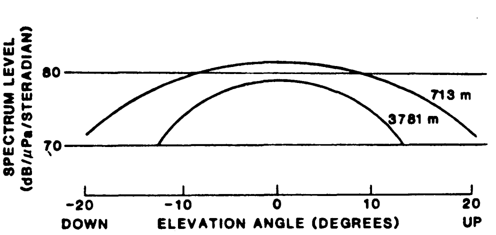

FIG. 18. Vertical directionality of noise at the axis of the deep sound channel and at the critical depth (from Anderson, 1979).

5. ARRAYS AND ARRAY GAIN FOR SIGNALS IN NOISE

An array of hydrophones constitutes an acoustic antenna which can be used to enhance the signal to noise ratio at a receiver. This enhancement is often referred to as array gain and is realized in three interrelated ways. First, the level of the signal at the receiver can be increased by summing the outputs of the hydrophones coherently. This coherent sum can be related to a "look direction" and a "beam width." Recall that the coherent sum refers to adding (complex) amplitudes, and the total energy is the square of the sum of amplitudes. Second, the incoherent part of the noise, the white noise, adds incoherently so that the energies, not the amplitudes, add. Finally, the coherent part of the noise has directional properties so that an appropriately phased coherent sum of hydrophone outputs can be constructed. This limits the directional noise input by looking away from the noise and further limits the noise input in the direction of the noise by the finite beamwidth associated with the look direction. We can illustrate these ideas quantitatively as follows: Consider the simple case of an m-element array with signal $s_i(t)$ and noise $n_i(t)$ at the ith element of the array. The average signal to noise ratio at the output of the array will be (the angular brackets denote time average)

$$\frac{S^2}{N^2}=\frac{\left\langle\left[\sum_{i=1}^{m} S_i(t)\right]^2\right\rangle}{\left\langle\left[\sum_{i=1}^{m} n_i(t)\right]^2\right\rangle}. \qquad (66)$$

Summing the outputs of the hydrophones using various phase and amplitude shading is called beamforming. The simplest example of array gain is the situation in which the signal is a plane wave traveling in one direction and the noise field is isotropic (i.e., it has components in all directions). A single omnidirectional hydrophone receives all the signal and noise. An array of hydrophones can be used to sum the signal coherently by phasing the array to look in the direction of the plane wave. Hence the signal output of the array is the coherent sum of the signal at the hydrophones. On the other hand, only the noise in the look direction (aside from white noise) is output from the array beamformer with the total energy of the noise related to the beamwidth. Hence an extremely narrow beam picks up all the signal but only a portion of the noise, and there is an enhancement of ratio of signal to noise relative to an omnidirectional receiver. Below, we briefly derive these results. The ratio of the average signal power to the average noise power at the output of a hydrophone array can be written as

$$\frac{S^2}{N^2}\equiv\frac{\left\langle\left[\sum_{i=1}^{m} s_i(t)\right]^2\right\rangle}{\left\langle\left[\sum_{i=1}^{m} n_i(t)\right]^2\right\rangle}=\frac{\sum_{i,j=1}^{m} s_{ij}}{\sum_{i,j=1}^{m} n_{ij}}, \qquad (67)$$

where i and j subscripts imply a double summation, and the array signal and noise crosscorrelation coefficients between the ith and jth hydrophones are given by $s_{ij} \equiv \langle s_i(t)\hat{s}_j^*(t)\rangle$ and $n_{ij}\equiv\langle n_i(t)\,\hat{n}_j^*(t)\rangle$, respectively.

In the simple and common case where the signal and noise have the same amplitude at each hydrophone, we define $s_{ij}\equiv s^2\hat{s}_{ij}$ and $n_{ij}\equiv n^2\hat{n}_{ij}$, where the carets denote normalized crosscorrelation coefficients. For this case, Eq. (67) simplifies to

$$\frac{S^2}{N^2}=\frac{s^2}{n^2}\,\frac{\sum_{i,j=1}^{m}\hat{s}_{ij}}{\sum_{i,j=1}^{m}\hat{n}_{ij}}, \qquad (68)$$

where, consequently, the second fraction on the right side of Eq. (68) is a measure of the array performance with respect to increasing the signal to noise ratio over a single omnidirectional hydrophone. Array gain (AG) is defined in decibels as

$$\mathrm{AG}=10\log\frac{S^2/N^2}{s^2/n^2}=10\log\frac{\sum_{i,j=1}^{m}\hat{s}_{ij}}{\sum_{i,j=1}^{m}\hat{n}_{ij}}, \qquad (69)$$

so that the array gain is a function of the signal and noise structure projected onto the geometry of the array. The directivity index (DI) is a special case of the array gain formula. DI equals AG when the signal is a single plane wave and the noise is isotropic (i.e., the noise is uniform distribution of plane waves in all directions and is obtained by simple integration of a constant over 4π solid angle). For this case, $\hat{n}_{ij}$ is stationary in space (only related to hydrophone separation distance) and is given by $\hat{n}_{ij} = (kd)^{-1}\sin(kd)$ for $i\neq j$, where d is the hydrophone separation and $k=2\pi/\lambda$ is the acoustic wavenumber. Note for isotropic noise, and an array hydrophone spacing of $d=\lambda/2$, the noise appears uncorrelated (i.e., cross terms vanish). For the purpose of illustration, we consider a two-element array. For this case the (coherent) sum of the numerator is 4 and the denominator is $2+2(kd)^{-1}\sin(kd)$, so that the DI of a two element array is 10 log $\{2/[1+(kd)^{-1}\sin(kd)]\}$, or is 10 log 2 if the hydrophone separation is $\lambda/2$. An important generalization for DI is that a linear array of m hydrophones with $\lambda/2$ spacing in isotropic noise has DI$=$10 log n.

Working in the frequency domain, we can shade the array by amplitude and phase factors at each hydrophone. The simplest example is phase shading to look in a specific direction (i.e., to match a plane wave coming from the look direction). This is referred to as steering the array, and this type of linear beamformer is often referred to as the Bartlett beamformer. We take θ_s (which in general is a two-dimensional angle) as the beamsteered angle or the look direction. Referring to Fig. 19, a plane wave $\exp(i\mathbf{k}\cdot\mathbf{R})$ across the array is summed in phase if the hydrophone at position $\mathbf{d}_i$ is multiplied by the factor $w_i=\exp(-i\mathbf{k}\cdot\mathbf{d}_i)$. The array gain does not change since both signal and noise are altered by this same factor. The output of this beamforming process $B(\theta_s)$ is a quadratic form obtained by summing the shaded signal plus noise from each hydrophone:

$$B(\theta_s)=\sum_{i,j=1}^{m} w_i^*(\theta_s)(s_{ij}+n_{ij})w_j(\theta_s). \tag{70}$$

If the field of the source at the receiving array is a plane wave in a particular look direction, the beamformer has its peak in that direction; however, there are also sidelobes because of the finite sampling of the acoustic field by the array.

We can write the above expression in matrix notation where the boldface lower case letters denote vectors and boldface upper case letters denote matrices. Define a steering column vector $\mathbf{w}$ whose ith element is w_i and which has the dimension of the number of array elements, and a cross-spectral density matrix $\mathbf{K}$ of the signal and noise with elements $s_{ij}+n_{ij}$. Then Eq. (70) can be simply written as

$$B(\theta_s)=\mathbf{w}^\dagger(\theta_s)\mathbf{K}(\boldsymbol{\theta}_{\text{true}})\mathbf{w}(\theta_s), \tag{71}$$

where "$\dagger$" denotes the complex transpose operation, and the data across the array as represented in the matrix $\mathbf{K}$ contain the information that the source is in the direction θ_{true}. This form of the beamforming equation has a succinct generalization to matched field processing. Often, $\mathbf{w}(\theta_s)$ is referred to as a replica, and the above beamforming process is then matching the received data across the array $\mathbf{K}$ with a replica. In the above case, the replica is a plane wave in the look direction. Now take $\mathbf{w}$ as solution to the acoustic wave equation as discussed in Sec. 4. It then represents a replica field at each element of the array for a specific ocean environment and for an arbitrary source location $\mathbf{x}$. Rather than find just the direction of the source from the array, we can search for its actual location by matching the received data, $\mathbf{K}(\mathbf{x}_{\text{true}})$ from the true source location, against solutions of the wave equation. The output of this matched field processor, denoted $S(\mathbf{x})$, at each point in space $\mathbf{x}$ is in analogy to Eq. (71) (Baggeroer *et al.*, 1988):

$$S(\mathbf{x})=\mathbf{w}^\dagger(\mathbf{x})\mathbf{K}(\mathbf{x}_{\text{true}})\mathbf{w}(\mathbf{x}), \tag{72}$$

where the peak of the output of the beamformer $S(\mathbf{x})$ is also referred to as the ambiguity function (or surface) of the matched field processor because it also contains ambiguous peaks analogous to the sidelobes of a conventional plane wave beamformer. Sidelobe suppression can often be accomplished by using a nonlinear beamformer such as the Maximum Likelihood Method (MLM) beamformer:

$$S_{\text{MLM}}(\mathbf{x})=[w^\dagger(\mathbf{x})\mathbf{K}^{-1}(\mathbf{x}_{\text{true}})w(\mathbf{x})]^{-1}, \tag{73}$$

where the above beamformer was first derived for the plane wave beamformer, as discussed above, so that $\mathbf{x}$ refers to angles or spatial coordinates (or any other unknown parameter of the problem to be estimated, e.g., bottom type!). This beamformer gives the same peak level output at the true source location as the Bartlett beamformer.

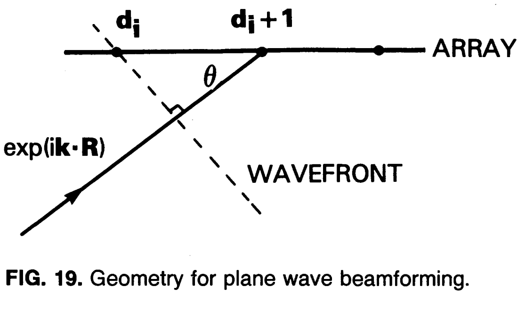

FIG. 19. Geometry for plane wave beamforming.

6. SIGNAL PROCESSING AND SONAR SYSTEMS

The main application of the field of underwater acoustics is to sonar system technology. There are two fundamental types of sonar systems: passive and active. Passive sonars listen for signals radiated by objects for the purpose of detection, classification, and localization of these acoustic sources. These signals are embedded in ocean noise. The performance of a passive sonar system requires sufficient signal above a threshold, such that the requisite signal information is extracted from the background noise. To give a simple example, a received signal of known source level can be used to estimate the distance between receiver and source if propagation conditions are known.

For the case of an active system, the sonar transmits a signal which is reflected or scattered from an object or ocean feature, and hence the modified signal carries information concerning the object or feature to a receiver (often colocated with the transmitter). This information must be extracted from the background interference, which for the active sonar is not only noise but also, and often more important, the reverberation generated by the original transmitted signal. The simplest type of active sonar system information is contained in a travel time measurement of an emitted and returning pulse from which the distance to an object or a feature (i.e., the ocean bottom for the case of a fathometer measuring water depth) can be estimated.

In either case, passive or active, the performance of a sonar system can to a large extent be described by a sonar equation. In this section, we shall introduce the sonar equation for passive and active systems. Because it is customary to use decibels in underwater acoustics, the forms of sonar equations are such that individual phenomena contributing to the performance of a sonar appear as additive terms and normally can be treated separately. Therefore all terms in the sonar equations presented below are expressed in decibels. The standard reference for this material is Urick (1983). More accurate representation of sonar system performance requires "simulation" of the relevant acoustic phenomena and subsequent insertion of these fields into a (computer) model of the system.

6.1 Passive Sonar Equation

A radiating object of source level "SL" (all units are expressed in dB) will be received at a hydrophone of a sonar system at a lower signal level "S" because of the transmission loss "TL" it suffers; hence,

$$\mathrm{S}=\mathrm{SL}-\mathrm{TL}, \tag{74}$$

where TL is a positive quantity; it is the negative of propagation loss which is defined to be 20 log (amplitude of the field from a unit source). Any of the propagation models in Sec. 4 or simpler geometric spreading laws can be used to estimate the field. The noise at a single hydrophone "N" is subtracted from Eq. (74) to obtain the signal-to-noise ratio at a single hydrophone:

$$\mathrm{SNR}=\mathrm{SL}-\mathrm{TL}-\mathrm{N}. \tag{75}$$

A sonar system normally consists of an array of hydrophones which are beamformed to obtain signal to noise enhancement. The directivity index "DI" [see discussion below Eq. (69)] is added to Eq. (75) to obtain the signal-to-noise ratio at the output of the beamformer:

$$\mathrm{SNR}_{\mathrm{BF}}=\mathrm{SL}-\mathrm{TL}-\mathrm{N}+\mathrm{DI}. \tag{76}$$

There exists a threshold SNR above which a sonar system will, with 50% probability (by convention), accomplish its detection purpose. Ideally, detection should occur when the signal is not marked by noise, i.e., $\mathrm{SNR}>0$, but normally because of the nature of the sonar, the signal, the interference, the operator training and alertment, and an assortment of other factors, a certain additional signal level above zero $\mathrm{SNR}_{\mathrm{BF}}$ is referred to as the recognition differential "RD" or the detection threshold "DT." Hence, if we include a term related to this detection threshold, we can write a sonar equation for the signal excess "SE," the difference between the actual received signal at the output of the beamformer and the minimum signal for detection (i.e., extra signal above what is needed for detection):

$$\mathrm{SE}=\mathrm{SL}-\mathrm{TL}-\mathrm{N}+\mathrm{DI}-\mathrm{DT}, \tag{77}$$

where even though all the quantities are in decibels, only SL and N must be defined with respect to the same reference pressure and frequency bandwidth (e.g., 1 Hz or a fraction of an octave such as the standard 1/3 octave filter convention). In any event, we will see below that an SE > 0 can be used to increase our effective probability of detection *p(D)*, which is defined as the probability that an existing signal will be detected.

Another useful quantity the sonar engineer uses is the figure of merit "FOM" which is the transmission loss that gives zero signal excess for a $p(D)=50\%$, i.e., the maximum allowable transmission loss for a detection. Hence, from Eq. (77),

$$\mathrm{FOM}=\mathrm{SL}-\mathrm{N}+\mathrm{DI}-\mathrm{DT}, \tag{78}$$

and we see that the FOM is a transmission loss number which actually encompasses target source level and sonar system parameters. Therefore, a specification of an FOM can be translated into a detection range if the propagation conditions (loss versus range) are known.

We note that the above sonar equations are for simplistic situations and must be modified accordingly to be more realistic. For example, in reality the signal and noise levels have vertical and azimuthal dependence so that they are a function of beam steered angle θ_s, and the signal is also likely to have a dispersed arrival structure because of multipath type propagation. Furthermore, the response of the sonar array is a function of θ_s. All of these complications can be approximated either by a more sophisticated sonar equation type analysis or by more precise combined model simulations of propagation, noise, and sonar signal processing packages. The latter requires considerably more detailed knowledge of the ocean acoustic environment and the sonar system under study.

Continuing with the simple sonar equation, we note that DT includes all the signal and noise processes associated with the sonar, including the operator, except for the array gain. Hence, we are in the realm of probabilistic phenomena. The detection threshold DT, in dB, is the ratio of the signal power S in the receiver bandwidth to the noise power N_0 in a 1-Hz band required for detection according to some detection decision criterion.

To understand the effect of detection threshold setting, we consider two possible cases. If the detection criterion is set too stringently and the DT is therefore high, the probability of detection is low. However, the probability of false alarm (the probability that noise crosses the detection threshold, DT) is also low. In this case only targets with high source level will be detected. Alternatively, for a low DT, low level targets are detected but there is a high probability of false alarm.

Also helpful in quantitatively characterizing the detection process are Receiving Operating Characteristic (ROC) curves, which are plots of probability of detection versus probability of false alarm using a detection index *d* as a parameter (Urick, 1983). The detection index is the standard deviation of the mean amplitude of the signal plus noise M_{S+N} about the mean noise amplitude M_N, normalized to the variance of the signal plus noise or noise alone. Both of the latter are assumed to be Gaussian with equal variance σ^2:

$$d=\frac{(M_{S+N}-M_N)^2}{\sigma^2}. \tag{79}$$

To understand further the utility of DT, we consider two extreme cases: Case 1 is for a completely known signal where the optimum receiver is a crosscorrelator (Urick, 1983); it is found that

$$\mathrm{DT}\equiv 10\log\frac{S}{N_0}=10\log\frac{d}{2t}, \tag{80}$$

where N_0 is the noise power spectrum in a 1-Hz bandwidth and t is the duration of the signal with power S. Case 2 is for an unknown weak signal in Gaussian noise and a long sample size (large time-bandwidth product) where the optimum receiver is a square-law detector (output proportional to the square of the input); it is found that

$$\mathrm{DT}\equiv 10\log\frac{S}{N_0}=5\log\frac{d\Delta f}{t}, \tag{81}$$

where Δf is the bandwidth of the signal with power S. However, the integration time T of the sonar system is an important additional factor: if it is too large, the signal peak is oversmoothed downward, hence increasing DT; if it is too small, the increased bandwidth also increases DT. Therefore, a filter mismatch to the signal always increases DT. In general, the time-bandwidth product is a very important parameter characterizing sonar performance. The detection threshold for the mismatched filter case can be estimated from a modified form of Eq. (81):

$$\mathrm{DT}=5\log\frac{d\Delta f}{t}+\left|5\log\frac{T}{t}\right|. \qquad (82)$$

Another important factor is that one normally tries to detect a signal over a number of independent (incoherently added) samples in order to increase the chances of detection. The incoherent aspect adds a 5 log n term to the received power and hence lowers the DT by that amount.

In reality, the performance of a sonar system has a more complicated behavior than the simplistic discussion above. For example, fluctuations of a signal alter the performance of the sonar and should be reflected in the ROC curve. For this particular example, one must consider modifications of the ROC curves that compensate for increased detection threshold crossings (for a fixed probability of false alarm). Hence, signal fluctuations in this case will result in a net increase in the probability of detection.

6.2 Active Sonar Equation

Active sonars have two fundamental configurations. A monostatic sonar transmits a pulse which interacts with a target, and a resulting echo return to the receiver array which is colocated with the transmitter. A bistatic sonar has the receiver in a different location than the transmitter. We will be mainly concerned with monostatic sonar but we will point out some of the pertinent differences between the two.

With respect to sonar equations, the main differences between the passive and active cases are that source level is modified by a target strength "TS"; reverberation is the dominant interference; and the transmission loss results from two paths, transmitter to target and target to receiver.

In the monostatic case, the transmission loss is 2TL, where TL is the one way transmission loss, and in the bistatic case, the transmission loss is $\mathrm{TL}_1+\mathrm{TL}_2$, where the transmission loss is a sum (in dB) over paths from the transmitter to target and from the target to the receiver. Reverberation is the additional interference term in the active problem that results primarily from scattering of the transmitted field from the boundaries and volume (including animal and vegetable matter) of the ocean. Hence, reverberation level at the receiver is a function of both the acoustic environment and the location of the receiver relative to the transmitter. The total interference term in the sonar equation is a sum of reverberation and noise terms, $\mathrm{RL}+\mathrm{N}$. The concept of detection threshold remains the same as for the passive case so that we can rewrite Eq. (77) for the active case as

$$\mathrm{SE}=\mathrm{SL}-\mathrm{TL}_1+\mathrm{TS}-\mathrm{TL}_2-(\mathrm{RL}+\mathrm{N})+\mathrm{DI}-\mathrm{DT}, \qquad (83)$$

where, in the monostatic case, the two transmission loss terms can be replaced by 2TL. The first two terms are for the outgoing path; the next two terms are for the returning echo; the quantities in the parentheses are the interference, and the last two terms are the system/operator parameters.

In most practical cases, reverberation is the dominant interference factor for active sonar performance. Hence we drop the noise term, noting that it may have to be retained in highly specialized cases. The directivity index used in the passive sonar equation approximated the interference (i.e., noise field) as isotropic; this is no longer a valid approximation for reverberation. It is therefore often convenient to define a quantity as equivalent plane-wave reverberation level "$\mathrm{RL}_{\mathrm{PW}}$," which replaces the terms $\mathrm{N}-\mathrm{DI}$ in passive sonar equations:

$$\mathrm{SE}=\mathrm{SL}-\mathrm{TL}_1+\mathrm{TS}-\mathrm{TL}_2-\mathrm{RL}_{\mathrm{PW}}-\mathrm{DT}. \qquad (84)$$

The corresponding FOM for an active system is defined similarly to the passive system case, Eq. (78), but is for the maximum allowable two-way transmission loss with $\mathrm{TS}=0$ dB. We can estimate the influence of surface and bottom reverberation on sonar performance by combining Eq. (17) or (18) with a propagation model from Sec. 4.

7. UNDERWATER ACOUSTICS AND REMOTE SENSING

Probably the most common usage for underwater acoustics is its application to determining water depth. A depth (echo) sounder or fathometer uses a travel time measurement on an emitted and bottom-reflected short acoustic pulse. The display is often a paper chart with time (which is associated with position) as the running axis versus two way reflection time interval which is translated

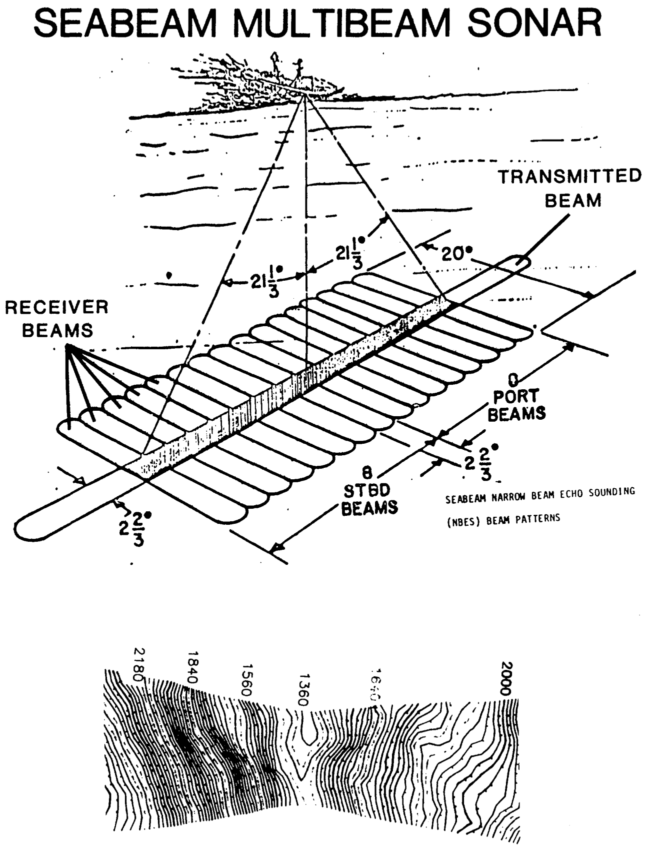

FIG. 20. Schematic of a multibeam bathymetry system with bathymetry contours as output showing a hill (shallow depth) in the center. [Courtesy P. R. Vogt.]

into depth (half-travel distance). Normally, the simplest depth sounders have a wide beamwidth so that they measure an average or minimum depth over a large area. Higher resolution depth sounders have beamwidths on the order of a few degrees and can be used for underwater positioning.

Underwater acoustics plays a major role in bathymetry, "the science and technology of ocean depth measurement," from which geologists/morphologists (who study undersea "geomorphology") infer basic understanding of undersea and earth geologic processes (Vogt and Tucholke, 1986; deMoustier, 1988). The simplest devices used for imaging the ocean bottom are the echo sounders described above. Bathymetric images are compiled from digitized data from the echo sounders combined with navigation/position data. More sophisticated sonar devices (see Fig. 20) have been developed which are essentially multi-narrow-beam ("multibeam") downward looking sonars. Some of these systems have dozens of beams. (The "SASS" system has 61 beams of width 1.5 degrees with a total swath width of up to 1.2 times the water depth.)

Recently introduced sidescan sonars (see Fig. 21), such as the SeaMARC (Sea Mapping and Remote Characterization) use phase measuring interferometric methods and give indication of bottom texture. The SeaMARC I (a 30 kHz system) is towed about 300 m above the ocean bottom at about 3 km/hr and has a swath width of about 2.5 km. Such a system can see objects less than a meter in height with a horizontal resolution of the order of 20 m. Longer range systems such as GLORIA (a 6.5 kHz system) have swath widths 15 to 30 km wide on each side of the ship and can see objects with heights of a few meters and horizontal resolution of the order of hundreds of meters. Higher resolution systems operate in the hundreds of kilohertz region with associated resolutions. In all cases, the key component in bathymetric analysis is the sophisticated data processing necessary to synthesize bathymetric/morphologic images.

With respect to the water column structure of the ocean, an extremely ambitious ocean acoustic remote sensing technology has recently emerged: "Ocean Acoustic Tomography" (Cornuelle *et al.*, 1985) (see ACOUSTICAL TOMOGRAPHY). Tomography is a remote sensing scheme which utilizes a series of acoustic time of flight measurements between sources and receivers on the periphery of a large ocean region (dimensions of a few hundred km or greater) of which knowledge of the sound speed structure is desired. This latter knowledge is primarily convertible to temperature (see Sec. 2). Oceanographers employ this technique to measure ocean mesoscale phenomena: temperature changes of the order of tenths of a degree over distance scales of the order of tens to hundreds of kilometers and times scales of days to weeks. The method utilizes the waveguide behavior of sound propagation in the ocean (Sec. 3), where the information contained in the multipath time-of-flight measurements is inverted using Radon's theorem to give the index of refraction of the internal region that is being insonified.

GLOSSARY

Active Sonar: A sonar which emits sound and receives its echo.

Adiabatic Mode Theory: Solution to the range-dependent wave equation under the assumption that the normal modes adapt to the gradually changing environment.

Array Gain (AG): The signal to noise ratio of an array divided by the average signal to noise of a hydrophone element expressed in decibels.

Beamforming: Phasing an array to form a set of "look directions."

Bistatic Reverberation: Reverberation at a point not colocated with the source.

Continuous Spectrum: The part of the solution spectrum of the waveguide problem which corresponds to the energy which is eventually radiated out of the waveguide.

Convergence Zone Propagation: Spatially periodic ($\approx$35–65 km) refocusing of sound from a shallow source producing zones of high intensity near the surface due to the upward refracting nature of the sound speed profile and the absence of bottom interaction.

Coupled Mode Theory: Solution to the range-dependent wave equation including mode conversion due to the changing environment.

Critical Depth: The depth (below the deep sound channel axis) at which the sound speed is the same as that at the surface.

Critical Grazing Angle: The angle with respect to the horizontal below which perfect reflection at an interface occurs.

Decibels: Ten times the logarithm in base 10 of a ratio of intensities.

Deep Scattering Layer: A layer in the water column populated by organisms which scatter sound and which typically undergoes diurnal variations in depth.

Deep Sound Channel: A sound channel occurring in deep water whose axis is at the minimum of the sound speed profile and in which propagation does not involve interaction with the ocean surface or bottom.

Detection Threshold (DT): The additional signal level above zero signal to noise ratio at the output of a sonar array necessary for a detection.

Directivity Index: The array gain under the assumption that the noise is isotropic.

Discrete Spectrum: The part of the solution of the waveguide problem which corresponds to long range normal mode propagation.

Fast Field Program (FFP): Direct numerical full field solution of the range-independent acoustic wave equation including both the continuous and discrete spectra.

Figure of Merit (FOM): The transmission loss that gives zero signal excess for a specified probability of detection.

Geometric Spreading Loss: For a point source, the amplitude decay with range (r) is spherical (r^{-2}) in free space and is cylindrical (r^{-1}) in a waveguide.

Lambert's Law: The scattering from a rough interface is diffuse.

Matched Field Processing: Beamforming by matching the data on an array with the solutions of the wave equation specific to the environment.

Micropascal: (μPa) 10^{-5} dyne per square centimeter.

Mixed Layer: The layer of water below the surface mixed by wave motion; it is essentially isothermal.

Monostatic Reverberation: Reverbation at the source.

Normal Modes: The eigenfunction solutions of the depth part of the range-independent wave equation.

Parabolic Equation (PE): Approximate version of the one-way wave equation for mildly changing environment including some mode coupling effects.

Passive Sonar: A sonar which only receives sound.

Probability of Detection [$p(D)$]: The probability that an existing signal will be detected.

Probability of False Alarm [p(FA)]: The probability that noise crosses the detection threshold and hence an incorrect detection is made.

Propagation Loss: In decibels, 20 log (amplitude of the field from a unit source).

Range-Dependent: An ocean environment which varies in range.

Range-Independent: A stratified ocean environment such that separation of variables, range, depth, and azimuth, can be employed to solve the wave equation.

Ray Theory: The high frequency limit of solving the acoustic wave equation which includes refraction but not diffraction effects.

Recognition Differential (RD): see Detection Threshold.

Reverberation: The scattered acoustic field from an active sonar source which acts as interference in the sonar system.

ROC (Receiving Operating Characteristic) Curves: Parametrized plots of probability of detection versus probability of false alarm.

Signal Excess (SE): The difference between the received signal at the output of the sonar array and the minimum signal for dectection.

Sound Channel: A local minimum in the sound speed profile in a stratified ocean causing ducted propagation according to Snell's law.

Sound Speed Profile: The speed of sound as a function of depth.

Split Step Algorithm: Extremely fast method to solve the parabolic equation based on fast Fourier transforms.

Surface Duct: A sound channel whose upper boundary is the ocean surface formed when there is a local speed profile minimum near the ocean surface.

Thermocline: A vertical negative temperature gradient typically below the mixed layer.

Transmission Loss: The negative of propagation loss and therefore a positive quantity.

INTRODUCTION

The aerodynamicist applies the principles of fluid mechanics to determine the forces and moments acting on an object moving through the air, e.g., a golf ball or an airplane, or due to the air moving past an object, e.g., the wind loads acting on a building. The proper determination of the aerodynamic forces and moments makes use of experimental measure-

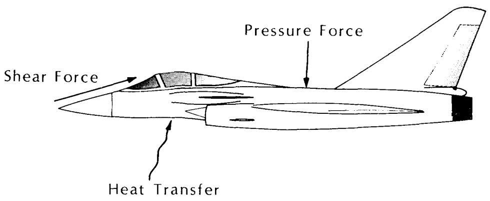

FIG. 1. Aerothermodynamic environment for a high-speed airplane.

ments and of computer-generated flow-field solutions. In most ground-based experimental investigations, e.g., wind-tunnel tests, the air moves around a model held stationary in the wind tunnel. In flight, however, the vehicle moves through the air. Thus, in one case, the analysis of the flow takes place in a vehicle-fixed coordinate system (the air moves around the stationary object), whereas in the other case, the analysis takes place in a ground-fixed coordinate system (the object moves through a stationary air mass). Although there are some significant differences between these two approaches regarding the treatment of the time-dependent terms in the analysis, the aerodynamic forces and moments acting on the object should be the same for either approach. Thus, in the discussion that follows, we shall usually refer to the flow around an object.

Aerodynamic forces acting on an object consist of the skin friction (or shear) forces and the pressure forces acting on its surface, as shown in Fig. 1. To determine the resultant pressure forces, one must know the local static pressure as a function of space and time, i.e., $p(x,y,z,t)$ where x, y, and z are also functions of time. For flight below 75 km (246 kft), the air may be considered a continuum. Because of viscosity, air particles that are immediately adjacent to the surface in this continuum move at the same speed as the surface, i.e., a "no-slip condition" exists at the surface of the object. As a result, there are large velocity gradients in the viscous boundary layer that exists between the no-slip boundary condition at the surface and the local "inviscid" flow away from the surface. These velocity gradients produce shear stresses which are transmitted to the surface as shown in the sketch of Fig. 1. Thus, to determine the shear forces acting on the vehicle, one must be able to define the velocity field, i.e., $\mathbf{V}(x,y,z,t)$, and the viscosity. For high-speed flight, on the order of three times the speed of sound or greater, point-to-point temperature variations in the flow field can cause significant variations in the fluid properties and can create sufficiently large temperature variations in the boundary layer, so that heat transfer to the vehicle becomes of concern to the analyst.

In the discussion that follows, the basic principles of fluid mechanics are discussed and then applied to aerodynamics. For an expanded discussion and for applications to a variety of projects, the reader is referred to Bertin and Smith (1989).

1. A REVIEW OF FLUID MECHANICS

We can define the aerothermodynamic environment of a vehicle, i.e., the aerodynamic forces and moments acting on the vehicle, and the heat transferred to the vehicle, if we can determine

$$p(x,y,z,t), \tag{1a}$$

$$\mathbf{V}(x,y,z,t), \tag{1b}$$

$$T(x,y,z,t). \tag{1c}$$

To obtain solutions for these variables (either experimentally or theoretically), one must develop flow models. Since we have three unknowns, we need three independent equations. The fundamental physical laws used to solve for the fluid motion in a general problem are as follows:

1. conservation of mass (or continuity equation),
2. conservation of linear momentum (or Newton's second law of motion),
3. conservation of energy (or the first law of thermodynamics).

Note that if we consider the velocity vector **V** as one of the unknown dependent variables, then we would use the vector form of the momentum equation (since the forces acting on a fluid particle and the resultant accelerations can be written as vector quantities). Therefore, the first and third physical relations are scalar equations, while the conservation of linear momentum is represented by a vector relation. However, the velocity field can be represented by its three components (u, v, and w). In this case, there would be three component momentum equations. Indeed, this will be the approach taken in the present development, since Eqs. (5a)– (5c) represent the three components of the conservation-of-momentum equation in Cartesian coordinates. In this approach, we have five scalar equations with five primary unknowns: p, u, v, w, and T. These laws can be expressed in differential form or in integral form.

1.1 Equations Governing Fluid Motion

1.1.1 Continuity Equation. If the principle of conservation of mass is applied to a small volume of space through which the fluid can move freely, the net outflow of mass through the surface surrounding the volume must be equal to the decrease of mass within the volume. In vector form, the general differential form of the continuity equation is

$$\frac{\partial \rho}{\partial t}+\nabla\cdot(\rho\mathbf{V})=0. \tag{2}$$

1.1.2 Conservation of Linear Momentum. The equation for the conservation of linear momentum is obtained by applying Newton's second law: The net force acting on a fluid particle is equal to the time rate of change of the linear momentum of the fluid particle. As the fluid element moves in space, its shape and volume may change, but its mass is conserved. Thus, using a coordinate system that is neither accelerating nor rotating, called an *inertial coordinate system,* we may write

$$\sum \mathbf{F}=m\frac{d\mathbf{V}}{dt}\,. \tag{3}$$

The velocity $\mathbf{V}$ of a fluid particle is, in general, an explicit function of time t as well as of its position x, y, z. Furthermore, the position coordinates x, y, z of the fluid particle are themselves a function of time. Since the time differentiation of Eq. (3) follows a given particle in its motion, the derivative is frequently termed the *particle, total,* or *substantial derivative* of $\mathbf{V}$:

$$\frac{d\mathbf{V}}{dt}=\frac{\partial\mathbf{V}}{\partial t}+(\mathbf{V}\cdot\nabla)\mathbf{V}, \tag{4}$$

where $d\mathbf{V}/dt$ is the total acceleration, $\partial\mathbf{V}/\partial t$ is the unsteady (time-dependent) acceleration, and $(\mathbf{V}\cdot\nabla)\mathbf{V}$ is the convective acceleration.

The principal forces with which we are concerned are those that act directly on the mass of the fluid element (the body forces) and those that act on its surface (the pressure forces and shear forces). The surface forces (per unit area) acting on the fluid particle are described by a stress tensor. In general, the various stresses change from point to point, producing net forces on the fluid particle which cause it to accelerate or to decelerate.

We can relate the stresses to the fluid motion. Stress components for a Newtonian fluid are a linear function of the components of the rate of strain. Thus, for a one-dimensional flow, $\tau=\mu(\partial u/\partial y)$. The viscosity μ is called the first viscosity coefficient.

With the appropriate expressions for the stresses substituted into the expressions for the forces in Eq. (3), we obtain

$$\rho\frac{\partial u}{\partial t}+\rho(\mathbf{V}\cdot\nabla)u=\rho f_x-\frac{\partial p}{\partial x}+\nabla\cdot(\mu\nabla u)+\nabla\cdot\left(\mu\frac{\partial\mathbf{V}}{\partial x}\right)-\frac{2}{3}\frac{\partial}{\partial x}(\mu\nabla\cdot\mathbf{V}) \tag{5a}$$

$$\rho\frac{\partial v}{\partial t}+\rho(\mathbf{V}\cdot\nabla)v=\rho f_y-\frac{\partial p}{\partial y}+\nabla\cdot(\mu\nabla v)+\nabla\cdot\left(\mu\frac{\partial V}{\partial y}\right)-\frac{2}{3}\frac{\partial}{\partial y}(\mu\nabla\cdot\mathbf{V})\,, \tag{5b}$$

$$\rho\frac{\partial w}{\partial t}+\rho(\mathbf{V}\cdot\nabla)w=\rho f_z-\frac{\partial p}{\partial z}+\nabla\cdot(\mu\nabla w)+\nabla\cdot\left(\mu\frac{\partial\mathbf{V}}{\partial z}\right)-\frac{2}{3}\frac{\partial}{\partial z}(\mu\nabla\cdot\mathbf{V}). \tag{5c}$$

These general, differential equations for the conservation of linear momentum are known as the *Navier–Stokes equations.* Navier in 1827 and Stokes in 1845 contributed to the inclusion of the frictional resistance terms in the equations of motion. Note that the viscosity μ is considered to be dependent on the spatial coordinates. This is done since, for a compressible flow, the changes in velocity and pressure, together with the kinetic-energy dissipation due to friction, bring about considerable temperature variations. The temperature dependence of viscosity in the general case should, therefore, be incorporated into the governing equations.

1.1.3 Conservation of Energy. The equation for the conservation of energy is obtained by applying the first law of thermodynamics to a small volume in space through which the fluid can move freely. The rate at which heat is added to the system of fluid particles, less the rate at which work is done by the system, is equal to the time rate of change of energy within the control volume plus the net efflux of energy across the system boundary. The energy of the system can take a variety of forms. They are usually grouped as follows:

1. *Kinetic energy* (e_k): energy associated with the directed motion of the mass.
2. *Potential energy* (e_p): energy associated with the position of the mass in an external field.
3. *Internal energy* (e): molecular and atomic energy associated with the internal fields of the mass.

The total energy of the system (e_t) may be written as

$$e_t = e_k + e_p + e. \tag{6}$$

Thus, the energy equation becomes

$$\frac{\delta q}{\delta t} - \frac{\delta w}{\delta t} = \frac{d(e_k)}{dt} + \frac{d(e_p)}{dt} + \frac{d(e)}{dt}. \tag{7}$$

The rate at which heat is transferred to the system and work is done by the system are path dependent, as indicated by $\delta/\delta t$. Introducing Fourier's law of heat conduction, the relations between stress and rate of strain, and the forms of energy, one obtains the general differential form of the energy equation as

$$\rho \frac{dh}{dt} - \frac{dp}{dt} = \nabla \cdot (k \nabla T) + \phi, \tag{8a}$$

where

$$\begin{aligned}\phi = & -\frac{2}{3}\mu(\nabla \cdot \mathbf{V})^2 \\ & + 2\mu\left[\left(\frac{\partial u}{\partial x}\right)^2 + \left(\frac{\partial v}{\partial y}\right)^2 + \left(\frac{\partial w}{\partial z}\right)^2\right] \\ & + \mu\left[\left(\frac{\partial u}{\partial y} + \frac{\partial v}{\partial x}\right)^2 + \left(\frac{\partial v}{\partial z} + \frac{\partial w}{\partial y}\right)^2 \right. \\ & \left. + \left(\frac{\partial w}{\partial x} + \frac{\partial u}{\partial z}\right)^2\right].\end{aligned} \tag{8b}$$

Equation (8b) defines the dissipation function ϕ. The specific enthalpy h is defined as

$$h = e + p/\rho, \tag{8c}$$

where e is the specific internal energy and p/ρ is related to the flow work.

1.2 General Remarks on the Equations of Motion

The continuity equation [Eq. (2)], the three components of the momentum equation [Eqs. (5a)–(5c)], and the energy equation [Eq. (8a)] represent a system of scalar equations in terms of five unknowns: p, T, u, v, and w. These five scalar equations of motion contain additional variables: density (ρ), enthalpy (h), viscosity (μ), and thermal conductivity (k). These four variables are, in general, functions of the pressure, the temperature, and the composition of the gas. Thus, our system of five equations of motion with five unknowns can be supplemented with additional relations from the kinetic theory of gases.

The evaluation of these four parameters presents varying degrees of difficulty, which depend on the application. For an application such as the Aeroassisted Space Transfer Vehicle (ASTV), which operates at velocities of 10 km s^{-1} (32.8 kft s^{-1}) at altitudes exceeding 90 km (295 kft), one must be able to model the noncontinuum and the nonequilibrium character of the flow. However, for low-velocity flows, i.e., less than 100 m s^{-1} (194 knots), temperature variations in the flow field are relatively small. Thus, for low-speed flows, the transport properties (μ and k) and the density (ρ) are usually assumed constant. Constant-density flows are termed incompressible flows.

For velocities in excess of 100 m s^{-1}, the density is often calculated using the equation of state for a thermally perfect gas:

$$\rho = p/RT. \tag{9}$$

In Eq. (9), the gas constant (R) is the universal gas constant ($\hat{R}$) divided by the molar mass ($\mathscr{M}$).

Clearly, in order to determine the aerodynamic forces and moments acting on an object, one must be able to define a complex flow field. For the purpose of the present discussion, we will say that there are four ways to generate design information about the flow field:

1. Experimental programs employing scale models in a wind tunnel.

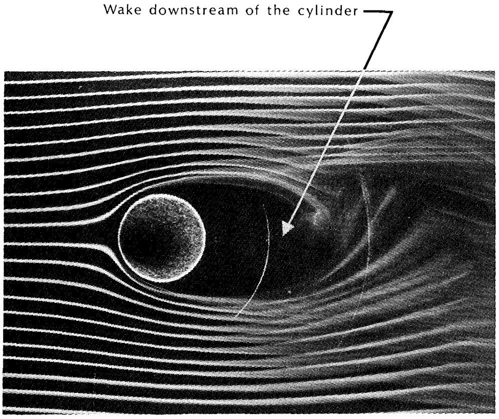

FIG. 2. Flow-visualization photograph of low-speed flow around a cylinder (flow from left to right).

2. Analytical-numerical formulations in which the flow field is divided into two regions, one in which the flow is essentially inviscid and a second in which the effects of viscosity are important.
3. Analytical-numerical formulations in which the entire flow field is determined simultaneously.
4. Flight-test programs employing a full-scale (or prototype) model.

The full-scale flight test is the only one of the four techniques that does not involve compromises. Because wind-tunnel tests usually employ small-scale models, there are often compromises even in such basic simulation parameters as the Reynolds number. Furthermore, the support system which holds the model in position in the wind tunnel may influence the data of interest. Although numerical codes incorporating a two-layer (inviscid-viscous) model of the flow field provide powerful design tools, the analyst must be sure that the flow model used in the code is appropriate. For instance, the two-layer model cannot be used to compute the flow field downstream of a blunt object, such as the flow in the wake of a cylinder, as shown in Fig. 2.

Because of the increased capability of computer hardware and of the improved software developed by numerous researchers, the third method is a rapidly developing tool. As discussed by Li (1989), the development and application of a computational fluid dynamics (CFD) code involves several steps:

1. Selecting the physical processes to be modeled.
2. Selecting the mathematical and topological models.
3. Defining the body geometry and constructing the spatial grid.
4. Developing a numerical solution algorithm.
5. Incorporating steps (1)–(4) in a computer code.
6. Calibrating and validating the code against benchmark experimental data or "classic" analytical solutions.
7. Using the CFD code to predict the desired aerodynamic coefficients, flow-field properties and/or heating-rate environment.

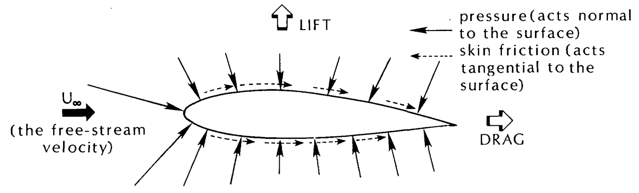
The development, calibration, and verification of a really useful CFD code may require several years.

In reality, the design process will integrate programs involving all four techniques. The data from experimental programs will be used to improve the flow models used in the computer codes. The computer codes can be used to generate flow-field solutions at conditions outside the test envelopes.

2. CHARACTERIZING THE FLOW FIELD

To predict accurately the aerodynamic forces and moments that act on a vehicle in flight, it is necessary to be able to describe the pattern of flow around the configuration. The resultant flow pattern depends on the geometry of the vehicle, its orientation with respect to the undisturbed free stream, and the altitude and speed at which the vehicle is traveling. Simplifying assumptions can be made for the equations of motion depending upon the flight regime of the aircraft. A discussion of some of these simplifying assumptions and their regions of applicability is presented in the following sections.

Consider the forces acting on the airfoil shown in the sketch of Fig. 3. We will assume that an airfoil is of infinite span, i.e., its length into the paper is infinite, and every cross section is identical to that appearing in the plane of the paper. Thus, the flow over an airfoil is two dimensional, i.e., the same in every plane parallel to the plane of the paper. Since a wing is a series of airfoil sections of finite span, the flow over a wing will be three di-



LIFT
pressure(acts normal to the surface)
skin friction (acts tangential to the surface)
U∞
(the free-stream velocity)
DRAG

FIG. 3. A sketch of the forces acting on a two-dimensional airfoil.

mensional, introducing additional complexity to its analytical description.

For simplicity, the present discussion will describe the phenomena and simplifying assumptions using two-dimensional flow fields. As discussed earlier and as depicted in Fig. 3, the forces distributed over the vehicle consist of pressure forces acting normal to the surface and skin-friction forces that are tangential to the surface. The varying lengths of the arrows representing the local pressure and the local skin friction reflect the fact that the air particles accelerate and decelerate as they move around the airfoil. Thus, even outside of the viscous boundary layer, the local velocity of the air particles at the edge of the boundary layer (u_e in Fig. 4) will be a function of the streamwise location. The aerodynamicist resolves the integrated effect of these forces into a lift (that acts normal to the free-stream velocity, upward being considered positive) and a drag force (which acts in the direction of the free-stream flow). Based on the sketch presented in Fig. 3, the pressure forces constitute the dominant contributor to the lift acting on the airfoil. Force coefficients for a two-dimensional flow will be designated with a lower-case subscript. Thus, C_l is the lift coefficient for an airfoil. Force coefficients for a three-dimensional flow will be designated with an upper-case subscript. Thus, C_L is the lift coefficient for a wing.

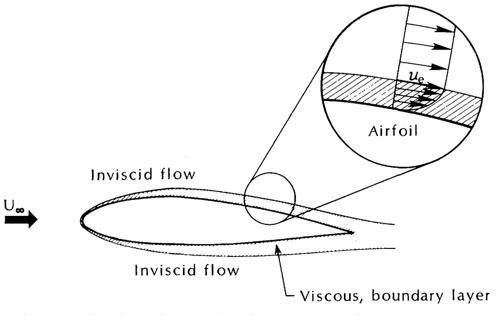


FIG. 4. A sketch of the flow around an airfoil for a two-region flow model.

As illustrated in the sketch of Fig. 4, there is a thin boundary layer adjacent to the surface of the airfoil, where the streamwise velocity component (u) varies from zero at the surface (the no-slip condition) to the (local inviscid) value outside the boundary layer (u_e). The large velocity gradients ($\partial u/\partial y$) in this region produce shear stresses which cannot be neglected. Let us examine the x-momentum equation [Eq. (5a)], and the y-momentum equation [Eq. (5b)], for our two-dimensional flow. Let us assume further that the density variations are negligible (i.e., the flow is incompressible). This implies, as noted earlier, that the velocity is less than 100 m s^{-1}. Thus, the continuity equation [Eq. (2)] becomes

$$\nabla \cdot \mathbf{V} = \frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} = 0. \tag{10}$$

Furthermore, since the density is assumed constant, the viscosity should be constant too. As a result, the x- and y-momentum equations for a two-dimensional, incompressible flow may be written

$$\rho \frac{\partial u}{\partial t} + \rho u \frac{\partial u}{\partial x} + \rho v \frac{\partial u}{\partial y} = -\frac{\partial p}{\partial x} + \mu \frac{\partial^2 u}{\partial x^2} + \mu \frac{\partial^2 u}{\partial y^2}$$

and

$$\rho \frac{\partial v}{\partial t} + \rho u \frac{\partial v}{\partial x} + \rho v \frac{\partial v}{\partial y} = -\frac{\partial p}{\partial y} + \mu \frac{\partial^2 v}{\partial x^2} + \mu \frac{\partial^2 v}{\partial y^2},$$

where the x coordinate is measured parallel to the airfoil surface and the y coordinate is measured perpendicular to it. Solving for the pressure gradients gives us

$$-\frac{\partial p}{\partial x} = \left(\rho \frac{\partial}{\partial t} + \rho u \frac{\partial}{\partial x} + \rho v \frac{\partial}{\partial y} - \mu \frac{\partial^2}{\partial x^2} - \mu \frac{\partial^2}{\partial y^2} \right) u,$$

$$-\frac{\partial p}{\partial y} = \left(\rho \frac{\partial}{\partial t} + \rho u \frac{\partial}{\partial x} + \rho v \frac{\partial}{\partial y} - \mu \frac{\partial^2}{\partial x^2} - \mu \frac{\partial^2}{\partial y^2} \right) v.$$

Near a solid surface, the normal component of velocity is usually much less than the streamwise component of velocity (i.e., v

$<u$). Since there is a similar correlation between the gradients of these velocity components,

$$\frac{\partial p}{\partial y} < \frac{\partial p}{\partial x}\,.$$

The pressure variation across the boundary layer is usually negligible. Therefore, the pressure distribution around the airfoil is essentially that of the inviscid flow (accounting for the displacement effect of the boundary layer).

The assumption that the pressure variation across the boundary layer is negligible breaks down for turbulent boundary layers at very high Mach numbers. Bushnell, Cary, and Harris (1977) cite data for which the wall pressure is significantly greater than the edge value for turbulent boundary layers where the edge Mach number is approximately 20. The characteristics distinguishing laminar and turbulent boundary layers will be discussed in a later section. Thus, we can obtain valuable information about the forces and moments, if we can describe the flow outside of the boundary layer where the velocity gradients associated with shear stresses are negligible, i.e., the *inviscid flow.*

2.1 Inviscid Flows

In the preceding section, we have seen that, for thin boundary layers having streamlines that are relatively straight, the pressure gradient across the boundary layer is negligible. Furthermore, we have seen that the lift generated by a streamlined shape depends primarily on the pressure distribution. In fact, the pitching moments about some reference point (which relate to the stability of the vehicle) also depend primarily on the pressure distribution for a streamlined shape. Thus, if we can determine the pressure distribution for the flow at the edge of the boundary layer, we can generate reasonable estimates for the lift and the pitching moment acting on a vehicle. Furthermore, even though the experimental pressure distributions both from flight tests and from wind-tunnel tests are determined from the pressures sensed by orifices located in the wall, they provide information about the flow outside of the boundary layer. This information can be used to verify computer-generated flow fields or to improve flow models used in these codes.

2.1.1 Euler's Equation.

As indicated in the sketch of Fig. 4, the velocity gradients that give rise to the viscous forces are negligible outside of the boundary layer. Thus, although the viscosity is the same within the boundary layer as outside of it (for a constant property flow), the shear forces (the products of the coefficient of viscosity and the velocity gradients) are small compared to the inertia and the pressure forces acting on the air particles. Thus, we can neglect all the terms involving the coefficient of viscosity (μ) in Eqs. (5a)–(5c). As a result, the components of the conservation of linear momentum equation for an inviscid flow become

$$\rho\,\frac{du}{dt} = \rho f_x - \frac{\partial p}{\partial x}\,, \tag{11a}$$

$$\rho\,\frac{dv}{dt} = \rho f_y - \frac{\partial p}{\partial y}\,, \tag{11b}$$

$$\rho\,\frac{dw}{dt} = \rho f_z - \frac{\partial p}{\partial z}\,. \tag{11c}$$

We have used the term *inviscid flow* to emphasize the fact that it is the character of both the velocity field and the fluid viscosity that allows us to neglect the viscous forces. In vector form, the equation is

$$\frac{d\mathbf{V}}{dt} = \frac{\partial \mathbf{V}}{\partial t} + (\mathbf{V}\cdot\nabla)\mathbf{V} = \mathbf{f} - \frac{1}{\rho}\,\nabla p. \tag{12}$$

No assumption has been made about the density at this point, so these equations apply to both a compressible and an incompressible flow. These equations, derived in 1755 by Leonhard Euler, are called the *Euler equations.*

2.1.2 Bernoulli's Equation.

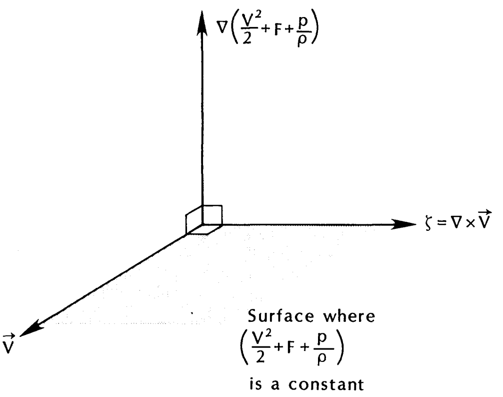
If we further assume that the flow is steady, then

$$\frac{\partial \mathbf{V}}{\partial t} = 0.$$

The body force most often encountered is that due to gravity. Since gravity can be represented by a force potential,

$$\mathbf{f} = -\nabla F = -\frac{\partial F}{\partial z}\hat{k} = -g\hat{k}, \tag{13}$$

where we have used the convention that the z axis is positive when pointing upward and normal to the surface of the earth, and that



$\nabla\left(\frac{V^2}{2}+F+\frac{p}{\rho}\right)$
$\zeta=\nabla\times\vec{V}$
$\vec{V}$
Surface where
$\left(\frac{V^2}{2}+F+\frac{p}{\rho}\right)$
is a constant

FIG. 5. Geometry for Lamb's equation.

the force per unit mass due to gravity is directed downward and is of magnitude g.

Substituting these relations into Eq. (12) with the additional restriction that the flow is incompressible, we obtain the relation

$$\nabla\left(\frac{V^2}{2}+F+\frac{p}{\rho}\right)=\mathbf{V}\times\zeta, \tag{14}$$

where ζ, the curl of the velocity ($\nabla\times\mathbf{V}$), is the vorticity. This equation, which is called *Crocco's equation* or *Lamb's equation*, provides important information about the geometric relationships between the velocity vector $\mathbf{V}$, the vorticity vector ζ, and the quantity $(V^2/2)+F+(p/\rho)$. From the properties of cross products, the vector $\mathbf{V}\times\zeta$ must be perpendicular to the plane containing $\mathbf{V}$ and ζ. Thus, as shown in Fig. 5, the gradient of $(V^2/2)+F+(p/\rho)$ is perpendicular to the plane of $\mathbf{V}$ and ζ or, equivalently, $(V^2/2)+F+(p/\rho)$ is constant in the plane of $\mathbf{V}$ and ζ.

Furthermore, since the streamlines are parallel to the velocity $\mathbf{V}$, the plane of $\mathbf{V}$ and ζ contains the paths of the fluid flow. Since the streamlines are tangent to $\mathbf{V}$ and the vortex lines are tangent to ζ, the grid of streamlines and vortex lines must lie on the surface where $(V^2/2)+F+(p/\rho)$ equals a constant. Thus, for a flow that is inviscid, incompressible, steady, and irrotational (or, if the flow is rotational, we consider displacements along a vortex line or along a streamline), and for which the body force is gravity, which is conservative,

$$V^2/2+gz+p/\rho=\text{const.} \tag{15}$$

Equation (15) is known as *Bernoulli's equation.*

Because the density has been assumed constant, it is not necessary to include the energy equation in the procedure to solve for the velocity and pressure fields. Note that, in deriving Eq. (15), we have assumed that dissipative mechanisms do not significantly affect the flow. As a corollary, Bernoulli's equation is valid only for flows where there is no mechanism for dissipation, such as viscosity. In thermodynamics, the flow process would be called *reversible.*

Bernoulli's equation can also be derived using the integral form of the energy equation. For this derivation, the flow is assumed to be steady, inviscid, incompressible, and one dimensional with no heat transfer, no shaft work, and no perceptible changes in the internal energy. These assumptions are consistent with the five stated previously, when deriving Bernoulli's equation from the momentum equation. Again, we obtain

$$V^2/2+gz+p/\rho=\text{const},$$

where $V^2/2$ is the kinetic energy, gz is the potential energy, and p/ρ is the flow work, and where we have defined the individual terms by their physical significance based on the energy equation.

2.1.3 Bernoulli's Equation for Gaseous Flows and the Pressure Coefficient. The terms in Eq. (15) have units of energy per unit mass. The aerodynamicist usually multiplies through by ρ, so that the terms have units of force per unit area, i.e., pressure. For most gas flows, the changes in potential energy between two points in the flow field are negligible. (One exception would be in describing the atmospheric flow field where we must account for large changes in altitude.) Neglecting the change in potential energy, Eq. (15) may be written as

$$p+\tfrac{1}{2}\rho U^2=\text{const.} \tag{16}$$

This equation establishes a direct relation between pressure and velocity. Thus, if either parameter is known, the other can be uniquely determined, provided that the flow does not violate the assumptions required to apply Bernoulli's equation. This equation can be used to relate the flow at various points in the inviscid flow around a vehicle. Consider an incompressible flow around an airfoil, as

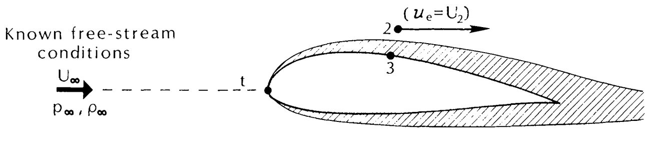


FIG. 6. Application of Bernoulli's equation to airflow around an airfoil.

shown in the sketch of Fig. 6. Recall that, if the airfoil is flying through a mass of air at rest, we superimpose the negative of the velocity of the airfoil so that the airfoil is at rest (in our vehicle-fixed reference frame), and the air is flowing around it. Typical free-stream properties (such as density and static pressure) are known as a function of altitude, e.g., *U. S. Standard Atmosphere* (1976). As the flow approaches the airfoil, it slows down, and there is one point near the leading edge where the local velocity is zero. Because the local velocity is zero, the pressure is equal to its maximum value in the flow field, which we will designate as the total pressure, and represent by the subscript *t*. Referring to Fig. 6,

$$p_\infty+\tfrac{1}{2}\rho_\infty U_\infty^2=p_t. \tag{17}$$

Aeronautical engineers refer to p_∞ as the free-stream static pressure, $\frac{1}{2}\rho_\infty U_\infty^2$ as the dynamic pressure (which is also represented by the symbol q_∞), and p_t as the total, or stagnation, pressure. Thus, for this steady, inviscid, incompressible flow, the total pressure is the sum of the static pressure plus the dynamic pressure. Thus, p_t is the constant of Bernoulli's equation as it appears in Eq. (17). The total pressure is not the sum of $p_\infty + \frac{1}{2}\rho_\infty U_\infty^2$ if density variations are significant, i.e., if the flow is compressible.

The fluid is said to be a *static fluid medium* if the fluid particles, when viewed as a continuum, are either all at rest or all moving with the same velocity. Thus, the term *static fluid properties* may be applied to situations in which elements of the fluid are moving, provided there is no relative motion between fluid particles. Since we have superimposed the velocity of the airfoil to create a steady flow in which all the free-stream air particles are moving at the same speed (U_∞), the free-stream static pressure (p_∞) is the ambient atmospheric pressure for the altitude at which the airfoil is operating. Furthermore, as given by Eq. (17), the pressure at the stagnation point, where the air particles have zero velocity with respect to the wing, is p_t, the total pressure. If we were to analyze this problem in the ground-fixed coordinate system, i.e., with the wing moving through a mass of air which is at rest, the ambient atmospheric pressure is not the total pressure, even though the air particles in the free stream are at rest in this coordinate system. In this reference frame, the time-dependent terms must be included in the flow model.

Consider an air particle that moves from point *t* to point 2 (in Fig. 6), remaining outside the boundary layer. Since the particle remains outside of the boundary layer, it is not affected by viscosity. With the five conditions for Bernoulli's equation satisfied,

$$p_\infty+\tfrac{1}{2}\rho_\infty U_\infty^2=p_t=p_2+\tfrac{1}{2}\rho_\infty U_2^2.$$

Note that, since the local inviscid velocity (U_2) may be greater than or less than the free-stream velocity (U_∞), the local static pressure (p_2) may be less than or greater than the free-stream static pressure (p_∞).

What about the pressure and the velocity at point 3, which is adjacent to the surface of the airfoil but at the same streamwise location as point 2? Since there is the "no-slip" boundary condition at the wall, $U_3=0$. From our discussion of thin boundary layers, $\partial p/\partial y \approx 0$ across the boundary layer. As a result, the static pressure at point 2 equals the static pressure at point 3, i.e., $p_2 = p_3$. This combination of pressure and velocity does not violate Bernoulli's equation, because point 3 lies buried within a viscous region. Therefore, the conditions for Bernoulli's equation are not met. Thus, we cannot apply Eq. (16) to determine the pressure or the velocity at point 3.

The engineer often uses experimental data or theoretical solutions for one flow condition to gain insight into the flow field that exists at another flow condition. Wind-tunnel data, where scale models are exposed to flow conditions that simulate the design flight environment, are used to gain insight to describe the full-scale flow field at other flow conditions. Therefore, it is most desirable to present (experimental or theoretical) correlations in terms of dimensionless coefficients that depend only on the configuration geometry and the angle of attack. This also eliminates problems associated with the choice of units. One such dimensionless coefficient is the pressure coefficient:

$$C_p = \frac{p - p_\infty}{\frac{1}{2}\rho_\infty U_\infty^2} = \frac{p - p_\infty}{q_\infty} . \tag{18}$$

This particular choice of a parameter to nondimensionalize the local static pressure can be understood by referring to Bernoulli's equation without the potential-energy term. Rearranging Eq. (16), we find

$$C_p = \frac{p - p_\infty}{\frac{1}{2}\rho_\infty U_\infty^2} = 1 - \frac{U^2}{U_\infty^2} . \tag{19}$$

Thus, at the stagnation point, where the local velocity is zero, $C_p = 1.0$ for an incompressible flow. Note that the stagnation point value is independent of the free-stream flow conditions, the configuration geometry, and the choice of units.

2.1.4 Pressure Gradients. Both Bernoulli's equation and Euler's equation indicate that, for an inviscid flow with negligible body forces,

$$dp = -\rho U\, dU \tag{20}$$

along a streamline. Thus, if dp/dx is positive, i.e., the pressure increases in the streamwise direction, it is called an adverse pressure gradient, since it acts against the fluid motion and the flow decelerates. Similarly, if dp/dx is negative, it is called a favorable pressure gradient and the flow accelerates. The sign of the pressure gradient is of great importance when the pressure field established by the inviscid flow interacts with the boundary layer. This will be discussed later.

2.1.5 Irrotational Flows. If $\nabla \times \mathbf{V} = 0$, the flow is said to be *irrotational.* According to Lord Kelvin's theorem, a flow remains irrotational in the absence of viscous forces or discontinuities provided that the fluid is homogeneous and the body forces can be described by a potential function. A homogeneous (or barotropic) fluid is one in which the density depends only on the pressure. Such is the case for incompressible flow (since ρ is a constant) and for isentropic, compressible flow (for which p is proportional to ρ^γ).

In most flow problems (certainly those of interest to this article), the undisturbed, free-stream flow is a uniform parallel flow in which there are no shear stresses. Kelvin's theorem implies that, although the fluid particles in the subsequent flow patterns may follow curved paths, the flow remains irrotational except in those regions where the dissipative viscous forces are an important factor.

For an irrotational flow, the velocity may be expressed in terms of a potential function:

$$\mathbf{V} = \nabla \phi . \tag{21}$$

For relatively low-speed flows (i.e., incompressible flows), the continuity equation is

$$\nabla \cdot \mathbf{V} = 0 . \tag{22}$$

Combining Eqs. (21) and (22), one finds that for an incompressible, irrotational flow,

$$\nabla^2 \phi = 0 . \tag{23}$$

Thus, the governing equation, which is known as *Laplace's equation,* is a linear, second-order partial differential equation.

Within certain constraints on geometric slope continuity, a bounded, simply connected velocity field is uniquely determined by the distribution on the flow boundaries either of the normal component of the total velocity, $\nabla\phi \cdot \hat{n}$, or of the total potential ϕ. These boundary-value problems are respectively designated Neumann or Dirichlet problems. For applications in this article, the Neumann formulation is most common since most practical cases involve prescribed normal velocity boundary conditions. Specifically, the flow tangency requirement associated with inviscid flow past a solid body is expressed mathematically as

$$\nabla\phi \cdot \hat{n} = 0 .$$

The computational solutions to the flow field around the vehicle may be obtained using surface-singularity methods or by field methods. For surface-singularity (or panel) methods, the configuration is modeled by a large number of panels. To each panel, there is attached one or more types of singularities, such as sources, vortices, and doublets. (Since Laplace's equation is linear, individual solutions can be added to each other provided the boundary conditions are satisfied.) The strengths of the singularities are determined by applying the appropriate boundary conditions. Once the singularity strengths have been determined, the velocity and pressure fields can be determined. For the field methods, solutions to the Euler equations or to Laplace's equation are generated for the flow around the configuration.

2.1.6 Isentropic, Compressible Flows. The use of the first law of thermodynamics to obtain the energy equation does not place any constraints on what types of processes are physically possible and what types are not. We know from experience that not all processes permitted by the first law actually occur in nature. It is the second law of thermodynamics which provides insight into which processes may occur. It is not possible for a process to occur if the entropy of the system and its surroundings decreases.

However, for an adiabatic, frictionless process, there is no change in entropy, i.e., the flow is isentropic. This is not an overly restrictive assumption, since heat transfer in aerodynamic problems usually occurs only in the boundary layer and has a negligible effect on the flow in the inviscid region. Thus, for an inviscid flow, one can derive the following from Gibbs equation:

$$p/\rho^{\gamma}=\text{const.} \tag{24}$$

The energy equation for a one-dimensional, adiabatic flow requires that the total enthalpy (H) is constant:

$$H=h+U^2/2, \tag{25}$$

where h (the static enthalpy) is equal to $e+p/\rho$. For a (calorically) perfect gas, the enthalpy is proportional to the temperature:

$$H=c_pT_t, \tag{26a}$$

$$h=c_pT, \tag{26b}$$

i.e., the specific heat at constant pressure is constant. The speed of sound is

$$a=\left[\left(\frac{\partial p}{\partial \rho}\right)_s\right]^{1/2}=\sqrt{\gamma RT}. \tag{27}$$

Combining Eqs. (24)–(27), we obtain

$$p_{t1}=p\left(1+\frac{\gamma-1}{2}M^2\right)^{\gamma/(\gamma-1)}. \tag{28}$$

In Eq. (28), p_{t1} is that stagnation pressure that is achieved when a flow whose Mach number is M and whose static pressure is p is brought to rest isentropically. We have used the subscript $t1$ (rather than merely t, as was done with Bernoulli's equation), since the total pressure changes when shock waves are present. As will be discussed later, shock waves are possible when the flow is supersonic. The ratio of specific heats (γ) is 1.4 for perfect air.

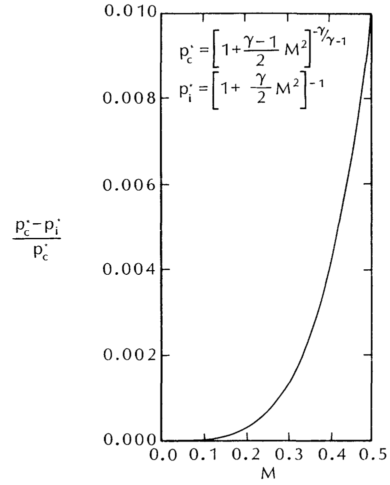

FIG. 7. The effect of compressibility on the theoretical value for the pressure ratio.

If we use Eq. (27) to express the parameters in Bernoulli's equation in terms of the Mach number, we obtain

$$p_i^*=\frac{p}{p_t}=\left(1+\frac{\gamma}{2}M^2\right)^{-1},$$

where the superscript $*$ represents the dimensionless pressure for incompressible flow. By rearranging Eq. (28), we obtain

$$p_c^*=\frac{p}{p_{t1}}=\left(1+\frac{\gamma-1}{2}M^2\right)^{-\gamma/(\gamma-1)}$$

as a dimensionless pressure ratio for compressible flow. Using these two parameters, we can estimate the effect of compressibility on the theoretical pressure ratio from the correlation presented in Fig. 7. This parameter increases rapidly with Mach number, reaching a value of 0.01 when the Mach number is 0.5. Thus, beginning with Mach numbers of approximately 0.5, one should take into account the effects of compressibility when solving for the flow field.

2.2 Viscous Flow

The general differential equations for the conservation of linear momentum, i.e., the Navier–Stokes equations, Eqs. (5a)–(5c), de-

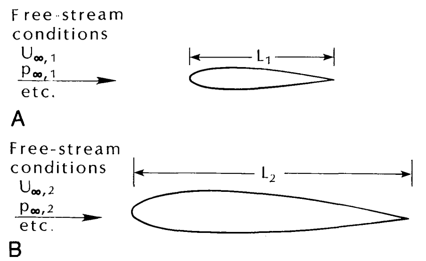

FIG. 8. Nomenclature for a flow around a prototype configuration and that around a scale model: (a) model flow; (b) prototype flow.

fine the motion in the viscous boundary layer adjacent to the surface. The Navier–Stokes equations for a general viscous flow are nonlinear partial differential equations. Even today, there are no general solutions for the complete Navier–Stokes equations. However, by evaluating the relative magnitude of the terms and eliminating the less significant terms for a particular application, one can introduce simplifying assumptions that allow us to obtain solutions of the viscous flow more easily. Advances in computer software and hardware allow us to generate flow-field solutions using reasonably rigorous models of the flow. Nevertheless, a turbulent boundary layer flowing over a complex airplane still provides a formidable challenge to the analyst.

Let us now consider the question of fluid dynamic similarity. Consider an incompressible flow around two objects that are geometrically similar (but of different size), as shown in Fig. 8. It is as if you took a photograph of the prototype and reduced it until it exactly matched the model configuration. For a constant-property flow with negligible body forces, the x component of the momentum equation [Eq. (5a)] becomes

$$\rho\frac{\partial u}{\partial t}+\rho u\frac{\partial u}{\partial x}+\rho v\frac{\partial u}{\partial y}+\rho w\frac{\partial u}{\partial z}$$
$$=-\frac{\partial p}{\partial x}+\mu\frac{\partial^2 u}{\partial x^2}+\mu\frac{\partial^2 u}{\partial y^2}+\mu\frac{\partial^2 u}{\partial z^2}. \tag{29}$$

Let us divide each of the thermodynamic properties by the value of that property at a point far from the vehicle (i.e., the free-stream value of the property) for each of the two flows. Thus, for the first flow

$$p_1^*=\frac{p}{p_{\infty,1}},\quad \rho_1^*=\frac{\rho}{\rho_{\infty,1}},\quad \mu_1^*=\frac{\mu}{\mu_{\infty,1}};$$

and for the second flow

$$p_2^*=\frac{p}{p_{\infty,2}},\quad \rho_2^*=\frac{\rho}{\rho_{\infty,2}},\quad \mu_2^*=\frac{\mu}{\mu_{\infty,2}}.$$

Note that the free-stream values for all three nondimensionalized ($*$) thermodynamic properties are unity for both cases.

Similarly, let us divide the velocity components by the free-stream velocity. Thus, for the first flow

$$u_1^*=\frac{u}{U_{\infty,1}},\quad v_1^*=\frac{v}{U_{\infty,1}},\quad w_1^*=\frac{w}{U_{\infty,1}};$$

and for the second flow

$$u_2^*=\frac{u}{U_{\infty,2}},\quad v_2^*=\frac{v}{U_{\infty,2}},\quad w_2^*=\frac{w}{U_{\infty,2}}.$$

With the velocity components thus nondimensionalized, the free-stream boundary conditions are the same for both flows. That is, at points far from the vehicle,

$$u_1^*=u_2^*=1 \quad\text{and}\quad v_1^*=v_2^*=w_1^*=w_2^*=0.$$

A characteristic dimension L is used to nondimensionalize the independent variables:

$$x_1^*=\frac{x}{L_1},\quad y_1^*=\frac{y}{L_1},\quad z_1^*=\frac{z}{L_1},\quad t_1^*=\frac{tU_{\infty,1}}{L_1}$$

and

$$x_2^*=\frac{x}{L_2},\quad y_2^*=\frac{y}{L_2},\quad z_2^*=\frac{z}{L_2},\quad t_2^*=\frac{tU_{\infty,2}}{L_2}.$$

In terms of these dimensionless parameters, Eq. (29) becomes

$$\rho_1^*\frac{\partial u_1^*}{\partial t_1^*}+\rho_1^* u_1^*\frac{\partial u_1^*}{\partial x_1^*}+\rho_1^* v_1^*\frac{\partial u_1^*}{\partial y_1^*}+\rho_1^* w_1^*\frac{\partial u_1^*}{\partial z_1^*}$$
$$=-\left[\frac{p_{\infty,1}}{\rho_{\infty,1}U_{\infty,1}^2}\right]\frac{\partial p_1^*}{\partial x_1^*}$$
$$+\left[\frac{\mu_{\infty,1}}{\rho_{\infty,1}U_{\infty,1}L_1}\right]\left(\mu_1^*\frac{\partial^2 u_1^*}{\partial x_1^{*2}}+\mu_1^*\frac{\partial^2 u_1^*}{\partial y_1^{*2}}\right.$$
$$\left.+\mu_1^*\frac{\partial^2 u_1^*}{\partial z_1^{*2}}\right) \tag{30a}$$

for the first flow. For the second flow

$$\rho_2^* \frac{\partial u_2^*}{\partial t_2^*}+\rho_2^* u_2^* \frac{\partial u_2^*}{\partial x_2^*}+\rho_2^* v_2^* \frac{\partial u_2^*}{\partial y_2^*}+\rho_2^* w_2^* \frac{\partial u_2^*}{\partial z_2^*}$$

$$=-\left[\frac{p_{\infty,2}}{\rho_{\infty,2}U_{\infty,2}^2}\right]\frac{\partial p_2^*}{\partial x_2^*}+\left[\frac{\mu_{\infty,2}}{\rho_{\infty,2}U_{\infty,2}L_2}\right]$$

$$\times\left(\mu_2^* \frac{\partial^2 u_2^*}{\partial x_2^{*2}}+\mu_2^* \frac{\partial^2 u_2^*}{\partial y_2^{*2}}+\mu_2^* \frac{\partial^2 u_2^*}{\partial z_2^{*2}}\right). \quad (30b)$$

Both the dependent and independent variables have been nondimensionalized, as indicated by the quantities with asterisks. The dimensionless *boundary-condition values* for the dependent variables are the same for the two flows around geometrically similar configurations. As a consequence, the solutions of the two problems in terms of the dimensionless variables will be identical, provided that the differential equations are identical. The differential equations will be identical if the dimensionless parameters in the brackets have the same values for both problems. In this case, the flows are said to be dynamically similar, as well as geometrically similar.

Let us now consider the first similarity parameter in Eq. (30):

$$p_\infty/\rho_\infty U_\infty^2 \,. \quad (31)$$

This similarity parameter can be interpreted in relation to gas flows. Recall that for a perfect gas the equation of state is

$$p_\infty=\rho_\infty RT_\infty,$$

and the free-stream speed of sound is given by

$$a_\infty=(\gamma RT_\infty)^{1/2}.$$

Substitution of these relations into Eq. (31) yields

$$\frac{p_\infty}{\rho_\infty U_\infty^2}=\frac{RT_\infty}{U_\infty^2}=\frac{a_\infty^2}{\gamma U_\infty^2}=\frac{1}{\gamma M_\infty^2}\,, \quad (32a)$$

since the *Mach number* is defined as

$$M_\infty=U_\infty/a_\infty \,. \quad (32b)$$

The inverse of the second similarity parameter is written as

$$\rho_\infty U_\infty L/\mu_\infty \,, \quad (33)$$

which is the *Reynolds number*, a measure of the ratio of inertia forces to viscous forces. Named after Osborne Reynolds, a British engineer, the Reynolds number is important for all flows in which we account for the effects of viscosity. Since the coefficient of viscosity is never zero, the Reynolds number is one of the most important similarity parameters. However, as noted earlier, there are many regions of the flow field where the product of the viscosity times the shear velocity gradient is negligible. Since the viscous terms of Eqs. (5a)–(5c) (i.e., the Navier–Stokes equations) are negligible for these inviscid flows, the Reynolds number would not be important for inviscid flows.

The Reynolds number may vary over several orders of magnitude during the entry flight of a hypersonic vehicle. During the high-altitude portion of the flight, i.e., the initial stages of reentry, the density and, therefore, the Reynolds number are very low. As the spacecraft descends towards the earth's surface, the density and the Reynolds number increase dramatically. Typical Reynolds numbers for some representative vehicles are presented in Fig. 9. The Reynolds number is an important parameter when trying to determine if the boundary layer is laminar or turbulent. Although there are many phenomena that influence the process by which the boundary layer transitions from a laminar state to a turbulent state, the lower the Reynolds number, the more likely the flow is to be laminar.

2.2.1 Boundary-Layer Characteristics.

When the boundary layer is laminar, the transverse exchange of momentum (i.e., the momentum transfer in a direction perpendicular to the principal flow direction) takes place on a microscopic scale. As a result of the molecular movement, slower-moving fluid particles from the lower layer (or lamina) of fluid move upward, slowing the particles in the upper layer. Conversely, when the faster-moving fluid particles from the upper layer migrate downward, they tend to accelerate the fluid particles in that layer. This molecular interchange of momentum for a laminar flow is depicted in Fig. 10(a).

For a turbulent boundary layer, there is a macroscopic transport of fluid particles, as shown in Fig. 10(b). Thus, in addition to the laminar shear stress described in the preceding paragraph, there is an effective *turbulent shear stress* that is due to the transverse trans-

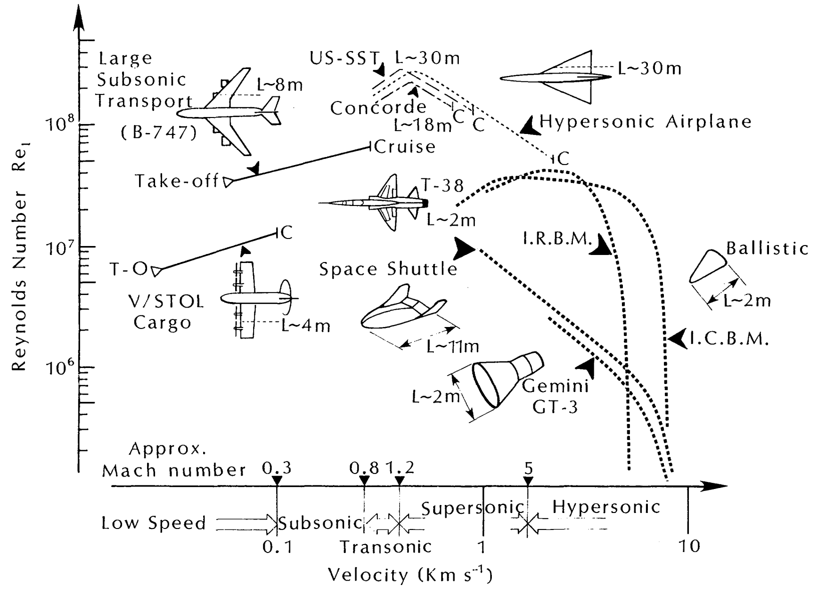

FIG. 9. Typical Reynolds numbers for some representative vehicles.

port of momentum which is very large. Because slower moving fluid particles near the wall are transported well upward, the turbulent boundary layer is relatively thick. Because faster-moving fluid particles (which are normally located near the edge of the boundary layer) are transported toward the wall, they produce relatively high velocities for the fluid particles near the surface. Thus, the shear stress at the wall for a turbulent boundary layer is larger than that for a laminar boundary layer, and yet the turbulent boundary layer is thicker. Because the macroscopic transport of fluid introduces large localized variations in the flow at any instant, the values of the fluid properties and the velocity components are (in general) the sum of the "average" value and a fluctuating component.

2.2.2 Boundary-Layer Transition. Near the forward stagnation point on a wing or near the leading edge of a flat plate, the boundary layer is laminar. As the flow proceeds downstream, the boundary layer thickens and the viscous forces continue to dissipate the energy of the airstream. Disturbances to the flow in the growing viscous layer may be caused by surface roughness, a temperature variation in the surface, pressure pulses, and so on. If the Reynolds number is low, the disturbances will be damped by viscosity and the boundary layer will remain

FIG. 10. Momentum-transport models: (a) laminar boundary layer; (b) turbulent boundary layer.

laminar. At higher Reynolds numbers, the disturbances grow. In such cases, the boundary layer may become unstable and, eventually, turbulent (i.e., transition will occur). The details of the transition process are quite complex and depend on many parameters.

The engineer who must develop a transition criterion for design purposes usually uses the Reynolds number. For instance, if the surface of a flat plate is smooth and if the external airstream has no turbulence, transition "occurs" at a Reynolds number (Re_x) of approximately 500 000. However, experience has shown that the Reynolds number at which the disturbances will grow and the length over which the transition process takes place depend on the magnitude of the disturbances and on the flow field. Let us consider briefly the effect of surface roughness, of the surface temperature, of a pressure gradient in the inviscid flow, and of the local Mach number on transition.

1. *Surface roughness.* Since transition is the amplification of disturbances to the flow, the presence of surface roughness significantly promotes transition (i.e., causes transition to occur at relatively low Reynolds numbers).
2. *Surface temperature.* The boundary-layer thickness decreases as the surface temperature is decreased. Cooling the surface usually delays transition.
3. *Pressure gradient.* A favorable pressure gradient (i.e., the static pressure decreases in the streamwise direction or, equivalently, the inviscid flow is accelerating) delays transition. Conversely, an adverse pressure gradient promotes transition.
4. *Mach number.* The transition Reynolds number is usually higher when the flow is compressible (i.e., as the Mach number is increased).

Stability theory, e.g., Mack (1984), can be an important tool that provides insights into the importance of individual parameters without introducing spurious effects that might be due to flow disturbances peculiar to a test facility (e.g., "noise" in a wind tunnel). For a more detailed discussion of transition, the reader is referred to a textbook on boundary-layer theory, e.g., Schlichting (1979).

If the skin friction is the dominant component of the drag, transition should be delayed as long as possible to obtain a low-drag section. To delay transition on a low-speed airfoil section, the point of maximum thickness should be moved aft so that the boundary layer is subjected to a favorable pressure gradient over a longer run. Consider the NACA 0009 section and the NACA 66-009 section (from the National Advisory Committee for Aeronautics), as shown in Fig. 11. Both are symmetric, having a maximum thickness of 0.09*c*. The parameter *c* is the *chord length* (as measured along a line from the leading edge to the trailing edge) of the airfoil. The maximum thickness for the NACA 66-009 section is at 0.45*c*, while that for the NACA 0009 section is at 0.3*c*. As a result, the minimum pressure coefficient occurs at $x=0.6c$ for the NACA 66-009 and a favorable pressure gradient acts to stabilize the boundary layer to this point. For the NACA 0009, the minimum pressure occurs near $x=0.1c$. The lower local velocities near the leading edge and the extended region of favorable pressure gradient cause transition to be farther aft on the NACA 66-009. Since the drag for a streamlined airfoil at low angles of attack is primarily due to skin friction, one would expect that the drag is lower for the laminar flow for the NACA 66-009. This is verified by the data from Abbott and von Doenhoff (1949), which are reproduced in Fig. 12. The subsequent reduction in

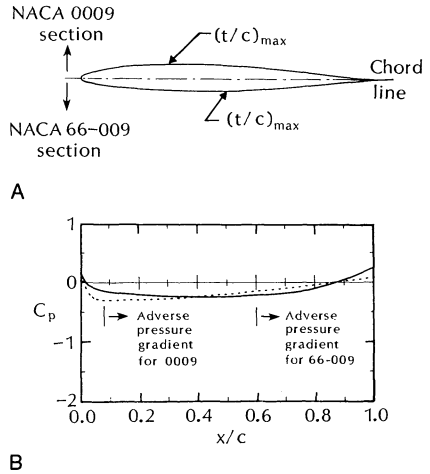

FIG. 11. Comparison of geometries and resultant pressure distributions for a "standard" airfoil section (NACA 0009) and for a laminar airfoil section (NACA 66-009): (a) comparison of cross section for an NACA 0009 airfoil with that for an NACA 66-009 airfoil; (b) static pressure distribution.

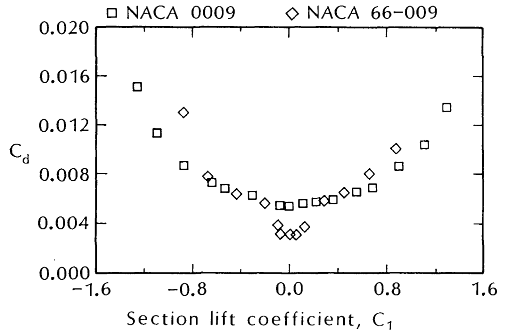

FIG. 12. Section drag coefficients for NACA 0009 airfoil and the NACA 66-009 airfoil, $Re_c = 6 \times 10^6$ [data from Abbott and von Doenhoff (1949)].

the friction drag for the NACA 66-009 section creates a *drag bucket*, i.e., that region of relatively low drag that occurs when the section lift coefficient is small. Note that the section drag coefficient varies only slightly with C_l for small excursions in angle of attack near zero lift, since the skin-friction coefficient varies little with angle of attack. At the very high Reynolds numbers that occur at some flight conditions, it is difficult to maintain a long run of laminar boundary layer, especially if surface roughnesses develop during the flight operations. However, a *laminar-flow section*, such as the NACA 66-009, offers additional benefits. Comparing the cross sections presented in Fig. 11, the cross section of the NACA 66-009 airfoil provides more flexibility for carrying fuel and for accommodating the load-carrying structure.

For larger angles of attack, the section drag coefficient depends both on Reynolds number and on angle of attack. As the angle of attack and the section lift coefficient increase, the minimum pressure coefficient decreases. The adverse pressure gradient that results as the flow decelerates toward the trailing edge increases. When the air particles in the boundary layer, already slowed by viscous action, encounter the relatively strong adverse pressure gradient, the boundary layer thickens and separates. The term *stall* is used to describe the flow situation when the boundary layer separates from the airfoil surface. Because the thickening boundary layer and its separation from the surface cause the pressure distribution to be significantly different from the inviscid model at the higher angles of attack, form drag dominates. Note that, at the higher angles of attack (where form drag is important), the drag coefficient for the NACA 66-009 is greater than that for the NACA 0009.

Thus, the aerodynamic forces and moments are a function of vehicle geometry and angle of attack as well as Mach number and Reynolds number. By carefully tailoring the configuration, one can obtain significant improvements in the aerodynamic coefficients for flight conditions of most importance.

2.2.3 The Effect of the Boundary Layer on Flow Separation. A turbulent flow is one in which irregular fluctuations (mixing or eddying motions) are superimposed on the mean flow. Thus, the velocity at any point in a turbulent boundary layer is a function of time, even for a flow where the free-stream conditions and wall-boundary conditions are steady. The fluctuations occur in the direction of the mean flow and at right angles to it, and they affect macroscopic lumps of fluid. Thus, whereas momentum transport occurs on a microscopic (or molecular) scale in a laminar boundary layer, it occurs on a macroscopic scale in a turbulent boundary layer. It should be noted that, although the velocity fluctuations may be only several percent of the local streamwise values, they have a decisive effect on the overall motion. The size of these macroscopic lumps determines the scale of turbulence.

The effects caused by the fluctuations are as if the viscosity were increased by a factor of 10 or more. As a result, the shear forces at the wall and the skin-friction component of the drag are much larger when the boundary layer is turbulent. However, because of the macroscopic momentum transfer, air particles near the wall have a relatively high velocity (see Fig. 10). Thus, a turbulent boundary layer can negotiate an adverse pressure gradient for a longer distance. As a result, boundary-layer separation may be delayed or even avoided altogether if the boundary layer is turbulent. Delaying (or avoiding) the onset of separation reduces the pressure component of the drag (i.e., the form drag). For a blunt body or for a slender body at angle of attack, the reduction in form drag usually dominates the increase in skin-friction drag.

Figure 13 illustrates how a turbulent boundary layer can flow without separation into regions of much steeper adverse pressure

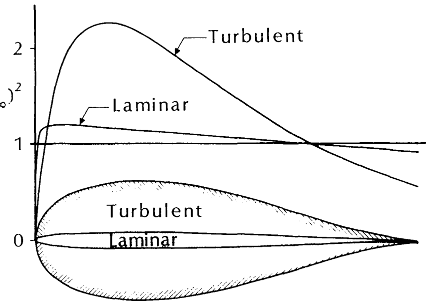

FIG. 13. Thickest symmetrical Joukowski airfoils capable of supporting fully attached laminar and turbulent flows. The angle of attack is 0°, and the Mach number is low. For turbulent flow, transition is assumed to occur at the velocity peak. The turbulent case is calculated for $Re_c = 10^7$. Results for laminar flow are independent of Reynolds number. Maximum thickness for laminar flow is about 0.046*c*, for turbulent flow, 0.31*c*. If displacement-thickness effects on pressure distribution were included, the turbulent airfoil would increase to about 0.33*c*. The change in the laminar case would be negligible. [From Cebeci and Smith (1974).]

gradients than can a laminar boundary layer. Incompressible boundary-layer solutions were generated for symmetrical Joukowski airfoils at zero angle of attack. The edge velocity and, therefore, the corresponding inviscid pressure distributions, are presented in Fig. 13. At the conditions indicated, boundary-layer separation will occur for any Joukowski airfoil that is thicker than 0.046*c*, if the flow is entirely laminar. However, if the boundary layer is turbulent, separation will not occur until a thickness of about 0.31*c* has been exceeded. The boundary layer effectively thickens the airfoil, especially near the trailing edge, since the boundary-layer thickness increases with distance. This thickening alleviates the adverse pressure gradients, which in turn permits somewhat thicker sections before separation occurs. To ensure that boundary-layer transition occurs and, thus, to delay or avoid separation altogether, one might use vortex generators or other forms of surface roughness, such as shown in Fig. 14.

2.3 Shock Waves

The formation of a *shock wave* occurs when a supersonic flow decelerates in response to a sharp increase in pressure or when a supersonic flow encounters a sudden, compressive change in direction. The shock wave is on the order of several mean free paths thick, and for flow conditions where the gas behaves as a continuum this distance is very small ($\sim 6 \times 10^{-6}$ cm at atmospheric pressure and temperature). Thus, there is an almost instantaneous change in the values of the flow parameters across a shock in a continuum flow. Because of the large streamwise variations in velocity, pressure, and temperature, viscous and heat-conduction effects are important within the shock wave. The difference between a shock wave and a Mach wave should be kept in mind. A *Mach wave* represents a surface across which some derivatives of the flow variables (such as the thermodynamic properties of the fluid and the flow velocity) may be discontinuous while the variables themselves are continuous. A *shock wave* represents a surface across which the thermodynamic properties and the flow velocity are essentially discontinuous. Thus, the characteristic curves, or Mach lines, are patching lines for continuous flows, whereas shock waves are patching lines for discontinuous flows.

Consider the curved shock wave illustrated in Fig. 15. The flow upstream of the shock wave, which is stationary in the body-fixed-coordinate system, is supersonic and designated by the subscript 1. The downstream values are designated by subscript 2. At the plane of symmetry, the shock wave is normal (or perpendicular) to the free-stream flow, and the flow downstream of the shock wave is subsonic. Away from the plane of symmetry, the shock wave is oblique and the downstream flow may be subsonic or supersonic, depending on the free-stream Mach number and the turning angle (δ). In order to have a

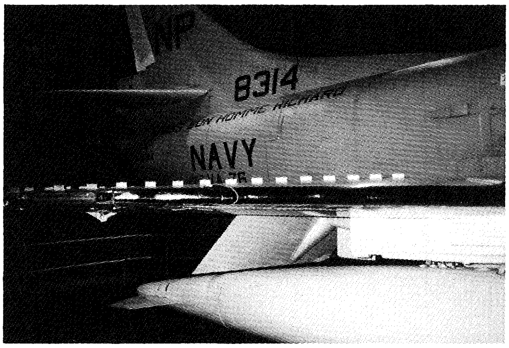

FIG. 14. Row of vortex generators on the wing of the A4 (author's collection).

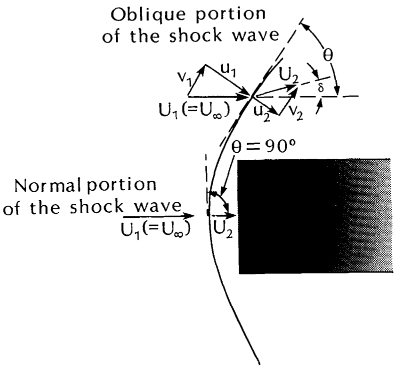

FIG. 15. Curved shock wave illustrating nomenclature for normal shock wave and for oblique shock wave.

shock wave, the upstream Mach number must be greater than 1, i.e., shock waves will not occur in subsonic flow. Referring to Fig. 16, the flow just downstream of a normal shock wave is subsonic, i.e., M_2 is less than 1. As noted earlier, shock waves occur in supersonic flow to accomplish compressive turns of the flow or to decelerate the flow (increase the pressure) to match boundary conditions. The entropy increases across the shock wave and the total (or stagnation) pressure decreases, i.e., p_{t2} is less than p_{t1}. The property variations across a normal shock wave are presented in Fig. 16.

Note that the density increases as the air particles cross the shock wave. The density gradients produced by a shock wave and the boundary layer in a compressible flow will bend a parallel beam of light passing through the flow field. The deflection of light by the changes in density will produce variations in the intensity of light impinging on a photographic plate. Thus, we can photographically record regions of the flow field with large density gradients. Shock waves are clearly evident in the schlieren photograph of a biconic configuration in a Mach 4.25 stream in the Trisonic Wind Tunnel at the U.S. Air Force Academy, presented in Fig. 17. Under certain circumstances, these density gradients allow us to "see" the shock waves for an airplane or for a missile in flight, as for the supersonic flight of a rocket-powered vehicle presented in Fig. 18.

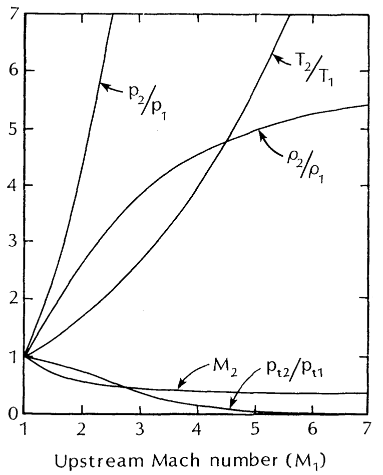

FIG. 16. Property variations across a normal shock wave.

3. CHARACTERIZATION OF AERODYNAMIC FORCES

The motion of the air around the vehicle produces pressure and velocity variations which produce the aerodynamic forces and moments. Although viscosity is a fluid property and, therefore, acts throughout the flow field, the viscous forces depend on the velocity gradients as well as on the viscosity. For many aerodynamics problems, the viscous forces are significant only within a narrow region near the wall where the velocity gradients are large (the boundary layer), or within the viscous wake should boundary-layer separation occur. When the viscous effects are confined to the boundary layer, it is possible

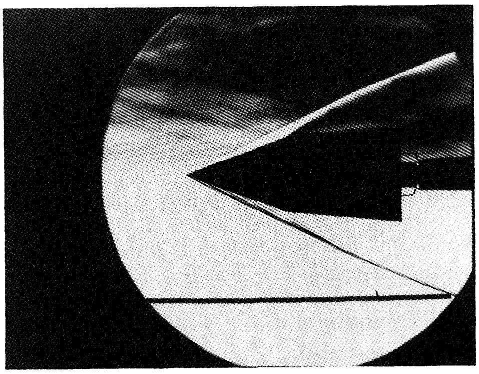

FIG. 17. Schlieren photograph of flow past a sharp biconic in a Mach 4.25 stream (photo courtesy of the U.S. Air Force Academy).

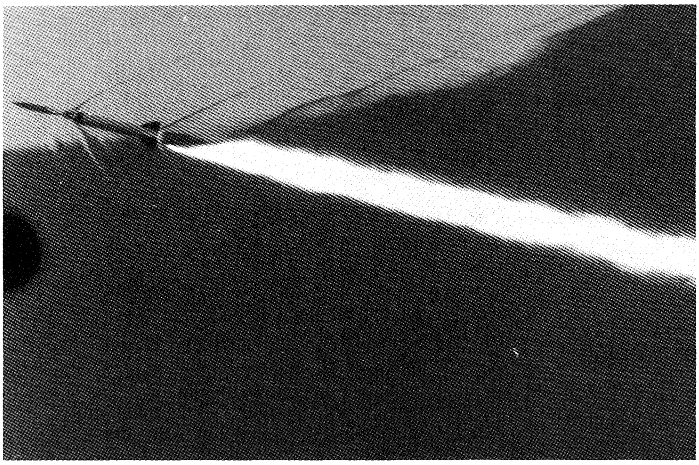

FIG. 18. Rocket-powered vehicle flying at Mach 3 with shock waves clearly visible (courtesy of R. C. Maydew of the Sandia National Laboratories).

to use the equations of motion for an inviscid flow to determine the pressure distribution around the vehicle and, hence, the velocity of the air particles at the edge of the boundary layer. With the inviscid flow field known, the velocity distribution across the viscous boundary layer, and hence the tangential shear forces at the wall, can be calculated. The normal and tangential forces, which act on the surface due to the fluid motion around an airfoil, are shown in Fig. 3.

3.1 Aerodyamic Forces and Moments

It is conventional to resolve the sum of the normal, or pressure, forces and the tangential, or viscous shear, forces into three components along axes parallel and perpendicular to the free-stream direction. The three components are designated as lift, drag, and side force. The relation of the lift and the drag forces with respect to the free-stream velocity is shown in Fig. 3.

1. *Lift.* Lift is the force component acting upward, perpendicular to the undisturbed free-stream velocity. The aerodynamic lift is produced primarily by the pressure forces acting on the vehicle surface.
2. *Drag.* Drag is the net aerodynamic force acting in the same direction as the undisturbed free-stream velocity. The aerodynamic drag is produced by the pressure forces and by skin friction forces that act on the surface.
3. *Side force.* Side force is the component of force in a direction perpendicular to both the lift and the drag. The side force is positive when acting toward the starboard wing (i.e., the pilot's right).

The resulting aerodynamic force usually will not act through the origin of the airplane's axis system (e.g., the center of gravity). The moment due to the resultant force acting at a distance from the origin may be divided into three components, referred to the airplane's reference axes. The three moment components are the pitching moment, the rolling moment, and the yawing moment, as shown in Fig. 19.

1. *Pitching moment.* The moment about the lateral axis (the y axis of the airplane-fixed-coordinate system) is the pitching moment. The pitching moment is the result of the lift and the drag forces acting on the vehicle. A positive pitching moment is in the nose-up direction.
2. *Rolling moment.* The moment about the longitudinal axis of the airplane (the x axis) is the rolling moment. A rolling mo-

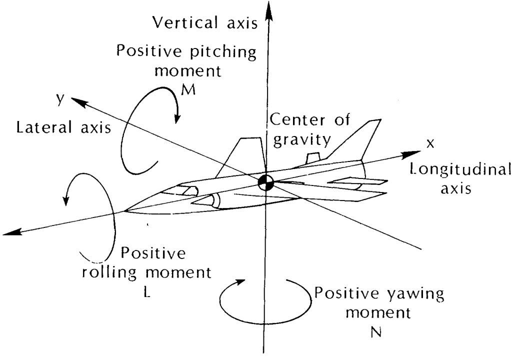

FIG. 19. Reference axes of the airplane and the corresponding aerodynamic moments.

ment is often created by a differential lift, generated by some type of ailerons or spoilers. A positive rolling moment causes the right, or starboard, wingtip to move downward.

3. *Yawing moment.* The moment about the vertical axis of the airplane (the z axis) is the yawing moment. A positive yawing moment tends to rotate the nose to the pilot's right.

3.2 Parameters that Govern Aerodynamic Forces

The magnitude of the forces and the moments that act on a vehicle depend on the combined effects of many different variables. Personal observations of the aerodynamic forces acting on an arm extended from a car window or on a ball in flight demonstrate the effect of velocity and of configuration. Pilot manuals advise that a longer length of runway is required if the ambient temperature is relatively high or if the airport elevation is high (i.e., the ambient density is relatively low). The parameters that govern the magnitude of aerodynamic forces and moments include the following:

1. configuration geometry,
2. angle of attack,
3. vehicle size or model scale,
4. free-stream velocity,
5. density of the undisturbed air,
6. Reynolds number (as it relates to viscous effects), and
7. Mach number (as it relates to compressibility effects).

The calculation of the aerodynamic forces and moments acting on a vehicle often requires that the engineer be able to relate data obtained at other flow conditions to the conditions of interest. Thus, the engineer often uses data from the wind tunnel, where scale models are exposed to flow conditions that simulate the design environment, or data from flight tests at other flow conditions. So that one can correlate the data for various stream conditions and configuration scales, the measurements are usually presented in dimensionless form. Ideally, once in dimensionless form, the results would be independent of all but the first two parameters listed above, configuration geometry and angle of attack. In practice, flow phenomena, such as boundary-layer separation, shock-wave–boundary-layer interactions, and compressibility effects, limit the range of flow conditions over which the dimensionless force and moment coefficients remain constant.

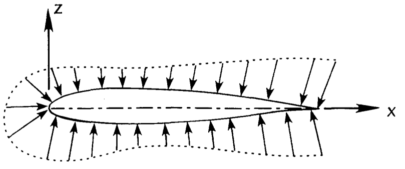

FIG. 20. Pressure distribution for a lifting airfoil section.

3.3 Lift Coefficient

To illustrate the physical significance of a dimensionless force coefficient, consider the normal force coefficient. The normal (or z) component of the resultant force is chosen since it is relatively simple to calculate and it has the same relation to the pressure and the shear forces as does the lift. For a relatively thin airfoil section at a relatively low angle of attack, it is clear from Fig. 3 that the lift (and similarly the normal force) results primarily from the action of the pressure forces. The shear forces act primarily in the chordwise direction (i.e., contribute primarily to the drag). Therefore, to calculate the force in the z direction, we need consider only the pressure contribution, which is illustrated in Fig. 20. The pressure force acting on a differential area of the vehicle surface is $dF = p\, ds\, dy$, as shown in Fig. 21. The elemental surface area is the product of ds, the wetted length of the element in the plane of the cross section, times dy, the element's length in the direction perpendicular to the plane of the cross section (or spanwise direction). Since the pressure force acts normal to the surface, the force component in the z direction is the product of the pressure times the projected planform area:

$$dF_z = p\, dx\, dy. \qquad (34)$$

Integrating over the entire wing surface (including the upper and the lower surfaces), the net force in the z direction is given by

$$F_z = \oint p\, dx\, dy. \qquad (35)$$

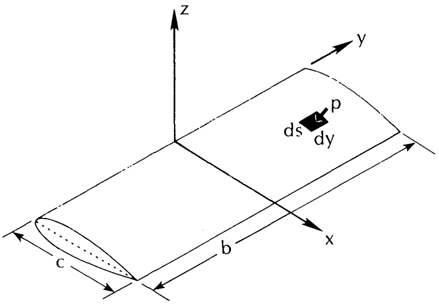

FIG. 21. Pressure acting on an elemental surface area.

Note that the resultant force in any direction due to a constant pressure acting over a closed surface is zero:

$$\oiint p_\infty \, dx \, dy = 0. \tag{36}$$

Combining Eqs. (35) and (36), the resultant force component is

$$F_z = \oiint (p - p_\infty) dx \, dy. \tag{37}$$

To nondimensionalize the factors on the right-hand side of Eq. (37), divide the pressure by q_∞ (the free-stream dynamic pressure), x by c (the chord length), and y by b (the span). Thus, we obtain the dimensionless parameter,

$$\frac{F_z}{q_\infty cb} = \oiint \frac{p - p_\infty}{q_\infty} \, d\left(\frac{x}{c}\right) d\left(\frac{y}{b}\right) .$$

Since the product cb represents the planform area S (i.e., the projection on a horizontal plane) of the rectangular wing of Fig. 21,

$$\frac{F_z}{q_\infty S} = \oiint C_p d\left(\frac{x}{c}\right) d\left(\frac{y}{b}\right) . \tag{38}$$

When the boundary layer is thin, the pressure distribution around the airfoil is essentially that of an inviscid flow. Thus, the pressure distribution is independent of Reynolds number and does not depend on whether the boundary layer is laminar or turbulent. When the boundary layer is thin, the pressure coefficient at a particular location on the surface given by the dimensionless coordinates $(x/c, y/b)$ is independent of vehicle scale and of the flow conditions. Over the range of flow conditions for which the pressure coefficient is a unique function of the dimensionless coordinates $(x/c, y/b)$, the value of the integral in Eq. (38) depends only on the configuration geometry and on the angle of attack. Thus, the resulting dimensionless force parameter, or force coefficient (in this case, the normal force coefficient), is independent of model scale and of flow conditions.

A similar analysis can be used to calculate the lift coefficient, which is defined as

$$C_L = L/q_\infty S. \tag{39}$$

3.4 Moment Coefficients

The moment created by the aerodynamic forces acting on a wing (or airfoil) is determined about a particular reference axis. The reference axis may be the leading edge, the quarter-chord location, the aerodynamic center, and so on. The aerodynamic center (or ac) is that point at which changes in lift effectively act. The procedure used to nondimensionalize the moments created by the aerodynamic forces is similar to that used to nondimensionalize the lift. To demonstrate this nondimensionalization, the pitching moment about the leading edge due to the pressures acting on the surface will be calculated (refer again to Fig. 21). The contribution of the chordwise component of the pressure force to the moment is small and is neglected. Thus, the pitching moment about the leading edge due to the pressure force acting on the surface element whose area is ds times dy, and which is located at a distance x from the leading edge, may be approximated by

$$dM_0 = p \, dx \, dy \, x, \tag{40}$$

where $dx \, dy$ is the projected area. Integrating over the entire wing surface, the net pitching moment is given by

$$M_0 = \oiint px \, dx \, dy. \tag{41}$$

When a uniform pressure acts on any closed surface, the resultant pitching moment due to this constant pressure is zero. Thus,

$$\oiint p_\infty x \, dx \, dy = 0. \tag{42}$$

By combining Eqs. (41) and (42), the resulting pitching moment about the leading edge is

$$M_0 = \oiint (p - p_\infty) \, x \, dx \, dy. \tag{43}$$

To nondimensionalize the factors on the right-hand side of Eq. (43), divide by $q_\infty c^2 b$, which has the units of force times length:

$$\frac{M_0}{q_\infty c^2 b}=\oiint \frac{p-p_\infty}{q_\infty}\frac{x}{c}\,d\left(\frac{x}{c}\right)d\left(\frac{y}{b}\right).$$

Since the product of *cb* represents the planform area of the wing, which is represented by the symbol *S*,

$$\frac{M_0}{q_\infty Sc}=\oiint C_p\frac{x}{c}\,d\left(\frac{x}{c}\right)d\left(\frac{y}{b}\right). \tag{44}$$

Thus, the dimensionless moment coefficient is

$$C_{M_0}=M_0/q_\infty Sc\,. \tag{45}$$

Since the derivation of Eq. (45) was for the rectangular wing of Fig. 21, the chord *c* is used. For a general wing, the mean aerodynamic chord is used together with *S* to nondimensionalize the pitching moment.

The section moment coefficient is used to represent the dimensionless moment per unit span (m_0) for an airfoil (i.e., for a two-dimensional flow):

$$C_{m_0}=m_0/q_\infty cc, \tag{46}$$

since the surface area per unit span is the chord length *c*.

The characteristic length (or moment arm) for the rolling moment and for the yawing moment is the wing span *b* (instead of the chord). Therefore, the rolling moment coefficient is

$$C_{\mathscr{L}}=\mathscr{L}/q_\infty Sb\,, \tag{47}$$

and the yawing moment coefficient is

$$C_N=N/q_\infty Sb. \tag{48}$$

3.5 Drag Coefficient

The drag force on a wing is due in part to skin friction and in part to the integrated effect of pressure. If $\mathbf{t}$ denotes the tangential shear stress at a point on the body surface, *p* the static pressure, and $\hat{n}$ the external normal to the element of surface *dS*, the drag can be formally expressed as

$$D=\oiint \mathbf{t}\cdot\hat{e}_\infty dS-\oiint p\hat{n}\cdot\hat{e}_\infty dS, \tag{49}$$

where $\hat{e}_\infty$ is a unit vector parallel to the free stream and the integration takes place over the entire wetted surface. The first integral represents the friction component and the second integral represents the pressure drag.

If an incompressible flow over a two-dimensional airfoil were truly inviscid, the pressure distribution would be such that the pressure coefficient would be 1, both at the leading edge and at the trailing edge, i.e., there would be a stagnation point at the trailing edge as well as at the leading edge. Furthermore, the pressure forces acting on the projected areas normal to the flow are balanced, so that the pressure drag would be zero. Of course, the drag due to skin friction is zero for a truly inviscid flow. Thus, for an incompressible, inviscid flow over a two-dimensional airfoil, the total drag is zero. Since this result is contrary to all experience, it is known as *d'Alembert's paradox.*

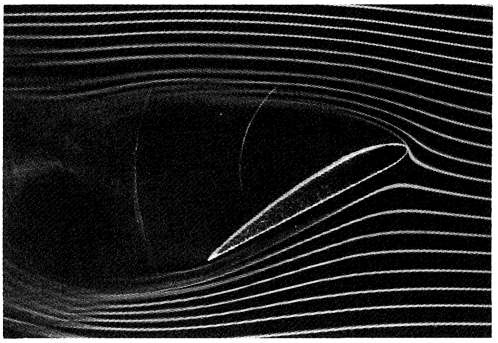
B
Pressure distribution (in terms of pressure coefficients)

FIG. 22. Incompressible flow past a two-dimensional airfoil at a small angle of attack.

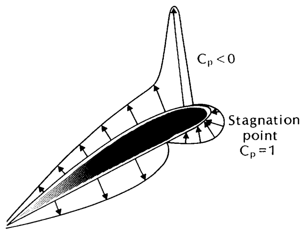
In reality, the viscous forces in a boundary layer not only produce the drag force due to friction, but modify the pressure distribution, producing a pressure, or form, drag. Thus, for incompressible, viscous flow past a two-dimensional airfoil, both terms of Eq. (49) are due to the viscous effects. Equation (49) may be written in a slightly different fashion:

$$D=D_f+D_p. \tag{50}$$

At low angles of attack, the pressure distribution is similar to that shown in Figs. 11 and 22. The adverse pressure gradient that exists over much of the airfoil (see Fig. 11) thickens the boundary layer, altering the pressure distribution slightly from that for an inviscid flow. However, separation does not occur and D_p is relatively small. As a result, since the skin-friction component (D_f) is significant,



A Smoke filaments



B Pressure distribution (in terms of pressure coefficients)

FIG. 23. Incompressible flow past a two-dimensional airfoil at a large angle of attack.

the drag is less when the boundary layer is laminar. This is illustrated in the data presented in Fig. 12. Note that the section drag coefficients for C_l near zero (i.e., at low angles of attack) are less for the NACA 66-009 laminar airfoil sections.

As the angle of attack increases, the flow accelerates rapidly over the top of the airfoil, creating relatively low pressures in this region (and generating lift). However, in a subsonic application, the flow decelerates toward the trailing edge. At these relatively large angles of attack, the air molecules already slowed by viscosity in the boundary layer cannot overcome the relatively large adverse pressure gradients, so they separate, i.e., break away from the surface, as shown in Fig. 23(a). Recall that this is known as stall. The pressure in the separated region is essentially constant at the (low) value corresponding to the point where separation occurred. Now there is a large difference between the pressure acting near the leading edge and that acting near the trailing edge. As a result, there is a large drag component due to pressure (D_p). This is indicated by the rapid increase in the drag coefficient with C_l (or, equivalently, the angle of attack) evident in the data of Fig. 12. Because a large adverse pressure gradient causes separation more quickly for a laminar boundary layer than for a turbulent one, the drag coefficient is greater for the laminar-flow airfoil section (NACA 66-009).

The drag coefficients presented thus far are for two-dimensional airfoils (i.e., configurations of infinite span). For a wing of finite span that is generating lift, the pressure differential between the lower surface and the upper surface causes a spanwise flow. The resultant three-dimensional flow field produces a drag component C_{D_v} which, as will be discussed later, is proportional to

$$C_L^2/\pi(\text{AR}). \qquad (51)$$

This is termed the *vortex drag*, the *induced drag*, or the *drag due to lift*. Let us introduce another term, designated ΔC_{D_M}, which will include compressibility effects and may, possibly, include the changes in the airflow accompanying thrust variations [according to Thomas (1985)]. Thus, the total drag for an airplane may be written as the sum of (1) the profile drag, which is independent of the lift coefficient, and therefore exists when the configuration generates zero lift (C_{D_0} or ΔC_{D_p}), (2) the drag associated with lift (kC_L^2), and (3) the compressibility-related effects that are correlated in terms of the Mach number and are known as *wave drag*:

$$C_D = C_{D_0} + kC_L^2 + \Delta C_{D_M}. \qquad (52)$$

Although the relative importance of the different drag sources depends on the aircraft type and the mission to be flown, approximate breakdowns (by category) for large, subsonic transports are presented in Fig. 24.

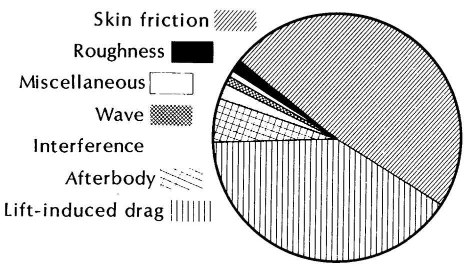


FIG. 24. Contributions of different drag sources for a typical transport aircraft. [From Thomas (1985).]

According to Thomas (1985), the greatest contribution arises from turbulent skin-friction drag. The next most significant contribution arises from lift-induced drag, which, when added to skin-friction drag, accounts for about 85% of the total drag of a typical transport aircraft. Thomas cited the pressure drag due to open separation in the afterbody and other regions, interference effects between aerodynamic components, wave drag due to the compressibility effect at near-sonic flight conditions, and miscellaneous effects, such as roughness effects and leakage, as constituting the remaining 15%.

3.5.1 Zero-Lift Drag. Skin friction and form-drag components can be calculated for the wing, tail, fuselage, nacelles, etc. When evaluating the zero-lift drag, one must consider interactions such as how the growth of the boundary layer on the fuselage reduces the boundary-layer velocities on the wing-root surface. Because of the interaction, the wing-root boundary layer is more easily separated in the presence of an adverse pressure gradient. Since the upper wing surface has the more critical pressure gradients, a low wing position on a circular fuselage would be sensitive to this interaction. Adequate filleting and control of the local pressure gradients can minimize the interaction effects.

A representative value of C_{D_0} would be 0.020, of which the wings may account for 50%, the fuselage and the nacelles 40%, and the tail 10%. Since the wing constitutes such a large fraction of the drag, reducing the wing area would reduce D_0 if all other factors are unchanged. Although other factors must be considered, the reasoning above implies that an optimum airplane configuration would have a minimum wing surface area and, therefore, highest practical wing loading (N/m^2).

3.5.2 Drag Due to Lift. The drag due to lift may be represented as

$$kC_L^2 = C_L^2/\pi(\text{AR})e, \tag{53}$$

where e is the airplane *efficiency factor* and AR the *aspect ratio*. Typical values of the airplane efficiency factor range from 0.6 to 0.9. At high lift coefficients (near $C_{L,\max}$), e should be changed to account for increased form drag. The deviation of the actual airplane drag from the quadratic correlation where e is a constant is significant for airplanes with low aspect ratios and sweepback.

3.5.3 Compressibility. Another factor to consider is the effect of compressibility. When the flight Mach number is equal to or greater than 0.5 (approximately), the drag increases very rapidly with speed. The correlation of Eq. (52) includes wave drag (i.e., the compressibility effects) as the third term. Low aspect ratios and sweepback are factors that delay and reduce the compressibility drag rise.

3.6 Lift/Drag Ratio

The configuration and the application of an airplane is closely related to the lift/drag ratio. Many important items of airplane performance are obtained in flight at $(L/D)_{\max}$. Performance conditions that occur at $(L/D)_{\max}$ include the following: (1) maximum range of propeller-driven airplanes, (2) maximum climb angle for jet-powered airplanes, and (3) maximum power-off glide ratio (for jet-powered or propeller-driven airplanes).

Representative values of the maximum lift/drag ratios for subsonic flight speeds are given below:

Type of airplane	$(L/D)_{\max}$
High-performance sailplane	25–40

4. AERODYNAMIC MODELS BY SPEED RANGE

The discussion of aerodynamics is divided into speed ranges: subsonic aerodynamics, transonic aerodynamics, supersonic aerodynamics, and hypersonic aerodynamics. Assumptions unique to these speed ranges will be discussed.

4.1 Subsonic Aerodynamics

At relatively low angles of attack, i.e., −10° to +10°, the section lift coefficient is independent of the Reynolds number and is a linear function of the angle of attack. This occurs because the boundary layer is thin and attached over the entire length of the profile. This is illustrated in the data for a NACA 2412 airfoil section, which are presented in Fig. 25.

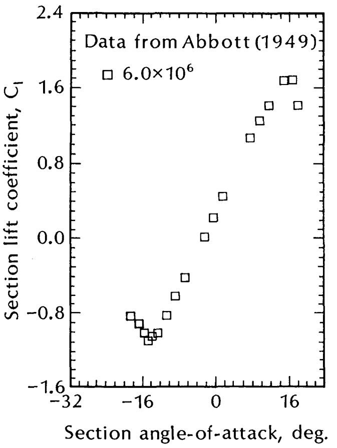

FIG. 25. Aerodynamic coefficients for a NACA 2412 airfoil section.

Note that, because this section is cambered, i.e., not symmetric about the chord line (or x axis), the angle of attack at which zero lift is generated is negative (specifically, −2°). As the angle of attack is increased, flow remains attached over the entire length of the profile [see Fig. 26(a)] and the lift is a linear function of the angle of attack.

In this linear range, the change in lift for a unit change in the angle of attack is known as the *lift-curve slope* and is an important design parameter. For inviscid flow past a two-dimensional airfoil, the lift-curve slope is 2π per radian. Viscous-induced changes to the pressure field (at low angles of attack, thickened boundary layers; at high angles of attack, boundary-layer separation) reduce the lift-curve slope. As will be discussed shortly, reducing the wing span, i.e., going from a two-dimensional (infinite-span) airfoil to a finite-span wing, further reduces the lift-curve slope.

As the angle of attack increases, the larger pressure gradients produce boundary-layer separation, starting at the trailing edge. (Note: Stall patterns are a function of the nose radius, section thickness, etc.) As a result, the lift is no longer a linear function of the angle of attack, as shown in Figs. 25 and 26(b). When the separation point reaches the midchord region, the maximum lift coefficient is achieved.

As the angle of attack is increased further, the separation point continues to move forward, as shown in Fig. 26(c). Lift actually decreases and the pressure drag increases rapidly with the angle of attack. One states that the airfoil is "stalled" when these conditions occur.

The lift is produced by pressure differences between the lower surface and the upper surface. For a wing of finite span, the high-pressure air beneath the wing spills out around the wing tips toward the low-pressure regions above the wing. As a consequence of the tendency of the pressures acting on the top surface near the tip of the wing to equalize with those on the bottom surface, the lift force per unit span decreases toward the tips. As another result of the spanwise pressure variation, the air on the upper surface flows inboard toward the root. Similarly, on the lower surface, air will tend to flow outward toward the tips. The resultant flow around a wing of finite span is three dimensional, having both chordwise and spanwise velocity components. Where the flows from the upper surface and the lower surface join at the trailing edge, the difference in spanwise velocity components will cause the air to roll up into a number of streamwise vortices, distributed along the span. These small vortices roll up into two large vortices just inboard of the wing tips. These features are illustrated in the sketches of Fig. 27. A photograph of smoke filaments illustrating the formation of the tip vortex as taken in the Aerodynamics Laboratory at the U.S. Air Force Academy is presented in Fig. 28.

air within the vortex system that is moving downward is called *downwash.* Eventually, the tip vortices weaken, their energy being dissipated by viscosity.

The problems of tip vortices are especially severe during the take-off and landings of the heavier jet airplanes. During these times, the speed of the airplane is low and the airplane is operating at high lift coefficients to maintain flight. The Federal Aviation Agency has shown that for a 0.27-MN (600 000 lb) plane, the tip vortices may extend back strongly for 8 km (5 miles) from the airplane and the downwash may approach 160 m min^{-1} (500 ft min^{-1}). Tests also show that a small light aircraft flying into such a vortex could be rolled over at rates exceeding 90° per second. These hazards are illustrated in the sketches of Fig. 29.

The vortex lines (or filaments) have an important role in the study of flow around wings. The lift produced by the pressure differences can be represented by a circulating (or vortex-like) flow. A computational technique for representing the lifting character of a wing may incorporate a lattice of vortices and is known as the vortex lattice method (VLM). The vortex theorems of Helmholtz provide a foundation for such techniques.

The tip vortices contribute to the downwash field at and downstream of the wing. To create downwash due to the finite-wing contribution requires the expenditure of energy per unit time (or power). The power required to induce this component of downwash is associated with an additional drag force, known as *induced drag.* This was discussed in Sec. 3.5.

The effect of finite wing span may also be viewed through changes in the flow field. The downwash has the effect of "tilting" the undisturbed air, so that the effective angle of attack is less than the geometric angle of attack for the airfoil section. As a result of the induced downwash velocity, the lift generated by a finite-span wing (C_L) having a particular airfoil section which is at the geometric angle of attack (α) is less than that for an infinite-span airfoil (C_l) having the same airfoil section and operating at the same angle of attack. This is illustrated in Fig. 30. Because the effective angle of attack is changed (in effect the flow is rotated), there is a component of the resultant force parallel to the actual free-stream flow which is, therefore, a drag force. This is the induced (or vortex) drag associated with the finite-span wing.

Recall that, according to Eq. (51), the induced drag varies inversely with the aspect ratio or, equivalently, as the $(\text{span})^{-2}$. Thus, consider two airplanes having rectangular wings as shown in the sketch of Fig. 31 [as taken from Talay (1975)]. Both wings are at the same lift coefficient and they have the same wing area. The only difference is that the wing span of the second wing is twice that of the first wing. Ideally, both wings should

produce the same lift. But the longer span wing (higher aspect ratio) has one-fourth the induced drag and, therefore, a greater efficiency. The thought arises that with less induced drag with longer wing spans, why not make a wing with an extremely long wing span (high aspect ratio). This would give nearly idealized flow, the tip vortex effects being very small. In fact, as the photographs of Fig. 32 illustrate, high-performance sailplanes that must rely on high efficiencies have large wing spans. As a result, sailplanes have aspect ratios in excess of 15, whereas single-engine light aircraft have wings with an aspect ratio of 7. Supersonic fighters typically have aspect ratios of 4, or less.

4.2 Transonic Aerodynamics

As the flight speed (or free-stream velocity) increases, a point is reached where the flow may no longer be considered incompressible. The pressure changes that occur as the air flows around the airfoil sections are sufficiently large that the density also varies. Even so, the flow is everywhere subsonic. Thus, the air accelerates from the (leading-edge) stagnation point, reaches a maximum velocity or, equivalently, the minimum pressure, then decelerates as it flows toward the trailing edge.

Eventually, the flight speed is sufficient for the Mach number to reach unity at some point. The free-stream Mach number for this condition is called the *critical Mach number.* Again, the air particles slow as they move toward the trailing edge, moving at subsonic speeds.

B High aspect ratio (High performance sailplane)

FIG. 32. Variations in aspect ratio.

However, once there are regions of locally supersonic flow, there exists the possibility that shock waves could occur. Three features which contribute to the location of a shock wave and, therefore, to the pressure distribution are the flow in the supersonic region ahead of the shock wave, the pressure rise across the shock wave itself (which involves considerations of the interaction with the boundary layer), and the subsonic flow downstream of the shock wave (which involves considerations of the boundary-layer development between the shock wave and the trailing edge, and of the flow in the near wake).

When the free-stream Mach number exceeds the critical Mach number, the flow is mixed subsonic/supersonic. Lift coefficient measurements [as taken from Farren (1956)] are presented as a function of the free-stream Mach number in Fig. 33. Line drawings made from schlieren photographs are presented in Fig. 34 to illustrate the following changes in the flow.

(a) When the free-stream Mach number is 0.75, the flow past the upper surface decelerates from local flow velocities which are supersonic without a shock wave. The lift coefficient is approximately 60% greater than the low-speed values at the same angles of attack.

(b) At $M_\infty = 0.81$, the lift coefficient reaches its maximum value, which is approximately twice the low-speed value. As indicated in Fig. 34(b), flow is supersonic over the first 70% of the surface, terminating in a shock wave. The flow on the lower surface is subsonic everywhere. Because the viscous flow separates at the foot of the shock wave, the wake is appreciably wider than for (a).

(c) At $M_\infty = 0.89$, flow is supersonic over nearly the entire lower surface and deceleration to subsonic speed occurs through a shock wave at the trailing edge. As a result, the lower surface pressures are lower at $M_\infty = 0.89$ than at $M_\infty = 0.81$. Flow on the upper surface is not greatly different than that for Fig. 34(b). As a result, the lift is drastically reduced. Separation at the foot of the upper surface shock wave is more conspicuous and the turbulent wake is wide. The shock wave at the trailing edge of the lower surface effectively isolates the upper surface from the lower surface. As a result, the pressure on the upper surface near the trailing edge is greater than that on the lower surface.

(d) When the free-stream Mach number is 0.98, the shock waves both for the upper

surface and for the lower surface have reached the trailing edge. The local Mach number is supersonic for most of the airfoil (both upper and lower surfaces).

(e) When the free-stream flow is supersonic, a bow shock wave (i.e., the detached shock wave in front of the leading edge) is generated. The flow around the airfoil is supersonic everywhere except very near the rounded nose. The shock waves at the trailing edge remain, but they have become weaker.

The data presented in Figs. 33 and 34 illustrate the effect of Mach number for a given airfoil section at a particular angle of attack. Parameters such as thickness ratio, camber, and nose radius also influence the magnitude of the compressibility effects. Transonic flows are very sensitive to the contour of the body surface, since changes in the surface slope affect the location of the shock wave and, therefore, the inviscid flow field as well as the downstream boundary layer.

Furthermore, the shock-wave–boundary-layer interaction and the possible development of separation downstream of the shock wave are sensitive to the character of the boundary layer, to its thickness, and to its velocity profile at the interaction location. Since a turbulent boundary layer can negotiate higher adverse pressure gradients than can a laminar one, the shock-wave–boundary-layer interaction is smaller for a turbulent boundary layer.

As the wing goes through the transonic speed regime, there is a rapid rise in the drag coefficient, as shown in Fig. 35. The Mach number corresponding to the drag increase is the *drag divergence Mach number* (M_{DD}). As noted in Sec. 3.5, the compressibility-related effects that are correlated in terms of the Mach number are known as the *wave drag*. Furthermore, there is a significant shift in the center of pressure which creates stability and control problems. Since these problems are associated with the formation of shock waves, the designer seeks configuration changes which eliminate the shock waves, move the shock waves to points where the Mach number is near unity (so that the shock wave is weaker), or reduce the pressure gradients which influence the shock strength. Two long-recognized solutions are thinner airfoil sections and sweeping the wing.

In the late 1930s, two aerodynamicists who had been taught by Prandtl, Adolf Busemann and Albert Betz, discovered that drag at transonic and supersonic speeds could be reduced by sweeping the wings. Betz, in 1939, was the first person to draw attention to the significant reduction in transonic drag which comes when the wing is swept back enough to avoid the formation of shock waves which occur when the flow over the wing is locally supersonic. The basic principle is that the component of the main flow parallel to the wing leading edge is not perturbed by the wing, so that the critical conditions are reached only when the component of the flow normal to the leading edge has been accelerated to the local sonic velocity at some point on the wing. This model is in fact a simplification, since the flow over a typical swept wing of relatively low aspect ratio is a complex, three-dimensional flow.

The effects of sweeping the wing on C_{D_0} and $C_{L_{\max}}$ are illustrated in Fig 36. As illustrated in these sketches, sweeping the wing

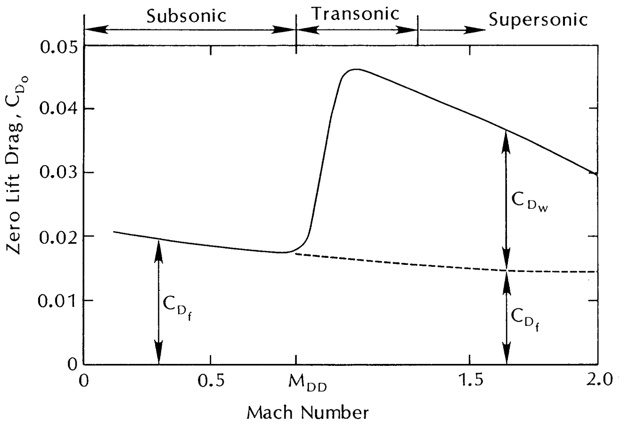

FIG. 35. Typical development of zero lift drag above the drag divergence Mach number.

not only delays the subsonic drag rise to a higher speed but reduces the peak drag coefficients. Benefits also occur at supersonic speeds for highly swept wings.

One can use a variable-geometry (or swing-wing) design to obtain a suitable combination of low-speed and high-speed characteristics. For the unswept, high-aspect-ratio configuration, one obtains efficient subsonic cruise and good maneuverability at the lower speeds needed for approaches and landings. For the highly swept, low-aspect-ratio configuration, the variable geometry wing provides low wave drag and eliminates the need for wing fold in the case of naval aircraft. Negative factors in a swing-wing design are complexity, a loss of internal fuel capacity, and the considerable weight of the hinge-pivot structure.

Where the fuselage and wing are joined together, the air flows around the two surfaces mutually interfere. This interference is especially important at high speeds because of the occurrence of shock waves, which give rise to wave drag. The interference effects total as much as a quarter of the sum of the individual drag contributions of the configuration's components.

Thus, the interaction between the central fuselage and the swept wing has a significant effect on the transonic flow over the wing. In the early 1950s, Küchemann (1957) recognized that a properly shaped waist-like indentation on the fuselage could be designed to produce a velocity distribution on the wing near the root similar to that on the corresponding infinite-span wing. Küchemann noted that "the critical Mach number can be raised and the drag reduced in the transonic and the supersonic type of flow, the wing behaving in some respects like a thinner wing." Whitcomb (1954) found that zero-lift drag rise is due primarily to shock waves. Furthermore, the shock-wave formations about relatively complex swept-wing–body combinations at zero lift near the speed of sound are similar to those which occur for a body of revolution with the same axial development of cross-sectional area normal to the airstream. Whitcomb concluded that "near the speed of sound, the zero-lift drag rise of a low-aspect-ratio thin-wing–body combination is primarily dependent on the axial development of the cross-sectional areas normal to the air stream." Therefore, the drag-rise increments near the speed of sound are less for fuselage-wing configurations which have a more gradual change in the cross-sectional

area (including the fuselage and the wing) with axial position (as well as a reduction in the relative magnitude of the maximum area). Whitcomb noted that it would be expected that indention of the body of a wing-body combination, so that the combination has nearly the same axial distribution of cross-sectional area as the original body alone, would result in a large reduction in the transonic drag rise. Design applications of this "theory," which is often known as *Whitcomb's area rule* for transonic configurations, are illustrated in Fig. 37. Early flight tests revealed that the prototypes of the YF-102 had serious deficiencies in performance. A major redesign effort included the first application of Whitcomb's area rule to reduce the transonic drag. The modified YF-102A achieved supersonic flight satisfactorily, providing the U.S. Air Force with its first operational delta-wing design.

4.3 Supersonic Aerodynamics

It should be clear from the previous discussion of shock waves and transonic flows that supersonic flows are very different from subsonic flows. Consider the flat plate traveling at twice the speed of sound at zero angle of attack, i.e., $U=2a$, as shown in Fig. 38(a). A piece of tape, which is placed on the plate, generates an infinitesimal disturbance, which propagates radially at the speed of sound, i.e., at a.

After the passage of time Δt, the disturbance front has moved $r=a\Delta t$, and the leading edge of the tape has moved $s=2a\Delta t$. The disturbances generated by the tape as it moves from its position in Fig. 38(a) to its position in Fig. 38(b) are contained within the cone bounded by the Mach angle μ. The boundary of the cone is known as the Mach wave. Thus, the perturbed flow is limited to points within the "Mach cone." This region is known as the *zone of action.* Points ahead of the Mach wave have no knowledge of the perturbations produced by the tape. This region is known as the *zone of silence.*

The geometry is such that

$$\sin\mu=\frac{a\Delta t}{2a\Delta t}=\frac{1}{2};$$

thus, $\mu=30°$. For a general case

$$\mu=\sin^{-1}\frac{a}{U}=\sin^{-1}\frac{1}{M}. \tag{54}$$

As the Mach number goes to 1.0, the Mach angle approaches 90°. Since the disturbance is infinitesimal, flow properties do not change

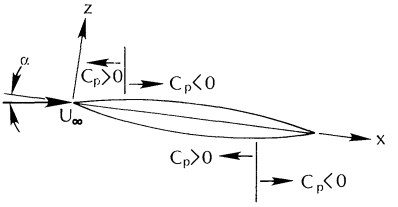

FIG. 39. General features for linearized supersonic flow past a thin airfoil.

across a Mach wave. If the disturbance increases in strength, i.e., is finite, it creates a shock wave. As shown in Fig. 15, shock waves make an angle θ with the free stream which is greater than μ. Of course, flow properties change across the shock wave, as discussed in Sec. 2.3.

4.3.1 Wave Drag at Supersonic Speeds. Experience has shown that the leading edge and the trailing edge of supersonic airfoils should be sharp and the section relatively thin. If the leading edge is not sharp (or only slightly rounded), the leading-edge shock wave will be detached and relatively strong, causing relatively large wave drag. Thus, configurations designed to operate at supersonic speeds are relatively long for a given cross section so that the flow deflections are small.

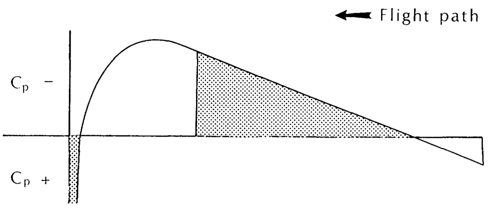
For small deflections of a supersonic flow, the pressure coefficient is proportional to the angle through which the flow is turned relative to the free-stream direction:

$$C_p=2\theta/(M_\infty^2-1)^{1/2}. \tag{55}$$

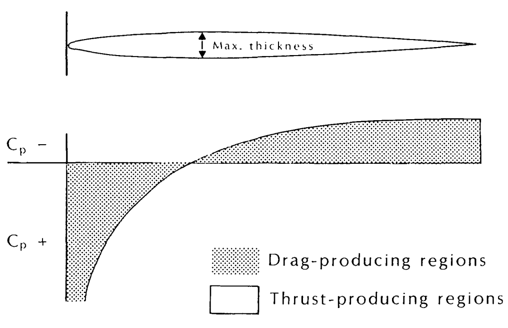
As shown in Fig. 39, a positive pressure coefficient is associated with a compressive change in the flow direction. Furthermore, for regions where C_p is positive, the local velocity is below the free-stream value. If the flow is turned toward the upstream Mach waves, it is a compressive turning of the flow. If the flow turns away from the upstream Mach waves, it is an expansive turning of the flow, i.e., an acceleration. Thus, for the double-convex-arc airfoil section shown in Fig. 39, the pressure is greatest at the leading edge, being greater on the lower surface when the airfoil is at a positive angle of attack. Note that the local flow accelerates continuously from the leading edge to the trailing edge both for the lower surface and for the upper surface. The pressure coefficient is zero, i.e., the local static pressure is equal to the free-stream value, at those points where the surface is parallel to the free stream. Downstream, the pressure coefficient is negative, which corresponds to an expansive change in direction.

The pressure distribution described in the preceding paragraph for a thin airfoil in a supersonic flow produces a drag force on a two-dimensional airfoil in an inviscid stream. Recall that, for incompressible, inviscid flow past a two-dimensional airfoil, the drag is zero. Typical pressure distributions for an airfoil in an incompressible stream and in a supersonic stream are presented in Fig. 40. Examining the sketch for the supersonic case, it can be seen that both the positive pressure coefficients on the forward portion of the airfoil and the negative pressure coefficients on the aft portion of the airfoil contribute to the drag. This pressure drag is known as *wave drag.*

The wave drag can be minimized by selecting the optimum area, or volume distribution, along the length of the body. Because of the complexity of the flow, there is no single equivalent body, as was the case for the *sonic area rule.*



A Subsonic flow



B Supersonic flow

FIG. 40. Typical pressure distributions for flow past a two-dimensional airfoil. [From Stinton (1966).]

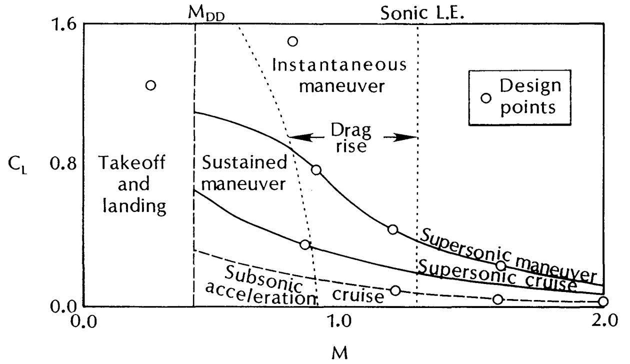


FIG. 41. Typical performance map for fighters. [From Bradley (1981).]

4.3.2 Design Considerations for Tactical Military Aircraft. As noted by Bradley (1981), the designer of a tactical military aircraft is faced with a multitude of design points throughout the subsonic-supersonic flow regimes plus many off-design constraints. The design goals for a tactical weapons system may include efficient cruise at both subsonic and supersonic Mach number, superior maneuverability at both subsonic and supersonic Mach number, and rapid acceleration.

Bradley states:

> The multiple design point requirement turns out to be the major driver for the designer of fighter aircraft. The aerodynamic requirements for each of the design points often present conflicting requirements. For example, the need for rapid acceleration to supersonic flight and efficient supersonic cruise calls for thin wing sections with relatively high sweep and with camber that is designed to trim out the moments resulting from aft ac movement at supersonic flight. However, these requirements are contrary to those requirements for efficient transonic maneuver, where the designer would prefer to have thicker wing sections designed with camber for high C_L operation and a high-aspect-ratio planform to provide a good transonic drag polar. Designers are thus faced with a situation of compromise. These conflicting requirements suggest the obvious solution of variable geometry, that is, variable sweep wing and/or variable camber. Although this is a satisfactory aerodynamic solution, in many cases the resultant weight increases to a configuration can be prohibitive. [In this paragraph "ac" refers to the aerodynamic center, which is defined in Sec. 3.4.]

A typical performance spectrum corresponding to mission requirements is illustrated in Fig. 41, which presents a map of lift coefficient versus Mach number. The low Mach end of the spectrum throughout the C_L range is typical of takeoff and landing for the configuration. The subsonic cruise and supersonic cruise portions are noted in the moderate lift range. Acceleration to high supersonic speeds occurs at the low lift coefficients. Sustained maneuver takes place in the C_L range of less than one for most fighter configurations. Above this lift coefficient, the aircraft is in the instantaneous maneuver regime. Drag rise occurs, depending on the wing geometry, in the range of 0.8 to 1.2 Mach.

The particular flow conditions that correspond to the flow map are shown in Fig. 42. At the cruise and acceleration points, the aircraft designer is dealing primarily with attached flow, and his design objective is to maintain attached flow for maximum efficiency. At the higher C_L's, corresponding to instantaneous maneuver, separated flow becomes the dominant feature. Current designs take advantage of the separated flow by forming vortex flows in this range. Intermediate C_L's corresponding to sustained maneuver are usually a mixture of separated and attached flow. Consequently, if the aircraft is designed with camber to minimize separation in the maneuver regime, the configuration will have camber drag and may have

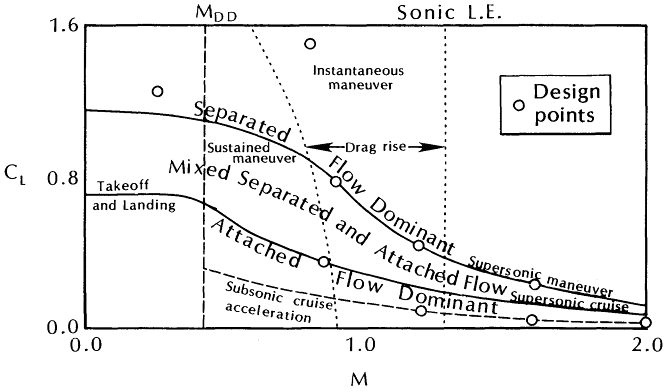

FIG. 42. General flow regimes encountered for fighters. [From Bradley (1981).]

lower surface separation, which increases drag at the low C_L's needed for acceleration.

Thus, the aircraft design is a compromise to achieve an optimal flow efficiency considering the numerous design points associated with the mission objectives. It is easily seen that the transonic flow problems that must be addressed in fighter design are driven to a very large extent by the constraints imposed at the other design points—supersonic and subsonic.

Bradley (1981) notes that "Supersonic design enjoys relatively precise computation and optimization thanks to wide applicability of linearized theory." Further, he noted:

> The design of efficient transonic configurations may proceed from two conceptual schools of logic. One acknowledges that the optimum low-drag flow must accelerate rapidly over the airfoil to supercritical flow and decelerate in a nearly isentropic manner, avoiding strong shocks and/or steep gradients that can lead to significant regions of separation. This approach sets attached flow or near fully attached flow as an intuitive design goal, and is typically used for aircraft that permit strong emphasis to be placed on transonic cruise or sustained maneuver design points.
>
> The second school of thought recognizes the inevitability of significant flow separations at design conditions and adopts a philosophy of controlling certain regions of separation through vortex flows to complement other regions of attached supercritical flow. This approach is appropriate for configurations constrained by multiple design points that emphasize added supersonic requirements. Current tactical fighters that rely on high wing loadings for transonic performance are good examples. The F-16 and F-18 employ a combination of controlled vortex flow and variable camber to achieve maneuverability.

Even though a designer has worked carefully to design a wing for attached flow, the flow fields associated with sustained and instantaneous maneuvers involve predominantly separated flows. The manner in which the flow separates, and how the separation develops over the configuration, will strongly affect the vehicle's drag and its controllability at the higher C_L's. Aircraft such as the F-16 and the F-18 employ strakes or leading-edge extension devices to provide a controlled separated flow. Controlled vortex flow can then be integrated with variable-camber devices on the wing surface to provide satisfactory high-lift, stability and control, and buffet characteristics. The resulting flow field is a complex one, combining attached flows over portions of the wing with the vortex flow from the strake.

4.4 Hypersonic Flow

4.4.1 General Characterization of Hypersonic Flows. The problems associated with determining the aerothermodynamic environment of a vehicle flying through the atmosphere offer diverse challenges to the designer. The characteristics of the hypersonic environment depend on the mission requirements and vehicle size constraints. Represen-

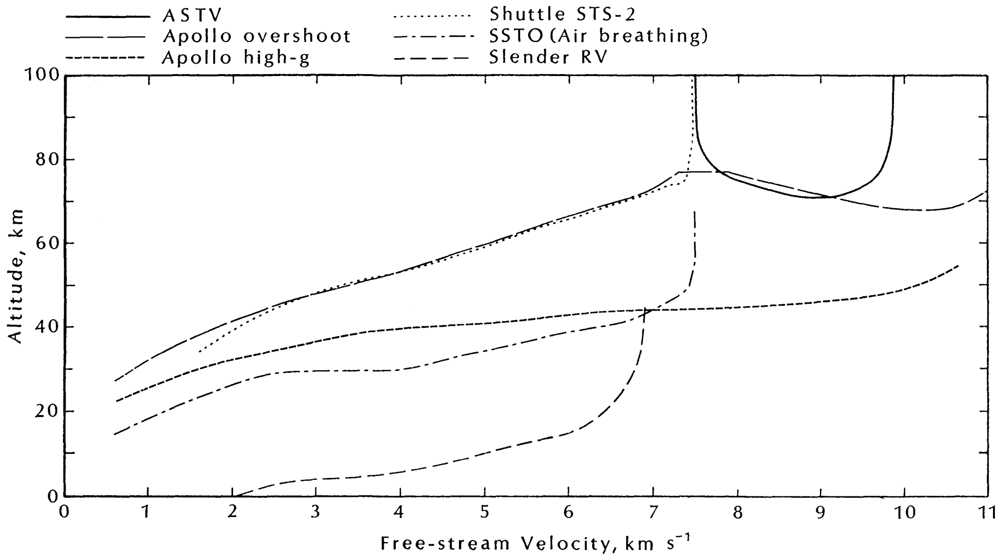

FIG. 43. Velocity-altitude parameters for several reentry vehicles. [From Bertin (1989).]

tative reentry trajectories for several different programs are presented in Fig. 43. Presented in Fig. 43 are the approximate velocity-altitude parameters for a trajectory for the Aeroassisted Space Transfer Vehicle (ASTV), for two trajectories for the Apollo Command Module (an overshoot trajectory and a 20-g limit trajectory), for the best-estimated trajectory for the STS-2 (Shuttle Orbiter) reentry, for the trajectory of a single-stage-to-orbit vehicle with an air breathing engine (SSTO), and for the trajectory for a slender (relatively low-drag) reentry vehicle. For some applications, the vehicle will be very blunt or fly at very high angles of attack, so that the drag coefficient is large and the hypersonic deceleration occurs at very high altitudes. Reentry vehicles from the U.S. manned spacecraft program, e.g., the Apollo and the Shuttle, are characteristic of these applications. The designer of such vehicles may have to account for nonequilibrium thermochemistry, viscous-inviscid interactions, and (possibly) noncontinuum flow models. Applications that require the time of flight to be minimal produce slender reentry vehicles that penetrate deep into the atmosphere before experiencing significant deceleration. The trajectory for the Slender RV, which is presented in Fig. 43, illustrates the velocity-altitude environment for a low-drag configuration. As a result, these relatively high ballistic coefficient β (i.e., W/C_DA) configurations experience severe heating rates and high dynamic pressures, but only for a short period of time.

For a free-stream velocity of 7 km s^{-1} (23 kft s^{-1}), the kinetic energy per unit mass, i.e., $U_\infty^2/2$, is 2.45×10^7 J kg^{-1} (1.05×10^4 Btu lb$_m^{-1}$). As the air particles pass through the shock wave ahead of the vehicle, they slow down, converting kinetic energy into internal energy. For a perfect gas, one for which the composition is frozen and one for which γ is constant, the increase in internal energy is in the form of random motion of the air particles (temperature). Thus, using a perfect-gas model for the air crossing a normal shock wave, the temperature would increase by approximately 2.4×10^4 K (4.4×10^4 °R). In reality, the change in kinetic energy of the air particles would go into increasing the random thermal motion of the air particles (temperature), exciting the vibrational (internal) energy of the diatomic particles, and dissociating the molecules (producing atomic species). If the density of the air is high enough, there are sufficient collisions between the air particles so that the air downstream of the shock wave quickly achieves the equilibrium state. For an equilibrium flow, the temperature of the air downstream of a normal shock wave is of the order 7×10^3 K (13×10^3 °R) for this case.

For most cases, the thermodynamic state will be between these limits of frozen flow and of equilibrium flow. Where the actual flow falls between these limits is a function of the density (or, equivalently, the altitude). At higher altitudes, there are fewer air particles and, therefore, fewer collisions between them. Thus, the air particles must travel further to experience the collisions required to excite the vibrational modes and to accomplish the dissociation process.

4.4.2 Defining Hypersonic Flow. Flow fields around blunt bodies begin to exhibit many of the characteristics of hypersonic flows when the Mach number is 4, or greater. By definition,

$$M_\infty = U_\infty / a_\infty \gg 1 \tag{56}$$

is the basic assumption for all hypersonic flow theories. Thus, the internal thermodynamic energy of the free-stream fluid particles is small compared with the kinetic energy of the free stream for hypersonic flows. In flight applications, this results because the velocity of the fluid particles is relatively large. The limiting case, where M_∞ approaches infinity because the free-stream velocity approaches infinity while the free-stream thermodynamic state remains fixed, produces extremely high temperatures in the shock layer. The high temperatures associated with hypersonic flight cannot be accommodated in ground-test facilities. Therefore, in wind-tunnel applications, hypersonic Mach numbers are achieved through relatively low speeds of sound, i.e., for the wind tunnel, M_∞ approaches infinity because the speed of sound (which is proportional to the square root of the free-stream temperature) goes to "zero" while the free-stream velocity is held fixed. As a result, the fluid temperatures remain below the levels that would damage the wind tunnel or the model.

Another assumption common to hypersonic flow is that

$$\epsilon = \rho_\infty / \rho_2 \ll 1, \tag{57}$$

which is known as the small-density-ratio assumption. Thus, this assumption relates primarily to the properties of the gas downstream of the shock wave. Recall that for a perfect gas [Ames Research Staff (1953)]:

$$\epsilon = \frac{\gamma - 1}{\gamma + 1} \tag{58}$$

for a normal shock wave as $M_\infty \to \infty$. Thus, ϵ is 1/6 for perfect air. Note that typical hypersonic wind tunnels operate at conditions where the test gas can be approximated by the perfect-gas relations. However, during the reentry flights of the Apollo Command Module, the density ratio approached 1/20. Thus, the density-ratio simulation in those wind tunnels where the air flow behaves as a perfect gas does not match the flight values. This will have a significant effect on the shock stand-off distance, as well as other parameters.

As the free-stream Mach number approaches infinity, the shock layer becomes very thin. As a result, one can assume that the speed and direction of the gas particles in the free stream remain unchanged until they strike the solid surface exposed to the flow. For this flow model (termed *Newtonian flow*, since it is similar in character to one described by Newton in the 17th century), the normal component of momentum of the impinging fluid particle is wiped out, while the tangential component of momentum is conserved.

The Newtonian flow model and the various theories for thin shock layers related to the Newtonian approximation are based on the small-density-ratio assumption. The small-density-ratio requirement for Newtonian theory also places implicit restrictions on the body shape in order that the shock layer be thin.

For slender configurations, such as sharp cones and wedges, the strong shock assumption is

$$M_\infty \sin\theta_b \gg 1, \tag{59}$$

where θ_b is the body deflection angle. Equation (59) is mixed in nature, since it relates both to the flow and to the configuration. The concept termed the *Mach number independence principle* depends on this assumption.

The Mach number independence principle was derived for inviscid flow by Oswatitsch. Since pressure forces are much larger than the viscous forces for blunt bodies or for slender bodies at relatively large angles of attack when the Reynolds number exceeds 10^5, one would expect the Mach number independence principle to hold at these conditions. This is demonstrated by the data presented in

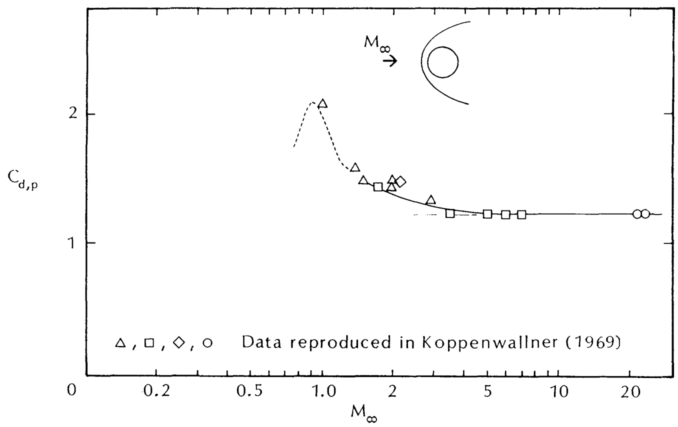

FIG. 44. Pressure drag of a right circular cylinder as a function of Mach number. [From Koppenwallner (1969).]

Fig. 44, which are taken from Koppenwallner (1969). Note that the pressure drag for the (blunt) right circular cylinder reaches its limiting value by $M_\infty = 4$.

4.4.3 Chemistry of Hypersonic Flows. It is well known that the air particles in the shock layer of a hypervelocity reentry vehicle undergo vibrational excitation, dissociation, and (possibly) ionization. These chemical phenomena absorb energy, limiting the temperature increase as the kinetic energy of the hypervelocity air particles crossing the bow shock wave is converted to thermal energy. At low altitudes, where the free-stream density is sufficiently high, these chemical phenomena tend to reach equilibrium, as shown in Fig. 45. At higher altitudes, where the free-stream density is relatively low, there are not sufficient collisions for the gas to reach an equilibrium state. For these nonequilibrium flows, the concentrations of individual species and the energy contained in the different internal modes must be calculated by integrating the conservation equations governing the phenomena.

For hypersonic flight, the gas molecules that pass through the bow shock wave are excited to higher vibrational and chemical energy modes. This lowers the specific-heat ratio of the gas below the free-stream value, if it is assumed that equilibrium exists and that dissociation is not driven to completion. A

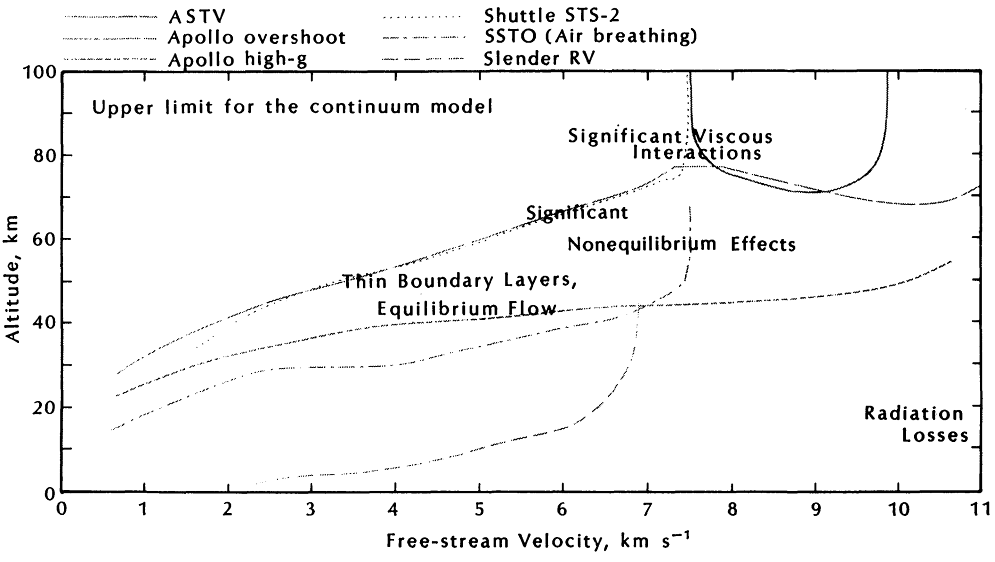

FIG. 45. Modeling flow phenomena for hypersonic flight.

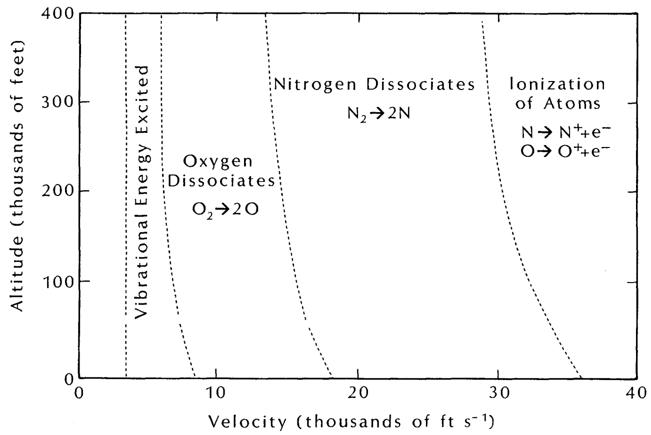

FIG. 46. Composition of equilibrium air in the stagnation region [Hansen and Heims (1958)].

large amount of the energy that would have gone into increasing the static temperature behind the bow shock wave for a perfect gas is used instead to excite the vibrational energy levels or to dissociate the gas molecules. The dominant chemical reactions that occur in the stagnation region for an equilibrium air flow [as presented in Hansen and Heims (1958)] are presented in Fig. 46. At about 914 m s^{-1} (3000 ft s^{-1}), the vibrational energy of the air molecules begins to become important. Oxygen dissociation begins when the free-stream velocity is between 1829 m s^{-1} (6000 ft s^{-1}) and 2438 m s^{-1} (8000 ft s^{-1}). Nitrogen dissociation occurs at velocities in excess of 4572 m s^{-1} (15 000 ft s^{-1}). Finally, ionization of atoms becomes important at velocities in excess of 9144 m s^{-1} (30 000 ft s^{-1}). Hansen and Heims (1958) note that

> the dissociation and ionization reactions are pressure dependent because each particle yields two product particles, and such reactions are inhibited by high pressure. Therefore, higher temperature and, consequently, higher velocity are required to produce the reactions at sea level than at high altitudes where much lower pressures occur.

5. ROTORCRAFT AERODYNAMICS

A complete dynamic analysis of the flow field for rotorcraft rotor blades is more complex than that for fixed wings. This is because the blades provide not only lift, but also propulsion and control. This complexity is accentuated by the fact that the long, thin rotor blades are very flexible and are subjected to a severely fluctuating aerodynamic environment. As a result, the structural dynamics and aerodynamics of rotor blades are tightly coupled and difficult to analyze.

A partial control loop for the dynamic analysis of rotor blades is presented in Fig. 47. The pilot controls the angle of attack of the blades via the "cyclic" (controls blade path angle) and the "collective" (controls blade pitch). Then the aerodynamic forces on the rotor blades create a flow field which can bend and twist the rotor blades, changing their angle of attack. So, the rotor blades' structural dynamics obviously feed back into the control of the blades. The bending and twisting of the rotor blades also affect the loads on the rotor "hub" which is connected to the power plant. This results in a torque which affects the power needed from the drive train and creates moments and shear

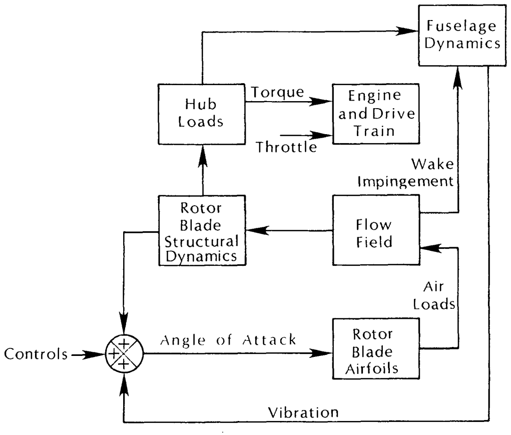

FIG. 47. Rotor-blade dynamic analysis.

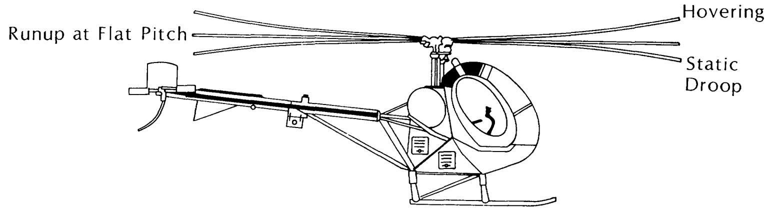

FIG. 48. Helicopter coning angles.

stresses transmitted to the fuselage which can also feed back into the control loop via vibration. The fuselage dynamics can also be affected directly by wake impingement from the rotor blade's flow field, resulting in a negative feedback loop.

This is only a basic view of the complexity of rotor-blade aero- and structural dynamics. This section will not attempt to address this very difficult problem fully, but will point out the most significant differences between the analysis of rotor blades and fixed wings.

All of the analysis of flow fields in Sec. 4.1 on subsonic flight also applies to the rotor blades of rotorcraft. The blades are, in fact, merely wings that rotate as well as translate through the air. This section will concentrate on some of the unique problems encountered in analyzing the aerodynamics of rotor blades by looking at three important phases of flight: hovering, forward motion, and descending flight.

5.1 Hovering Flight

An analysis of hovering flight in calm air is relatively straightforward since there is no translational motion and the blades only have to provide lift. Such an analysis does, however, point out the fundamental difference between a rotor blade and a fixed wing: each section of a rotor blade experiences a significantly different airspeed than the other sections along the span of the rotor. The "equivalent" free-stream velocity for each section of the rotor blade is related to the rotational speed of the rotor by the simple equation

$$v_r = r\omega. \tag{60}$$

Using RPM (revolutions per minute), the airspeed at any point along the rotor can be calculated by

$$v_r = \frac{\mathrm{RPM}\cdot r}{9.55} \quad (\mathrm{m\ s^{-1}}). \tag{61}$$

Since lift depends on the square of velocity (all other factors held constant), the tips of the rotor blades produce a disproportionate amount of lift, which is aerodynamically inefficient. The blade tips not only experience the largest lift force, but are also furthest away from the center hub. This results in a large torque applied to the tips which causes large "coning" angles about the hub, as shown in Fig. 48, which can cause structural problems.

To minimize the aerodynamic and structural problems associated with the differential airspeeds along the rotor blades, the shape of the blades is altered along the span. Typically, the blade pitch angle (the angle of the airfoil section's chordline relative to the plane of rotation) is 8°–10° smaller at the blade tips than near the rotor hub. This minimizes the lift differential between the rotor blade's center and tip, as shown in Fig. 49.

The total lift produced by the rotor blades during hover is more difficult to calculate than the lift produced by a fixed wing, developed in Sec. 3.3, and is given by

$$L = \tfrac{1}{2}\,\rho v^2 S C_L. \tag{62}$$

For the reasons discussed earlier, each section of the rotor blade will have a different velocity, a different blade path angle (affect-

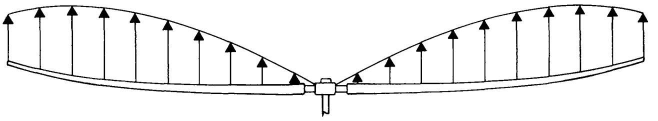

FIG. 49. Typical spanwise lift distribution for helicopter rotor blades.

ing its C_{l_i}), and a different cross-sectional area (for structural reasons). Therefore, the lift must be calculated by summing the contributions of each blade element:

$$\sum_i \Delta L = \sum_i \tfrac{1}{2} \rho v_{r_i}^2 S_i C_{l_i} = L_r, \qquad (63)$$

where L_r is the total lift due to rotation. Integration of Eq. (63) yields

$$L_r = \frac{1}{2} \rho \frac{v_{\text{tip}}^2}{3} S C_{L_{\text{ave}}}, \qquad (64)$$

where S is the total rotor blade area, and $C_{L_{\text{ave}}}$ is the average lift coefficient.

It is convenient, and customary, to replace several of the terms in Eq. (64) with terms more useful to the aerodynamicist. The solidity ratio represents the portion of the circular disk actually occupied by the blades, typically 4%–7%:

$$S^* = S/\pi R^2 \quad \text{(nondimensional)}. \qquad (65)$$

The tip velocity can be simplified using Eq. (61):

$$v_{\text{tip}} = \frac{\text{RPM} \cdot R}{9.55} \quad (\text{m s}^{-1}). \qquad (66)$$

The density ρ is usually replaced by a density ratio:

$$\rho^* = \rho/\rho_0 \quad \text{(nondimensional)}, \qquad (67)$$

where ρ_0 is the density at sea level.

Making all the substitutions into Eq. (64) and inserting the appropriate units, the total lift (in newtons) produced by the rotor blades during hover is

$$L_r = 1740 S^* \rho^* C_{L_{\text{ave}}} (\text{RPM})^2 R^4. \qquad (68)$$

This equation shows the linear dependence of lift on atmospheric density and the quadratic dependence on the RPM. The strong dependence on RPM is particularly important to the pilot since it is the only parameter in Eq. (68) that he has control over (although the pilot also has some control over $C_{L_{\text{ave}}}$ via the collective and cyclic).

The R^4 term is obviously the most important term in Eq. (68), but its usefulness is limited by two factors. The most obvious limitation is the structural problems created by the large torque at the blade tips. Another serious limitation is the speed of sound. Although it may seem strange to apply Mach-number-related effects to a stationary (hovering) helicopter, the blade tips can easily reach transonic speeds at high RPM. This causes all the problems encountered by transonic aircraft, as described in Sec. 4.2, most notably a huge increase in drag, which would put impractical loads on the drive train and power plant.

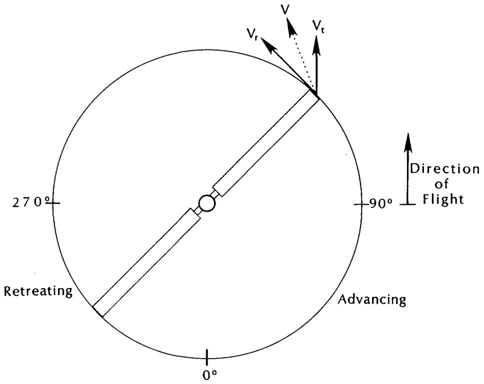

FIG. 50. Vector relation between rotational and translational velocities.

5.2 Forward Flight

The aerodynamic analysis of rotor blades in forward flight (or hovering on a windy day) is more complicated than that for hovering since, for each blade section, the magnitude and the direction of the relative wind are constantly changing. This results in an unsteady flow field. Each section experiences a translational velocity, v_t, in addition to its rotational velocity, v_r. The net velocity is the vector sum of v_t and v_r, as shown in Fig. 50. When the "advancing" blade is at the 90° position in Fig. 50, it has the greatest net velocity. Conversely, the "retreating" blade experiences the least net velocity at the 270° position. At intermediate angles, the magnitude of the net velocity is between these two values and its direction is not perpendicular to the blade, resulting in a condition very similar to a "swept" fixed wing, discussed in Sec. 4.2.

One unique problem caused by the vector addition of v_r and v_t is that there will be a part of the retreating blade where the flow will be reversed. This will occur since v_r decreases towards the hub, eventually becoming less than v_t. This causes the airflow to go from the trailing edge to the leading edge of the rotor blade. Obviously, this part of the rotor blade will be a very inefficient lift producer.

A more serious problem is the overall lift asymmetry between the advancing and retreating blades caused by the higher average airspeed on the advancing blade. In early rotorcraft, with rigid blades rigidly attached to the hub, the left rolling tendency caused by this lift asymmetry was often the chief limit on forward airspeed. The obvious solution to this problem is to reduce the angle of attack on the advancing blade and to increase it on the retreating blade, thus compensating for the velocity asymmetry. This is called *cyclic feathering*, and some helicopters do it by mechanically reducing the pitch on each advancing blade and increasing its pitch as it becomes the retreating blade.

However, most rotorcraft are able to avoid cyclic feathering by taking advantage of the natural structural dynamics of flexible rotor blades and hinges, in a process called *flapping*. As the rotor blade reaches the advancing side, the additional lift "upflaps" the blade (this happens because the moment applied to the blade is not instantaneously transmitted to the hub), giving a downward component to the relative wind, thereby decreasing the angle of attack. A similar "downflapping" occurs on the retreating blade which gives an upward component to the relative wind, naturally increasing the retreating blade's angle of attack. The natural frequency of this flapping motion is exactly equal to once per blade revolution regardless of the blade's lift characteristics or stiffness. Flexible blades attached by "flapping hinges" to the hub can be nearly as effective as cyclic feathering, and they are far simpler to implement and maintain.

A fundamental limit on the ability of flapping to correct the lift asymmetry between the advancing and the retreating blades is the *retreating blade stall*. The increase of the angle of attack on the retreating side eventually causes stalling of the blade, resulting in a large loss of lift and a severe lift asymmetry, and a need for additional power. Either the dramatic loss of lift or a lack of power could limit the forward speed of a rotorcraft. The analysis of a retreating blade stall is complex. First of all, this is a "dynamic" stall, i.e., the blade is only at a high angle of attack momentarily, so it does not necessarily stall at the static stall angle of attack. A second, more fundamental, complexity involves the spanwise "twisting" of the blades. An untwisted blade would have its maximum angle of attack at the blade tip and would stall there first. However, since the angle of attack of the blade is deliberately increased toward the center of the rotor blade, it is not obvious which part of the blade will stall first. Most helicopters have their maximum angle of attack in a region bounded by 270°–300° (see Fig. 50) at radii from 70% to 100% of the blade length.

5.3 Descending Flight

In level flight, the thrust of a rotorcraft is partially perpendicular to the direction of flight, to offset weight, and partially in the direction of flight, to offset drag. In a vertical descent, however, the thrust of the rotor is directly opposite the direction of flight, creating a very different flow field. The flow field for descending flight is usually categorized as one of the following four states: normal thrusting, vortex ring, autorotative, or windmill brake. An idealized flow field for each of the states is shown in Fig. 51. In all of the states, there will be a vortex due to pressure gradients (similar to the tip vortices discussed in Sec. 4.1) at the tip of the rotor blade and where the flow field reverses.

In the normal thrusting state, the velocity of the air induced through the rotor exceeds the rate of descent. This condition exists for hovering and low rates of descent up to approximately 70% of the ideal hovering velocity, given by

$$v_{i_{\text{hover}}} = \left(\frac{\text{Weight}}{2\rho A}\right)^{1/2} = \left(\frac{\text{Disk loading}}{2\rho}\right)^{1/2}. \tag{69}$$

All the flow is downward (relative to the rotor) in this state but of unequal magnitude because of the blade twist and the differences in rotational velocity along the span of the blade. The thrust is steady, and a constant amount of power is required from the engine to maintain RPM.

The vortex ring state occurs between 70% and 150% of $v_{i_{\text{hover}}}$. Thrust may vary by as much as plus or minus a third in this condition. There will also be increased vibration and a tendency to produce even higher descent rates. This state is somewhat analogous to a pilot in a fixed-wing aircraft flying through his own wake. This is because the

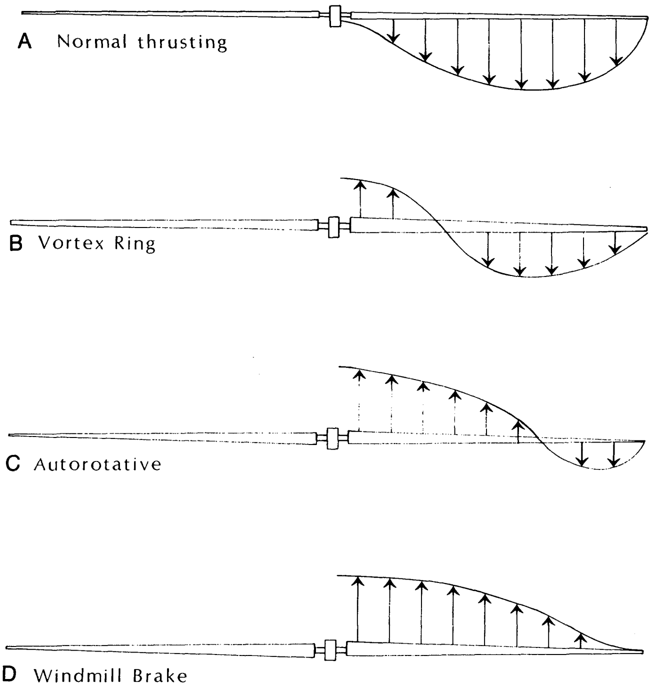

FIG. 51. Flow fields in vertical descents.

high rate of descent has overcome the relatively low downward-induced velocity near the rotor hub and caused a flow reversal. The vortex formed at the flow reversal is very turbulent, disturbing the flow field over a large area of the disk, resulting in a loss of thrust and thrust variations. Rotorcraft pilots are warned to avoid the vortex ring state.

At descent rates beyond the vortex ring state up to around 180% of $v_{i_{\text{hover}}}$, the vortex at the flow reversal will become steadier and much less turbulent. In this autorotative state, there will be some descent rate where no power will be required to maintain RPM. This state of autorotation is extremely important in case of engine failure because, although the pilot cannot maintain level flight, he can generate enough thrust to maintain a controlled equilibrium descent to the ground. In effect, the rate of loss of potential energy in autorotation is equal to the power required for the steady-state descent. The autorotative state can also be thought of as the boundary between conditions where power must be used to prevent RPM decrease, and conditions where power must be extracted from the rotor to prevent RPM increase.

The state where power must be extracted from the rotor to prevent RPM increase is called the *windmill brake state* and is, in fact, the state in which windmills operate in order to extract energy from the wind. This is not a normal operating state for any rotorcraft. However, pilots will purposely enter this state as a transient condition just prior to the landing from an autorotative approach. The increased rotational kinetic energy in the rotor can be used to "flare" the rotorcraft, reducing the rate of descent to nearly zero for landing.

5.4 Summary

All of the rotorcraft aerodynamics presented are idealized and simplified cases that are merely meant to show the most obvious differences in dealing with rotating wings versus a fixed wing. The flow field around rotor blades is, in general, very complex and is often handled these days through CFD (computational fluid dynamics), the topic of the next section.

6. COMPUTATIONAL FLUID DYNAMICS

6.1 General Remarks

Computational fluid dynamics (CFD) is certainly not pure theoretical analysis. CFD changes the fundamental nature of the analysis from calculus to arithmetic, and from the continuum domain to the discrete domain, so that it can be solved using a computer. The existing mathematical theory for numerical solutions of nonlinear partial differential equations is continuously being improved. In computational fluid dynamics, it is necessary to rely heavily on the mathematical analysis of simpler, linearized formulations and on heuristic reasoning, physical intuition, wind-tunnel experience, and trial-and-error procedures.

Miranda (1984) divides the flow fields into zones: (1) the inviscid zone, where the effects of viscosity are negligible; and (2) the viscous zone, where the effects of viscosity have a significant role, such as in the boundary layer and in the near wake. Kutler (1983) states that "The use of zonal methods is advantageous because (1) the regions over which complex equation sets are required are minimized, (2) the simpler equation sets have faster solution algorithms which result in improved computational efficiency, and (3) the computer storage requirements for the overall procedure are not as great."

Chapman (1979) cites four major stages of successively refined approximations to the full Navier–Stokes equations [Eqs. (5a)– (5c)] in order of their evolution and complexity: (I) linearized inviscid, (II) nonlinear inviscid, (III) Reynolds averaged Navier–Stokes, and (IV) full Navier–Stokes. Numerical methods using the stage-I approximation are termed *panel methods*, since complex aircraft geometries are modeled by a large number of contiguous surface panels. The stage-II approximations neglect only the viscous terms and have been used to predict transonic and hypersonic flow fields. For the stage-III approximations, the basic equations are averaged over a time interval, long compared to turbulent eddy fluctuations, yet small compared to macroscopic flow changes. Since terms representing the time-averaged transport of turbulent momentum and energy must be modeled, the principal inaccuracy of stage-III approximations is that of modeling turbulence. In its full complexity, the stage-IV approximation involves the direct simulation of turbulent eddies from the complete time-dependent Navier–Stokes equations. Chapman states that "Progressive advances in computer power and in numerical methods have made possible the development of a variety of computational codes ranging from stage-I codes for complex aircraft configurations to stage-IV codes for very simple geometry." Although there have been significant advances both in computer hardware and in computer software since that statement first appeared, it remains qualitatively correct.

Phenomenal progress in CFD has been made over the past decade and continues to be made. Thus, for design cases in which the flow is primarily attached with thin boundary layers such as transports in the cruise configuration, CFD can be used directly in the design cycle. However, as noted by Bradley (1987), "The CFD capability for more complex designs, such as tactical aircraft, has not progressed as far because the flow fields are dominated by flow separations and vortex interactions."

Boppe (1988) stated:

> It can be appreciated that subtle discrepancies between computed and experimental pressures will have different effects on drag and pitching moments obtained via pressure integration depending on local position and geometry. A small pressure anomaly near the middle of an aerodynamic configuration (where surface shaping is nearly aligned with the onset flow) will sum to produce a negligible contribution to total drag and if the location is near the moment center... a negligible effect on overall pitching moment. If the pressure anomaly, even though small, is positioned aft on the configuration, say on a nozzle boattail, a significant drag effect will register due to integration on an aft-facing surface and significant moment effects can register since the moment arm is large.

However, good agreement between the computed pressures and the measured values does not guarantee satisfactory predictions for the drag, since exact calculations of the boundary layer and, therefore, the skin friction are difficult. As noted by Jameson (1987), "Since a universally satisfactory turbulence model has yet to be found, current turbulence models have to be tailored to the particular flow."

7. NONAEROSPACE APPLICATIONS OF AERODYNAMICS

7.1 General Remarks

As noted in the Introduction, the aerodynamicist applies the principles of fluid mechanics to determine the forces and moments acting on an object moving through the air, e.g., a golf ball or an airplane, or due to the air moving past an object, e.g., the wind loads acting on a building. Some nonaerospace applications of aerodynamics are discussed in this section.

7.2 Automotive Aerodynamics

Aerodynamics has a significant effect on the road holding, driving performance, contamination of glass panels, and fuel economy of an automobile. In recent years, there have been extensive world-wide efforts to reduce fuel consumption by reducing the aerodynamic drag of motor vehicles. As shown in Fig. 52, there has been a considerable reduction in aerodynamic drag.

In order to achieve a low drag coefficient for a series production car, it is necessary to include the aerodynamic requirements into the styling and the construction concept throughout the development of the vehicle. For instance, side windows are an area in which aerodynamic optimization and production-cost control have conflicting requirements. Flush glass, desirable from the aerodynamic point of view, requires expensive manufacturing processes.

Design of the front end must accommodate the competing requirements of sufficient internal air flow to meet engine cooling and other requirements while minimizing drag of the external aerodynamics. Emmelmann, Berneburg, and Schulze (1990) note that "The optimum positioning of the front cooling air inlets on a vehicle plays an important part in achieving a low C_D value along with good engine-cooling characteristics. From an aerodynamic standpoint the optimum front would be completely closed, as air flow into the engine compartment causes drag.... Drag inducing airflow into the engine compartment is minimized by the use of flexible mouldings between the leading edge of the hood, and the headlamps and grill, and also between the headlamp assemblies and the bumpers." The size and location of the opening are other parameters in the front-end design.

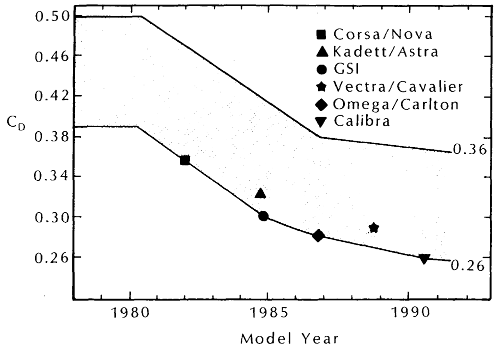

FIG. 52. The development of the drag coefficient of Opel/Vauxhall vehicles. [From Emmelmann, Berneburg, and Schulze (1990).]

Morel (1978) explored the dependence of the near-wake flow on the geometry of the afterbody characteristics of hatchback automobiles. The drag coefficient data showed a very strong variation of C_D with the slant angle. The data presented in Fig. 53, which are taken from Costelli (1984), illustrate the critically important parameter of back-window slant angle.

Nedley (1979) notes that subtle changes in the surface in critical areas influence drag significantly. Furthermore, the effect of a particular change is specific to the vehicle and may not apply to other vehicles. Emmelmann, Berneburg, and Schulze (1990) note that trend statements made on the basis of numerical code analysis of simplified body shapes cannot be expected to be valid for real vehicles.

As a result, extensive wind-tunnel tests are conducted throughout the development of an aerodynamically efficient vehicle. Scale models, typically 1:4 or 1:5, are tested early in the styling phase. Wind-tunnel tests using prototypes and pilot vehicles allow the designer to check that the obtained optimization features are effective. A photograph of a test conducted in the General Motors Aerodynamics Laboratory is presented in Fig. 54.

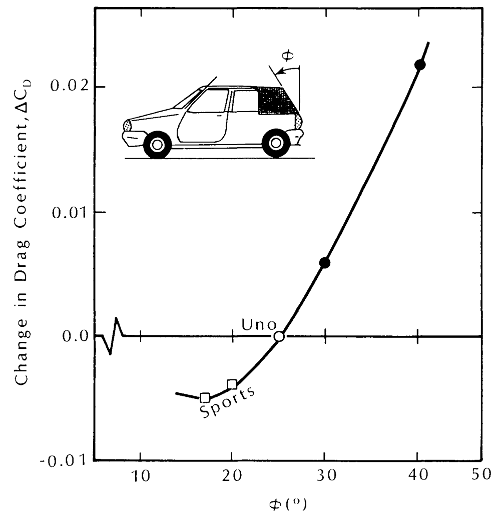

FIG. 53. The influence of back-window slant angle on the change in drag coefficient. [From Costelli (1984).]

7.3 Wind Loads on Buildings

To determine the wind loads acting on a building, one is confronted with a complex, unsteady, three-dimensional flow field containing turbulence, vortices, and large regions of separated flow. Even the approach flow away from the building (i.e., the free-stream flow of the previous discussions) is a complex, three-dimensional flow because it is in the atmospheric boundary layer adjacent to the earth's surface. The height at which viscous effects become negligible is the gradient height, which is a function of surface roughness. Typical values of the gradient height are 275 m for flat, open country, 400 m for suburban terrain, and 500 m for an urban area. Above the gradient height, the frictionless wind balance is established, and the air moves at the gradient wind velocity along isobars. Within the atmospheric boundary layer, the wind crosses the isobars. Thus, in the "free-stream" flow, the velocity varies with distance from the surface and forms a spiral.

Because the velocity approaching a tall building increases with distance above the ground, the pressures acting on the building differ from one floor to another. This is illustrated in the data of Dalgliesh (1970) that are reproduced in Fig. 55. On the windward surface, the positive pressure coefficients are much higher on the 33rd floor than on the 10th floor. Because subsonic flows cannot turn sharp corners, the flow separates from the side walls (those parallel to the free-stream flow) creating large negative pressure coefficients. Furthermore, the flow is unsteady in these separated regions with pressure fluctuations approaching $0.5q_\infty$. Windows located in these regions of large negative pressure coefficients may be sucked out of their frame, falling to the street below. Thus, the designer must be concerned not only with the integrated wind loads on a building but with local flow phenomena.

The proximity of adjacent buildings further complicates the flow field. As shown in the sketch of Fig. 56, a vortex forms off the lower building in the foreground. Air descending close to the windward wall flows through openings located at the ground level of the high-rise building. Regions of accelerated flow are produced around the vertical

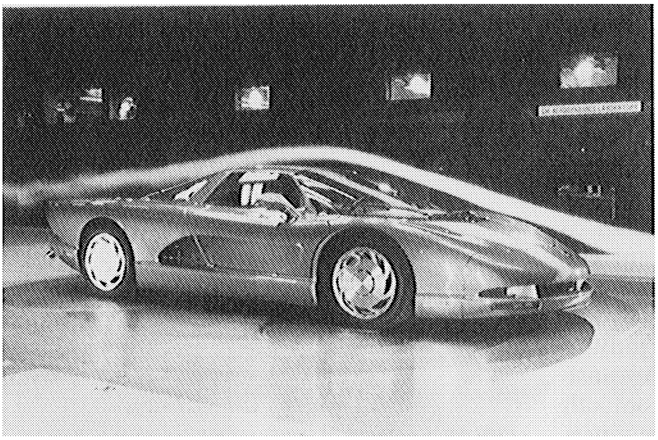

FIG. 54. Photograph of a test in the General Motors Aerodynamics Laboratory (photograph provided by K. Staggemeier).

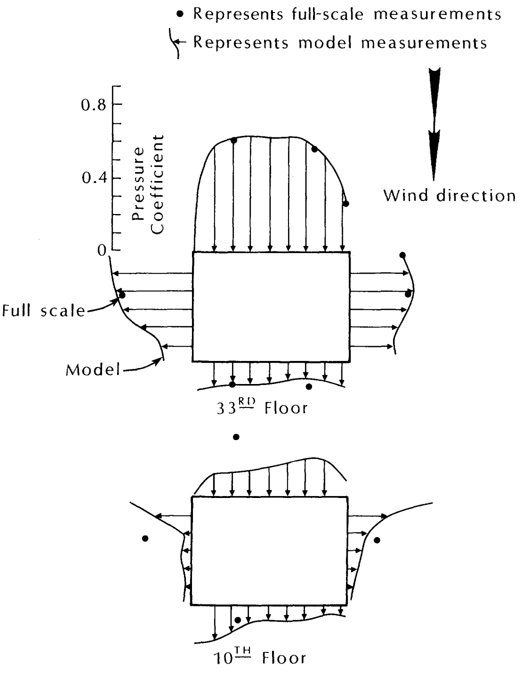

FIG. 55. Mean pressure coefficients acting on a 34-story office building. [From Dalgliesh (1970).]

and horizontal corners of the high-rise building. The flow separates from the roof and side walls, causing large negative pressure coefficients in these regions. Many design problems are presented in these regions containing vortices, separated flows, and through flow.

7.4 Aerodynamics of Sports Balls

Aerodynamics plays a prominent role in many sports where a ball is either struck or thrown through the air. Lateral deflection in flight (variously known as swing, swerve, or curve) is well recognized in cricket, baseball, golf, and tennis. In most of these sports, the swing is obtained by spinning the ball about an axis perpendicular to the line of flight, which gives rise to what is commonly known as Magnus effect. According to Mehta (1985), the Magnus effect has been attributed to asymmetric boundary-layer separation. The effect of spin is to delay separation on the retreating side and to enhance it on the advancing side. Clearly, this would occur only at postcritical Reynolds numbers, when transition has occurred on both sides. A smooth sphere rotating slowly can experience a negative Magnus force at precritical Reynolds numbers, when transition occurs first on the advancing side.

Mehta (1985) describes the aerodynamics of a cricket ball, a baseball, and a golf ball. Details of these balls, together with typical flow conditions, are presented in Fig. 57.

A cricket ball has six rows of prominent stitching, with typically 60–80 stitches in each row (primary seam). The stitches lie along the equator holding the two leather hemispheres together. The better cricket balls are, in fact, made out of four pieces of leather, so that each hemisphere has a line of internal stitching forming a "secondary seam."

Detailed pressure distributions along the equator of a cricket ball are reproduced in Fig. 58. The measurements on the seam side of the ball, which is at an angle of attack of 20°, are those for which θ is positive. At low Reynolds numbers, i.e., the lowest velocity, the pressure distribution is symmetric, so there would be no side force. When $V=25$ m s^{-1}, the pressure distribution exhibits an asymmetry, which would cause the ball to swing to the right. The maximum pressure difference between the two sides occurs when $V=29$ m s^{-1}, when presumably the boundary layer on the seam side is fully turbulent while that on the nonseam side is still laminar. The actual (critical) flight speeds at which the asymmetry appears or disappears were found to be a function of the seam angle, surface roughness, and spin rate of the ball.

In the aerodynamics of golf balls, an important objective is to obtain maximum distance of flight. Thus, the lift force (which is generated by imparting backspin to the ball), the drag force, and the gravitational force are critical parameters. The effect of dimples is to lower the critical Reynolds number. As shown in the data of Achenbach (1972),

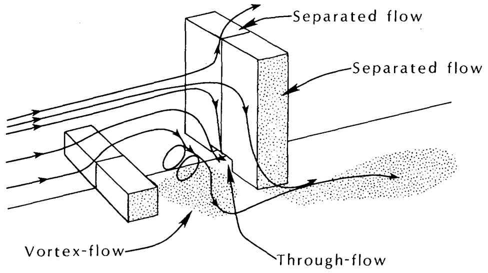

FIG. 56. Features of flow around adjacent buildings.

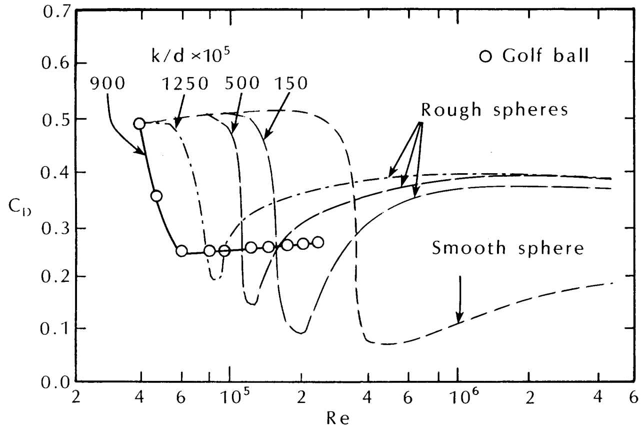

FIG. 59. Comparison of the drag for golf balls and for spheres with various heights of sand-grain roughness. The sand-grain roughness height is *k*, and *d* is the diameter of the ball. [From Achenbach (1972).]

which are reproduced in Fig. 59, dimples are more effective than sand-grain roughness at reducing the critical Reynolds numbers. The rapid rise in C_D for the sphere with sand-grain roughness is due to the forward movement of the transition point and the artificial thickening of the boundary layer by the roughness elements. The value of C_D for the golf ball does not rise in this way, which indicates that dimples are effective at tripping the boundary layer without causing the thickening associated with positive roughness. In golf, the Reynolds number changes continuously during flight, which means that C_D and C_L will also vary significantly.

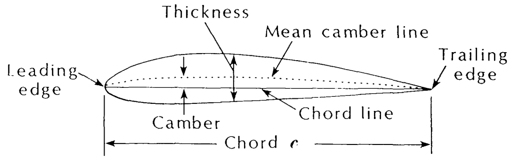
ACKNOWLEDGMENTS

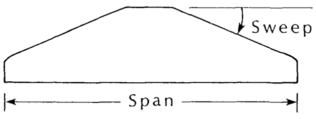
The authors would like to thank Jeanie Paterson for cheerfully typing the many drafts of this manuscript and Timothy Valdez for creatively illustrating the manuscript. The authors would also like to express their appreciation to DFSIV of the U.S. Air Force Academy for providing many of the photographs.

GLOSSARY

Aircraft Moments and Axes: The roll, pitch, and yaw moments and the vertical, lateral, and longitudinal axes are all illustrated in Fig. 19.

Airfoil Terminology: Standard terminology for the cross section of an airfoil is shown below:





Drag: Drag is discussed in Sec. 3.5. A summary of the types of drag is as follows: (i) *Friction drag or skin-friction drag* are synonomous terms. *Form drag* and *pressure drag* are also used interchangeably. Skin-friction drag and form drag are different components of "zero lift drag," caused by shear forces. (ii) *Vortex drag* is used interchangeably with *induced drag* and is the type of drag caused by lift. (iii) *Wave drag* is another type of drag. It is associated with compressibility effects at Mach numbers above 0.5.

INTRODUCTORY CONCEPTS

Definition of Aeronautics

Aeronautics is the name given to the general discipline of flight through the atmosphere. Aeronautics is synonymous with all aspects of the aircraft—the understanding of the principles of its flight, its design, and performance. The basic principles of aeronautics were of interest as early as the 15th century when Leonardo da Vinci (1452–1519) filled hundreds of pages of his notes with ideas and concepts for heavier-than-air flying machines. These involved designs with mechanically driven flapping wings—flapping for both lift and forward thrust. The first time that human beings left the ground in sustained flight was 21 November 1783, when a hot-air balloon designed by the Montgolfier brothers carried two people for thirty minutes across Paris. However, the first pivotal work on aeronautics, both as a science and with practical applications, was carried out by Sir George Cayley (1773–1857) in England. Cayley was the first person to make public the concept of the modern configuration airplane, namely, a vehicle with a fixed wing, fuselage, and tail. The fixed wing was for the production of lift; the mechanism of propulsion was considered by Cayley as a totally separate device. The tail was for stability. Although da Vinci made note late in his life that a flying machine with fixed wings, rather than flapping wings for both lift and propulsion, might be the appropriate approach for flying machine design, his notes were misplaced and were not available to the general scholarly audience until the 19th century. Hence it is George Cayley who deserves the credit for independently conceiving and building the first modern-concept flying machine in history—a yard-long, hand-launched glider in 1804. Moreover, he published two important scientific papers in 1809–1810 which were the first to point out the basic principles of flight. Cayley's ideas were extended by numerous investigators during the 19th century, and culminated in the work of Wilbur and Orville Wright, who achieved the first successful heavier-than-air,

sustained, controlled, manned flight on September 17, 1903, at Kill Devil Hills, near Kitty Hawk, North Carolina. This article will focus on such heavier-than-air machines, and therefore will deal primarily with aerodynamic phenomena.

The Source of Aerodynamic Force

A flight vehicle moving through the atmosphere experiences a net, resultant aerodynamic force exerted by the air on the vehicle. This force stems from two natural sources: the pressure distribution exerted by the airflow over the surface, and the shear stress due to frictional action between the airflow and the solid surface. Referring to Fig. 1, we see that pressure exerted by the gas on the solid surface of an object always acts *normal* to the surface, as shown by the directions of the arrows. The lengths of the arrows denote the magnitude of the pressure at each local point on the surface. Note that the surface pressure varies with location. The net *unbalance* of the varying pressure distribution over the surface creates a force, an aerodynamic force. The second source, shear stress acting on the surface, is due to the frictional effect of the flow "rubbing" against the surface as it moves around the body. The shear stress τ_w is defined as the force per unit area acting *tangentially* on the surface due to friction, as shown in Fig. 1. It is also a point property; it also varies along the surface; and the net unbalance of the surface shear stress distribution also creates an aerodynamic force on the body. *No matter how complex the flow field, and no matter how complex the shape of the body, the only way nature has of communicating an aerodynamic force to a solid object or surface is through the pressure and shear stress distributions which exist on the surface.* These are the basic fundamental sources of all aerodynamic forces.

Finally, we can state that a primary function of theoretical and experimental aerodynamics is to predict and measure the aerodynamic forces on a body. In many cases, this implies prediction and measurement of p and τ_w along a given surface. Furthermore, a prediction of p and τ_w on the surface frequently requires knowledge of the complete flow field around the body. This is the main function of the science of *aerodynamics*. (See AERODYNAMICS.)

The Standard Atmosphere

In order to standardize flight data and wind tunnel data in aeronautics, it is essential to have standardized values of atmospheric properties, namely, the variation of air pressure, density, and temperature with altitude. In reality, the properties of the real atmosphere depend on geographic location around the earth, time of day, season, and even solar sunspot activity. Indeed, the real atmosphere is always a dynamically changing system. However, the standard atmosphere is based on experimental data averaged over long periods of time, along with some judicious applications of the laws of physics, as explained below.

The keystone of the standard atmosphere is a *defined* variation of T with altitude, based on experimental evidence. This variation is shown in Fig. 2. Note that it consists of a series of straight lines, some vertical (called the constant-temperature, or *isothermal*, regions) and some inclined (called the *gradient* regions). Given $T=T(h)$ as defined by Fig. 2, where h is altitude, then $p=p(h)$ and $\rho=\rho(h)$ follow from the laws of physics. The first of these laws is the hydrostatic equation

$$dp=-\rho g\, dh,$$

where g is the acceleration of gravity, and the second is the equation of state for a perfect gas,

$$p=\rho RT.$$

From these equations, we obtain for the pressure and density variations in the isothermal regions

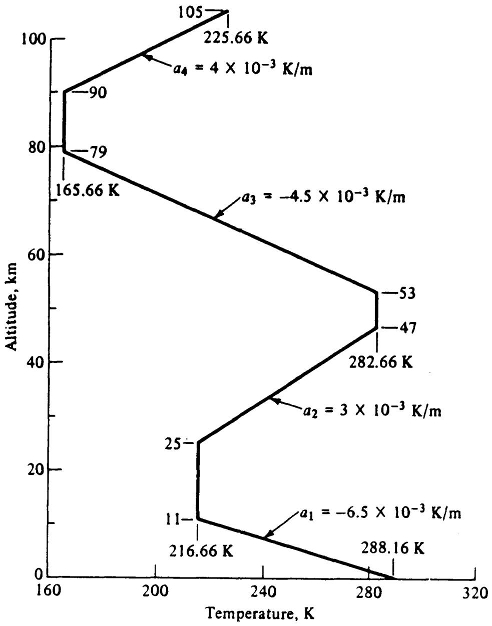

FIG. 2. Temperature distribution in the standard atmosphere. [From Anderson (1989).]

$$\frac{p}{p_1} = e^{-(g/RT)(h-h_1)}$$

and

$$\frac{\rho}{\rho_1} = e^{-(g/RT)(h-h_1)}.$$

In the gradient regions, we have

$$\frac{p}{p_1} = \left(\frac{T}{T_1}\right)^{-g/aR}$$

and

$$\frac{\rho}{\rho_1} = \left(\frac{T}{T_1}\right)^{-[(g/aR)+1]}.$$

Recall that in the gradient regions the variation of T is linear with altitude and is given by the specified relation

$$T = T_1 + a(h - h_1),$$

where a is the *lapse rate*, $a = dT/dh$. The standard atmosphere is pieced together from the above equations, starting from the standard sea level values of pressure, density, and temperature, which are

$$p_s = 1.0135 \times 10^5 \text{ N/m}^2 = 2116.2 \text{ lb/ft}^2,$$

$$\rho_s = 1.2250 \text{ kg/m}^3 = 0.002\,377 \text{ slug/ft}^3,$$

$$T_s = 288.16 \text{ K} = 518.69\ {}^\circ\text{R}.$$

Tables of the standard atmosphere are available in most technical libraries.

Historical Note

The driving philosophy of many advancements in aeronautics since 1903 has been to fly *faster and higher.* This is dramatically evident from Fig. 3, which gives the flight speeds for typical aircraft as a function of chronological time. Note the continued push for increased speed over the years, and the particular increase in recent years made possible by the jet engine. Singled out in Fig. 3 are the winners of the Schneider Cup races between 1913 and 1931 (with a moratorium during World War I). The Schneider Cup races were started in 1913 by Jacques Schneider of France as a stimulus to the development of high-speed float planes. They prompted some early but advanced development of high-speed aircraft. The winners are shown by the dashed line in Fig. 3, for comparison with standard aircraft of the day. Indeed, the winner of the last Schneider race in 1931 was the Supermarine S.6B, a forerunner of the famous Spitfire of World War II. Of course, today the maximum speed of flight has been pushed to the extreme value of 36 000 ft/s, escape velocity from the earth, by the Apollo lunar spacecraft.

As a companion to speed, the maximum altitudes of typical manned aircraft are shown in Fig. 4 as a function of chronological time. The same push to higher values is evident; so far, the record is the moon in 1969.

1. AERODYNAMICS OF THE AIRPLANE

1.1 Basic Airfoil Characteristics

The aerodynamic properties of a complete airplane are a synthesis of the properties of its parts—the wing, fuselage, tail, engine nacelle, etc. To describe the aerodynamics of the airplane, we start with the primary lifting surface, namely, the wing. The cross-sectional shape of the wing is called an *airfoil.* Such an airfoil is sketched in Fig. 5, which defines some basic terminology. The major design feature of an airfoil is the *mean camber line,* which is the locus of points halfway between

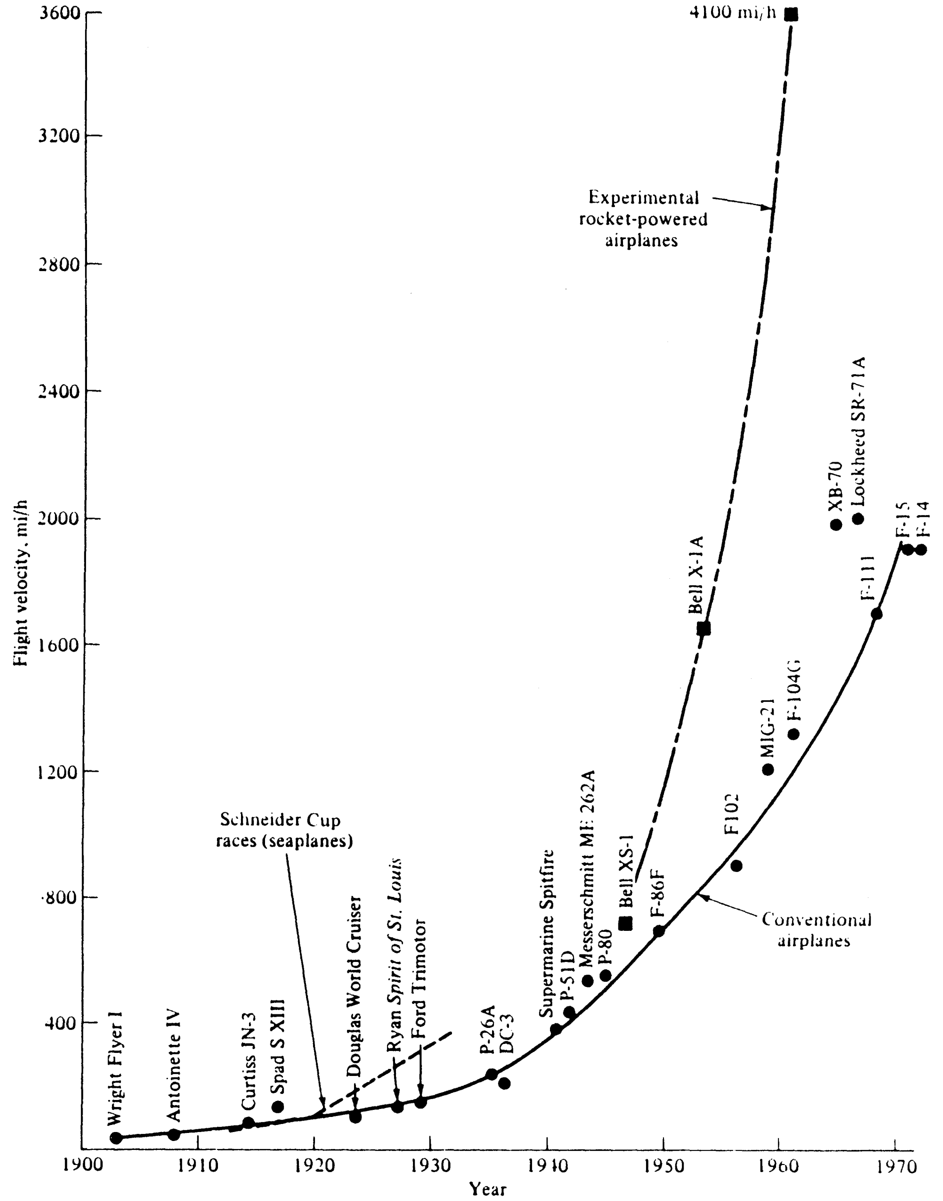

FIG. 3. Typical flight velocities over the years. [From Anderson (1989).]

the upper and lower surfaces as measured perpendicular to the mean camber line itself. The most forward and rearward points of the mean camber line are the *leading* and *trailing edges*, respectively. The straight line connecting the leading and trailing edges is the *chord line* of the airfoil, and the precise distance from the leading to the trailing edge measured along the chord line is simply designated the *chord* of the airfoil, given by the symbol *c*. The *camber* is the maximum distance between the mean camber line and the chord line, measured perpendicular to the chord line. The camber, the shape of the mean camber line, and, to a lesser extent, the thickness distribution of the airfoil essentially control the lift and moment characteristics of the airfoil.

More definitions are illustrated in Fig. 6, which shows an airfoil inclined to a stream of

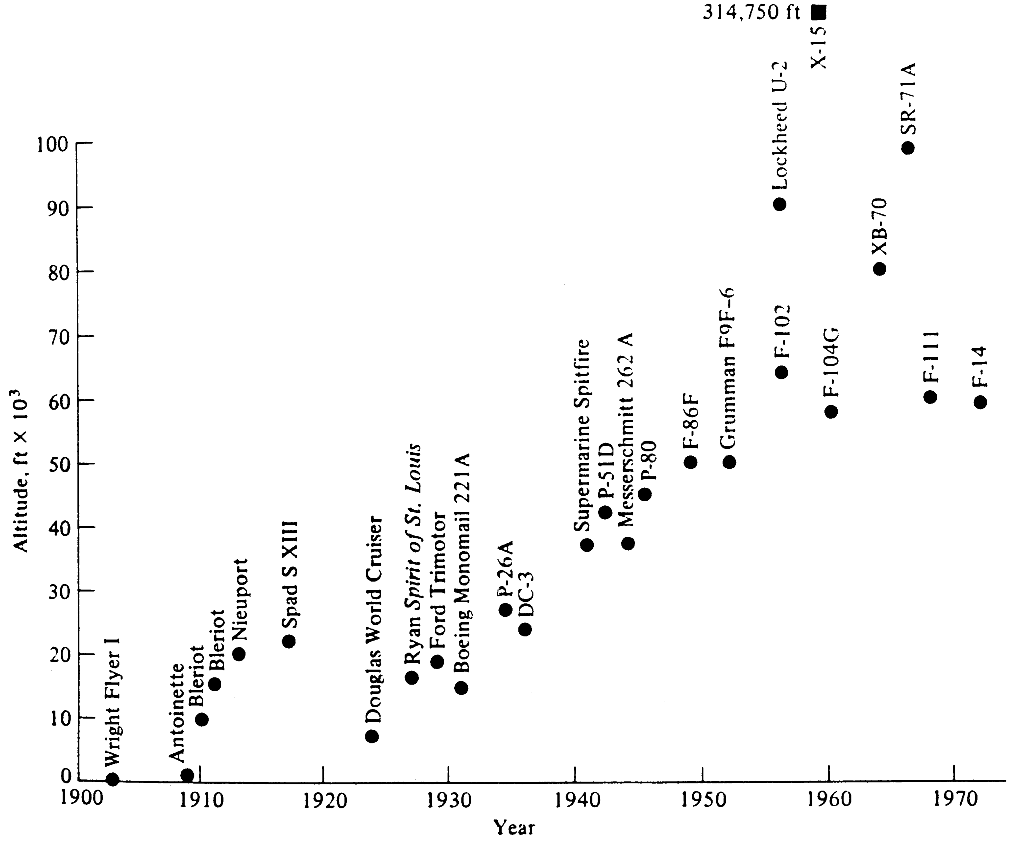

FIG. 4. Typical flight altitudes over the years. [From Anderson (1989).]

air. The freestream velocity V_∞ is the velocity of the air far upstream of the airfoil. The *direction* of V_∞ is defined as the *relative wind.* The angle between the relative wind and the chord line is the *angle of attack* α of the airfoil. As described earlier, there is an aerodynamic force created by the pressure and shear stress distributions over the wing surface. This resultant force is shown by the vector *R* in Fig. 6. In turn, the aerodynamic force *R* can be resolved into two forces, parallel and perpendicular to the relative wind. The *drag D* is always defined as the component of the aerodynamic force *parallel to the relative wind.* The *lift L* is always defined as the component of the aerodynamic force *perpendicular to the relative wind.*

In addition to lift and drag, the surface pressure and shear stress distributions also create a *moment M* which tends to *rotate* the

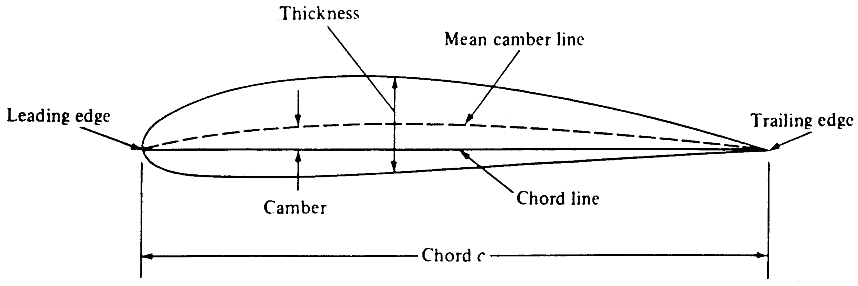

FIG. 5. Airfoil nomenclature. The shape shown here is a NACA 4415 airfoil. [From Anderson (1989).]

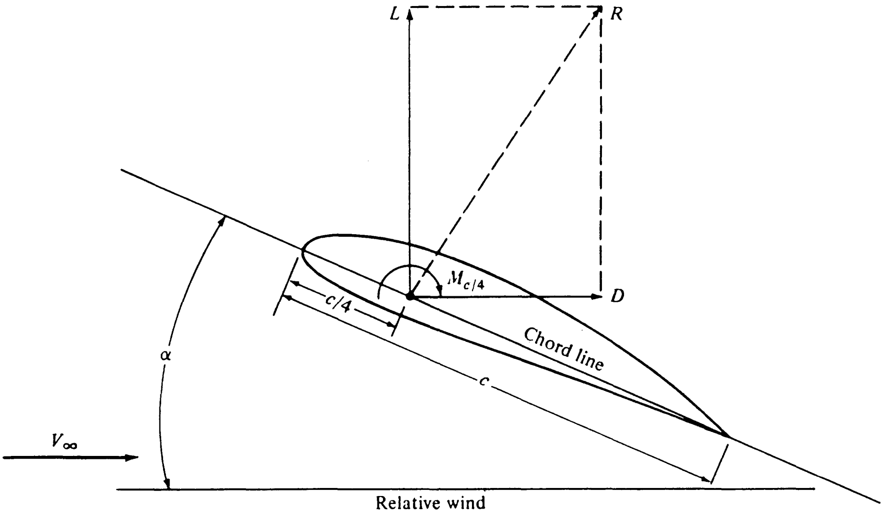

FIG. 6. Sketch showing the definitions of lift, drag, moments, angle of attack, and relative wind. [From Anderson (1989).]

wing. To see more clearly how this moment is created, consider the surface pressure distribution over an airfoil (we will ignore the shear stress for this discussion). Consider just the pressure on the top surface of the airfoil. This pressure gives rise to a net force F_1 in the general downward direction. Moreover, F_1 acts through a given point on the chord line, point 1, which can be found by integrating the pressure times distance over the surface (analogous to finding the centroid or center of pressure from integral calculus). Now consider just the pressure on the bottom surface of the airfoil. This pressure gives rise to a net force F_2 in the general upward direction, acting through point 2, where point 2 is generally a different location than point 1 on the airfoil. The total aerodynamic force on the airfoil is the *summation* of F_1 and F_2, and lift is obtained when $F_2 > F_1$. However, F_1 and F_2 will create a moment which will tend to rotate the airfoil. Moreover, the value of this aerodynamically induced moment depends on the point about which we chose to take moments. For example, if we take moments about the leading edge, the aerodynamic moment is designated M_{LE}. It is more common in the case of subsonic airfoils to take moments about a point on the chord at a distance $c/4$ from the leading edge, the *quarter-chord point*, as illustrated in Fig. 6. This moment about the quarter chord is designated $M_{c/4}$. In general, $M_{\mathrm{LE}} \neq M_{c/4}$. Intuition will tell you that lift, drag, and moments on a wing will change as the angle of attack α changes. In fact, the variations of these aerodynamic quantities with α represent some of the most important information that an airplane designer needs to know. We will address this matter in the following sections. However, it should be pointed out that, although M_{LE} and $M_{c/4}$ are both functions of α, there exists a certain point on the airfoil about which moments essentially *do not* vary with α. This point is defined as the *aerodynamic center*, and the moment about the aerodynamic center is designated M_{ac}. By definition,

$$M_{\mathrm{ac}} = \text{const}$$

independent of angle of attack. The location of the aerodynamic center for real aerodynamic shapes can be found from experiment. For low-speed subsonic airfoils, the aerodynamic center is generally very close to the quarter-chord point.

1.2 Lift, Drag, and Moment Coefficients

For an airfoil, it is convenient to define the lift, drag, and moment as those acting on a unit span of a wing, i.e., *L*, *D*, and *M* discussed earlier are per unit span. Referring again to Fig. 6, we visualize a section of a wing which extends a unit length perpendicular to the page. In turn, we can define a reference area,

S, as the planform area of this unit span, i.e., the projected area as seen looking down on the wing from above. Hence, $S=c\times 1=c$. Also, the freestream dynamic pressure, q_∞, is defined as $q_\infty=\frac{1}{2}\rho_\infty V_\infty^2$. With these quantities, nondimensional aerodynamic force and moment coefficients are defined as follows:

lift coefficient,

$$c_l=L/q_\infty S=L/q_\infty c; \tag{1}$$

drag coefficient,

$$c_d=D/q_\infty S=D/q_\infty c; \tag{2}$$

moment coefficient,

$$c_m=M/q_\infty Sc=M/q_\infty c^2. \tag{3}$$

In addition to their being dimensionless numbers, the use of c_l, c_d, and c_m is very fundamental to the science of aerodynamics. Dimensional analysis shows that, for a given shaped body, c_l, c_d, and c_m depend on angle of attack, α, and the dimensionless parameters, Mach number M and Reynolds number Re. The freestream Mach number is defined as

$$M_\infty=V_\infty/a_\infty,$$

where a_∞ is the freestream speed of sound, and the freestream Reynolds number is defined as

$$\mathrm{Re}=\rho_\infty V_\infty c/\mu_\infty$$

where μ_∞ is the coefficient of viscosity of the free stream. The results of dimensional analysis show that

$$c_l=f_1(\alpha,M_\infty,\mathrm{Re}), \tag{4}$$

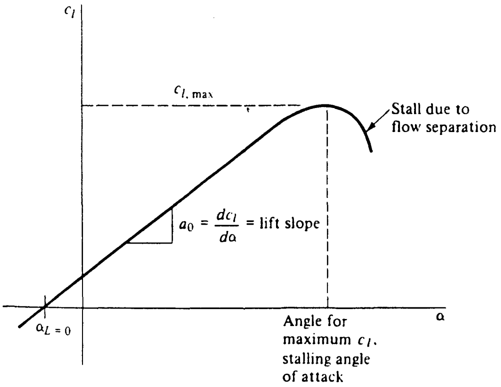
$$c_d=f_2(\alpha,M_\infty,\mathrm{Re}), \tag{5}$$

$$c_m=f_3(\alpha,M_\infty,\mathrm{Re}). \tag{6}$$

This is a powerful result. It is the basis of the concept of *dynamic similarity* between two different flows. That is, for two flows with different freestream velocities, densities, and temperatures, over two geometrically similar bodies of different sizes at the same angle of attack, the lift, drag, and moment coefficients obtained with the two different flows will be the *same* as long as M_∞ and Re are the *same for the two different flows.* This dynamic similarity principle is used to relate the values of aerodynamic coefficients measured in a wind tunnel to those in free flight through the atmosphere. Specifically, if in the wind tunnel, the free-flight values of M_∞ and Re are reproduced, then c_l, c_d, and c_m measured in the wind tunnel will be the same as obtained in free flight. In this context, M_∞ and Re are called *similarity parameters.* More detailed considerations that apply to compressible viscous flows involve additional similarity parameters: ratio of specific heats, $\gamma=c_p/c_v$; Prandtl number, $\mathrm{Pr}=\mu\, c_p/k$; and the wall-to-freestream temperature ratio, T_w/T_∞, where c_p and c_v are the specific heats at constant pressure and constant volume, respectively, and k is the thermal conductivity. However, for considerations of lift, drag, and moment coefficients, M_∞ and Re are the dominant similarity parameters.

Reflecting for an instant, we find there may appear to be a conflict in our aerodynamic philosophy. On the one hand, we emphasized that lift, drag, and moments on an aerodynamic shape stem from the detailed pressure and shear stress distributions on the surface and that measurements and/or calculations of these distributions, especially for complex configurations, are not trivial undertakings. On the other hand, Eqs. (1)–(3) indicate that lift, drag, and moments can be quickly obtained from simple formulas. The bridge between these two outlooks is, of course, the lift, drag, and moment coefficients. All the physical complexity of the flow field around an aerodynamic body is implicitly buried in c_l, c_d, and c_m. Before the simple Eqs. (1)–(3) can be used to calculate lift, drag, and moments for an airfoil, wing, or body, the appropriate aerodynamic coefficient must be known. From this point of view, the simplicity of Eqs. (1)–(3) is a bit deceptive. These equations simply shift the forces of aerodynamic rigor from the forces and moments themselves to the appropriate coefficients instead. So we are now led to the following questions: How do we obtain values of c_l, c_d, and c_m for given configurations and how do they vary with α, M_∞, and Re? The answers are introduced in the following paragraphs.

A goal of theoretical aerodynamics is to predict values of c_l, c_d, and c_m from the basic equations and concepts of physical science, some of which were discussed in previous chapters. However, simplifying assumptions are usually necessary to make the mathematics tractable. Therefore, when theoretical results are obtained, they are generally not "exact." The use of high-speed digital computers to solve the governing flow equations is now



c_l
$c_{l,\max}$
Stall due to flow separation
$a_0 = \frac{dc_l}{d\alpha}$ = lift slope
$\alpha_{L=0}$
Angle for maximum c_l, stalling angle of attack
α

FIG. 7. Sketch of a typical lift curve. [From Anderson (1989).]

bringing us much closer to the accurate calculation of aerodynamic characteristics; however, there are still limitations imposed by the numerical methods themselves, and the storage and speed capacity of current computers is still not sufficient to solve many complex aerodynamic flows. As a result, the practical aerodynamicist has to rely upon direct *experimental* measurements of c_l, c_d, and c_m for specific bodies of interest.

A large bulk of experimental airfoil data was compiled over the years by the National Advisory Committee for Aeronautics (NACA), which was absorbed in the creation of the National Aeronautics and Space Administration (NASA) in 1958. Lift, drag, and moment coefficients were systematically measured for many airfoil shapes in low-speed subsonic wind tunnels. These measurements were carried out on straight, constant-chord wings which completely spanned the tunnel test section from one side wall to the other. In this fashion, the flow essentially "saw" a wing with no wingtips, and the experimental airfoil data were thus obtained for "infinite wings." (The distinction between infinite and finite wings will be made in subsequent sections.)

Let us examine the variation of c_l with α more closely. This variation is sketched in Fig. 7. The experimental data indicate that c_l varies *linearly* with α over a large range of angle of attack. Thin-airfoil theory, which is the subject of advanced books on aerodynamics, also predicts the same type of linear variation. The slope of the linear portion of the lift curve is designated as $a_0 \equiv dc_l/d\alpha \equiv$ lift slope. Note that in Fig. 7, when $\alpha = 0$, there is still a positive value of c_l, that is, there is still some lift even when the airfoil is at zero angle of attack to the flow. This is due to the positive camber of the airfoil. All airfoils with such camber have to be pitched to some negative angle of attack before zero lift is obtained. The value of α when lift is zero is defined as *zero lift angle of attack* $\alpha_{L=0}$ and is illustrated in Fig. 7. Refer again to Fig. 7, at the other extreme: for large values of α, the linearity of the lift curve breaks down. As α is increased beyond a certain value, c_l peaks at some maximum value, $c_{l,\max}$, and then drops precipitously as α is further increased. In this situation, where the lift is rapidly decreasing at high α, the airfoil is *stalled.*

The phenomenon of airfoil stall is of critical importance in airplane design. It is caused by flow separation on the upper surface of the airfoil. This is illustrated in Fig. 8, which again shows the variation of c_l vs α for an airfoil. At point 1 on the linear portion of the lift curve, the flow field over the airfoil is attached to the surface, as pictured in Fig. 8. However, the effect of friction is to slow the airflow near the surface; in the presence of an adverse pressure gradient, there will be a tendency for this viscous boundary layer adjacent to the surface to separate from the surface. As the angle of attack is increased, the adverse pressure gradient on the top surface of the airfoil will become stronger, and at some value of α—the stalling angle of attack—the flow becomes separated from the top surface. When separation occurs, the lift decreases drastically and the drag increases suddenly. This is the picture associated with point 2 in Fig. 8.

The lift curves sketched in Figs. 7 and 8 illustrate the type of variation observed experimentally in the data measured by the NACA. A sample of these data is shown in Figs. 9 and 10 for a particular airfoil denoted as the NACA 2412 airfoil. The code for these curves is given in Fig. 10. Note in Fig. 9 that the lift curves are all virtually linear up to the stall. Also note that c_l vs α is given for three different values of the Reynolds number from 3.1×10^6 to 8.9×10^6. The lift curves for all three values of Re fall on top of each other in the linear region, i.e., Re has little influence on c_l when the flow is attached. However, flow separation is a viscous effect, and Re is a governing parameter for viscous flow. Therefore, it is not surprising that the experimental

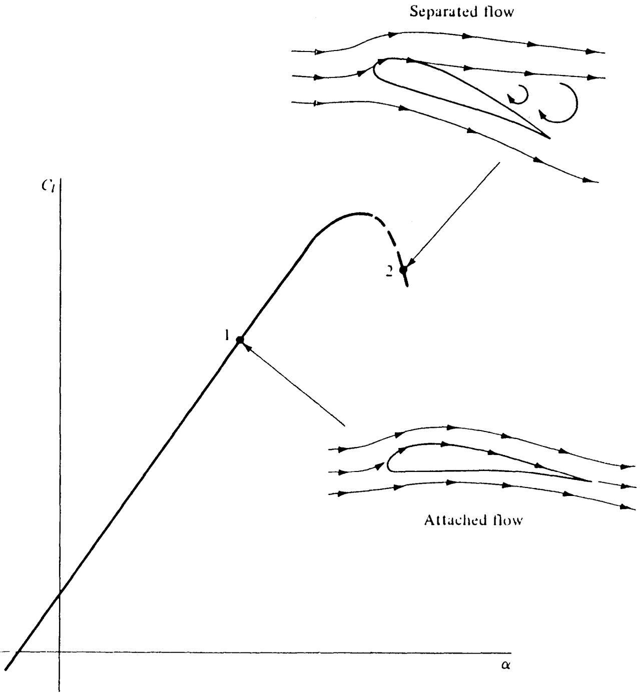


FIG. 8. Flow mechanism associated with stalling. [From Anderson (1989).]

data for $c_{l_{\max}}$ in the stalling region are affected by Re, as can be seen by the slightly different variations of c_l at high α for different values of Re. In fact, these lift curves at different Re answer part of the question posed in Eq. (4): the data represent $c_l = f(\text{Re})$. Again, Re exerts little or no effect on c_l except in the stalling region.

The variation of $c_{m,c/4}$ vs α is also given in Fig. 9. It has only a slight variation with α and is almost completely unaffected by Re. Also note that the values of $c_{m,c/4}$ are slightly negative. By convention, a positive moment is in a clockwise direction; it pitches the airfoil towards larger angles of attack, as shown in Fig. 6. Therefore, for the NACA 2412 airfoil, with $c_{m,c/4}$ negative, the moments are counterclockwise, and the airfoil tends to pitch downward. This is characteristic of all airfoils with positive camber.

The variation of c_d and $c_{m,ac}$ is given versus c_l in Fig. 10. Because c_l varies linearly with α as well, the shapes will be the same. Note that the drag curves have a "bucket" type of shape, with minimum drag occurring at small values of c_l (i.e., minimum drag occurs at small angles of attack). As α goes to large negative or positive values, c_d increases. Also note that c_d is strongly affected by Re, there being a distinct drag curve for each Re. This is to be expected because the drag for a slender aerodynamic shape is mainly skin friction drag, and Re strongly governs skin friction. With regard to $c_{m,\text{ac}}$ the definition of the aerodynamic center is clearly evident; $c_{m,\text{ac}}$ is constant with respect to α. Also, it is insensitive to Re and has a small negative value.

Refer to Eqs. (4)–(6); the airfoil data in Figs. 9 and 10 experimentally provide the variation of c_l, c_d, and c_m with α and Re. The effect of M_∞ on the airfoil coefficients will be discussed later. However, emphasis is made that the data in Figs. 9 and 10 were measured in low-speed subsonic wind tunnels. Hence, the flow was essentially incompressible. Thus, c_l, $c_{m,c/4}$, c_d, and $c_{m,ac}$ given in Figs. 9 and 10 are low speed, incompressible flow values. The final question associated with Eqs. (4)–(6), namely, how do the aerodynamic coefficients vary with Mach number, M_∞, requires some extended discussion, as given in the following paragraphs.

To understand the variation of lift and drag coefficients with Mach number, we first introduce the concept of the *critical* Mach number, denoted by M_{cr}. Consider the flow over an airfoil. As the gas expands around the top surface near the leading edge, the velocity and hence the Mach number will increase rapidly. Indeed, there are regions on the air-

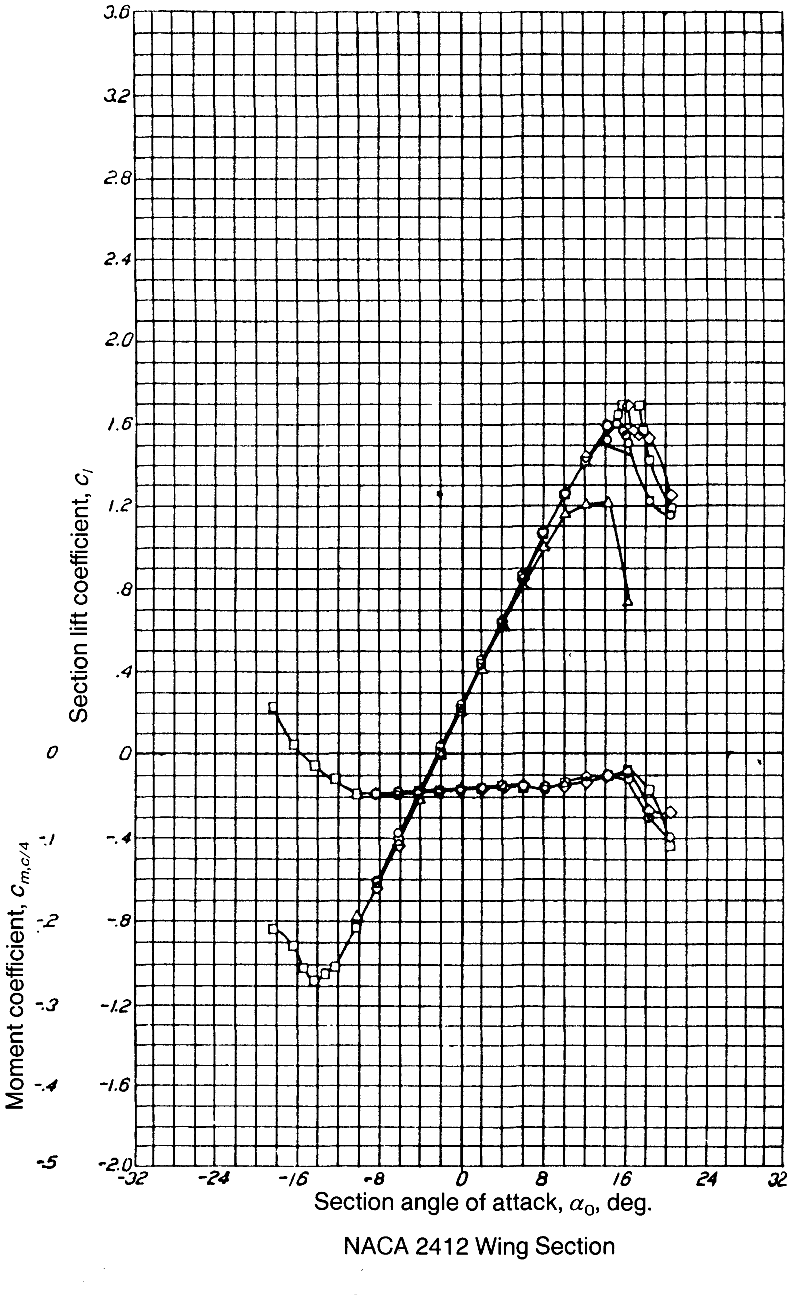

FIG. 9. Lift and moment coefficient curves for an NACA 2412 Wing Section. The moment coefficient is about the quarter-chord. [From Abbott and von Doenhoff (1949).]

foil surface where the local Mach number is greater than M_∞. Imagine that we put a given airfoil in a wind tunnel where $M_\infty = 0.3$ and that we observe the peak local Mach number on the top surface of the airfoil to be 0.435. This is sketched in Fig. 11(a). Imagine that we now increase M_∞ to 0.5; the peak local Mach number will correspondingly increase to 0.772, as shown in Fig. 11(b). If we further increase M_∞ to a value of 0.61, we observe that the peak local Mach number is 1.0, locally sonic flow on the surface of the airfoil. This is sketched in Fig. 11(c). Note that the flow over an airfoil can locally be sonic (or higher), even though the freestream Mach number is subsonic. By definition, that freestream Mach

FIG. 10. Drag and moment coefficients for an NACA 2412 airfoil. The moment coefficient is about the aerodynamic center. [From Anderson (1989).]

number at which sonic flow is first obtained somewhere on the airfoil surface is called the *critical Mach number* of the airfoil. In the above example, the critical Mach number M_{cr} for the airfoil is 0.61. M_{cr} is an important quantity, because at some freestream Mach number above M_{cr} the airfoil will experience a dramatic increase in drag. Figure 12 sketches the variation of c_d with M_∞. At low Mach numbers, less than M_{cr}, c_d is virtually constant and is equal to its low-speed value given in Fig. 10. The flow field about the airfoil for this condition (say, point *a* in Fig. 12) is noted in Fig. 13(a), where $M < 1$ everywhere in the flow. If M_∞ is increased slightly above M_{cr}, a "bubble" of supersonic flow will occur

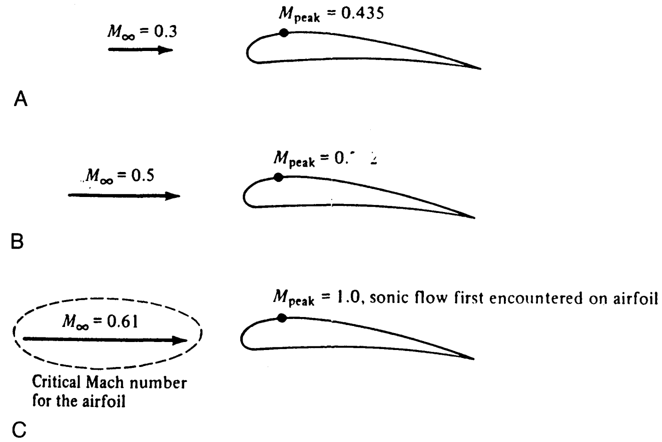

FIG. 11. Illustration of critical Mach number. [From Anderson (1989).]

surrounding the minimum pressure point as shown in Fig. 13(b). Correspondingly, c_d will still remain reasonably low, as indicated by point *b* in Fig. 12. However, if M_∞ is still further increased, a very sudden and dramatic rise in the drag coefficient will be observed, as noted by point *c* in Fig. 12. Here, shock waves suddenly appear in the flow, as sketched in Fig. 13(c). The shock waves themselves are dissipative phenomena, which result in an increase in drag on the airfoil. But in addition, the sharp pressure increase across the shock waves creates a strong adverse pressure gradient, hence causing the flow to separate from the surface. Such flow separation can create substantial increases in drag. Thus, the sharp increase in c_d shown in Fig. 12 is a combined effect of shock waves and flow separation. The *freestream* Mach number at which c_d begins to increase rapidly is defined as the *drag-divergence* Mach number and is noted in Fig. 12. Note that

$$M_{\mathrm{cr}} < M_{\text{drag-divergence}} < 1.0.$$

The shock pattern sketched in Fig. 13(c) is characteristic of a flight regime called transonic. When $0.8 \leqslant M_\infty \leqslant 1.2$, the flow is generally designated as transonic flow and it is characterized by some very complex effects only hinted at in Fig. 13(c). To reinforce these comments, Fig. 14 shows the variation of both c_l and c_d as a function of Mach number with angle of attack as a parameter. The airfoil is a standard NACA 2315 airfoil. Figure 14, which shows actual wind-tunnel data, illustrates the massive transonic-flow effects on both lift and drag coefficients. The analysis of transonic flows has been one of the major challenges in modern aerodynamics. Only in recent years, since about 1970, have com-

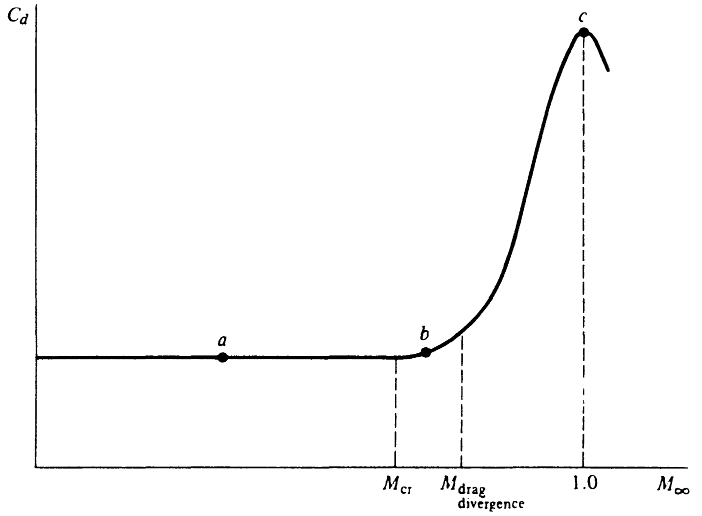

FIG. 12. Variation of drag coefficient with Mach number. [From Anderson (1989).]

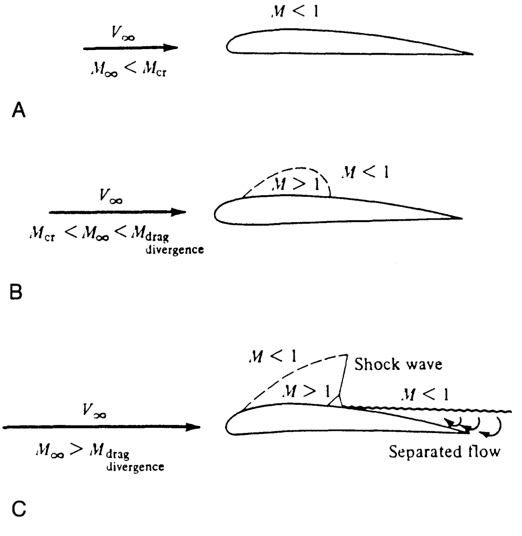

FIG. 13. Physical mechanism of drag divergence. (a) Flow field associated with point *a* in Fig. 12. (b) Flow field associated with point *b* in Fig. 12. (c) Flow field associated with point *c* in Fig. 12. [From Anderson (1989).]

puter solutions for transonic flows over airfoils come into practical use; these numerical solutions are still in a state of development and improvement.

The airfoils on modern subsonic jet aircraft, such as the McDonnell-Douglas DC-10 wide-body transport, are relatively thin profiles designed to increase the drag-divergence Mach number. In fact, NASA (mainly under the direction of Richard Whitcomb at the Langley Research Center) has developed a new *supercritical* airfoil, designed to place the drag-divergence Mach number extremely close to 1.0. Supercritical airfoils are of the general shape shown in Fig. 15. Here, the maximum thickness is designed close to the trailing edge. The flow over the airfoil is largely supersonic, and the airfoil shape is designed to discourage the formation of shock waves.

These considerations of M_{cr} and drag-divergence Mach number are important to subsonic transport design. The cruising

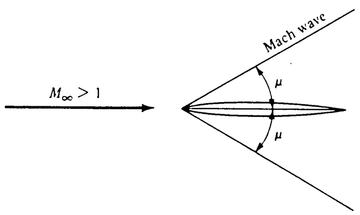

FIG. 16. Mach waves on a needlelike body. [From Anderson (1989).]

speeds of such airplanes can be increased by incorporating airfoils with high values of $M_{\text{drag-divergence}}$. Alternatively, in the spirit of energy conservation, supercritical airfoils should allow less drag, hence less fuel consumption, at the same cruising speed. In either case, the advantages are obvious, and this helps to explain why there has been a modern resurgence of interest in high-speed airfoil design.

As a final note in this section, the next time you have an opportunity to fly in a jet airliner and the sun is directly overhead (around noon and early afternoon), look out along the span of the wing. Due to the refraction of light waves through shock waves, you can sometimes see with the naked eye the transonic shock waves dancing about on the wing surface.

The preceding discussion has highlighted the variation of c_d with M_∞, where M_∞ ranges from low values near zero up to the transonic range around Mach one. In regard to the variation of lift coefficient with M_∞ for this same Mach number range, Fig. 14(a) gives typical results. Indeed, an approximate formula for the Mach number variation of c_l is given by the *Prandtl–Glauert rule,*

$$c_l = c_{l_0} / \sqrt{1 - M_\infty^2},$$

where c_{l_0} is the low speed, incompressible flow value of the airfoil lift coefficient. The moment coefficient also obeys the Prandtl–Glauert rule,

$$c_m = c_{m_0} / \sqrt{1 - M_\infty^2}.$$

The Prandtl–Glauert rule is based on subsonic thin airfoil theory; it is an approximate result that holds reasonably well for freestream Mach numbers less than 0.7. The Prandtl–Glauert rule is an example of a *compressibility correction,* intended to modify low speed, incompressible flow data to take into account the effects of compressibility at higher subsonic speeds. For more accuracy near Mach one, other, more sophisticated, compressibility corrections are available.

When the freestream Mach number is supersonic, shock waves will occur around the aerodynamic body; these shock waves create an additional source of drag called *wave drag.* Let us examine the source of this wave drag more closely.

A very thin object (such as a thin needle) moving at supersonic speeds ($M_\infty > 1$) creates a very weak disturbance in the flow, limited to a *Mach wave,* which makes the Mach angle μ with respect to the freestream direction. A Mach wave is illustrated in Fig. 16, where the Mach angle μ is defined as

$$\mu = \arcsin(1/M_\infty).$$

On the other hand, an object with some reasonable thickness, such as the wedge shown in Fig. 17, moving at supersonic speeds will create a strong disturbance called a *shock wave.* The shock wave will be inclined at an oblique angle β, where $\beta > \mu$, as shown in Fig. 17. As the flow moves across the oblique shock wave, the pressure, temperature, and density increase, and the velocity and Mach number decrease.

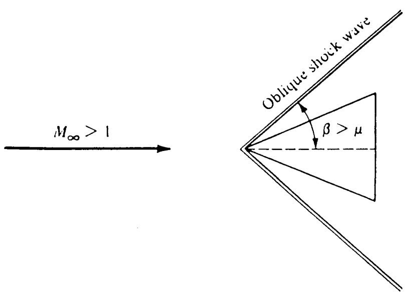

FIG. 17. Oblique shock waves on a wedge-type body. [From Anderson (1989).]

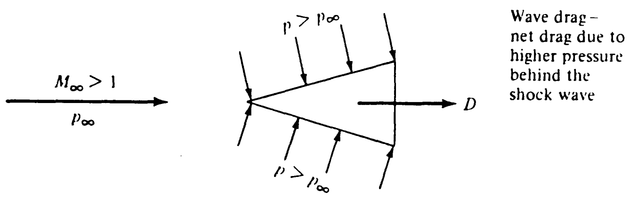

$p > p_\infty$
$M_\infty > 1$
p_∞
D
$p > p_\infty$
Wave drag – net drag due to higher pressure behind the shock wave

FIG. 18. Pressure distribution on a wedge at supersonic speeds; origin of wave drag. [From Anderson (1989).]

Consider now the pressure on the surface of the wedge, as sketched in Fig. 18. Since p increases across the oblique shock wave, then at the wedge surface, $p > p_\infty$. Since the pressure acts normal to the surface and the surface itself is inclined to the relative wind, there will be a net drag produced on the wedge, as seen by simple inspection of Fig. 18. This drag is called *wave drag*, because it is inherently due to the pressure increase across the shock wave.

In order to minimize the strength of the shock wave, all supersonic airfoil profiles are thin, with relatively sharp leading edges. (The leading edge of the Lockheed F-104 supersonic fighter is almost razor thin.) Let us approximate a thin supersonic airfoil by the flat plate illustrated in Fig. 19. The flat plate is inclined at a small angle of attack α to the supersonic freestream. On the top surface of the plate, the flow field is turned away from the freestream through an *expansion wave* at the leading edge; an expansion wave is a fan-shaped region through which the pressure decreases. At the trailing edge on the top side, the flow is turned back into the freestream direction through an oblique shock wave. On the bottom surface of the plate, the flow is turned into the freestream, causing an oblique shock wave with an increase in pressure. At the trailing edge, the flow is turned back to the freestream direction through an expansion wave. The expansion and shock waves at the leading edge result in a surface pressure distribution where the pressure on the top surface is less than p_∞, whereas the pressure on the bottom surface is greater than p_∞. The net effect is an aerodynamic force normal to the plate. The components of this force perpendicular and parallel to the relative wind are the lift and supersonic wave drag, respectively. Approximate relations for lift and drag coefficients are

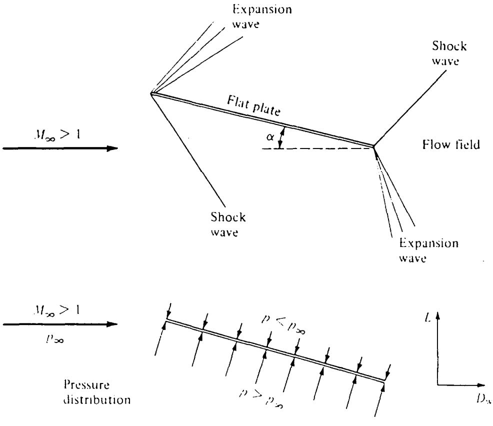

FIG. 19. Flow field and pressure distribution for a flat plate at angle of attack in supersonic flow. There is a net lift and drag due to the pressure distribution set up by the shock and expansion waves. [From Anderson (1989).]

$$c_l = 4\alpha/(M_\infty^2 - 1)^{1/2} \tag{7}$$

and

$$c_{d,w} = 4\alpha^2/(M_\infty^2 - 1)^{1/2}. \tag{8}$$

A subscript w has been added to the drag coefficient to emphasize that it is the wave drag coefficient. These are approximate expressions, useful for thin airfoils at small to moderate angles of attack in supersonic flow. Note that as M_∞ increases, both c_l and c_d decrease. This is not to say that the lift and drag forces themselves decrease with M_∞. Quite the contrary: for any flight regime, as the flight velocity increases, L and D usually increase because the dynamic pressure $q_\infty = \frac{1}{2}\rho V_\infty^2$ increases. In the supersonic regime, L and D increase with velocity, even though c_l and $c_{d,w}$ decrease with M_∞.

In summary, this section has discussed the definition and meaning of lift, drag, and moment coefficients, as well as their variations with angle of attack, Reynolds number, and Mach number. Of particular importance is the variation of drag coefficient with Mach number. To amplify on the aspects of drag, we can write the total drag of an airfoil as the sum of three contributions:

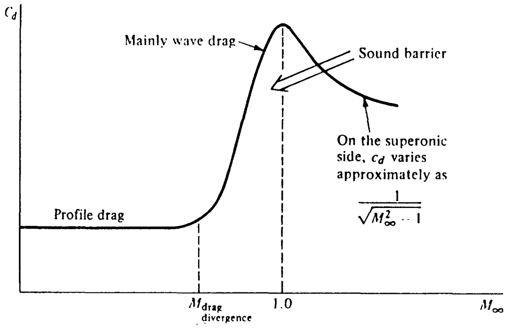

FIG. 20. Variation of drag coefficient with Mach number for subsonic and supersonic speeds. [From Anderson (1989).]

$$D_f + D_p + D_w,$$

where D=total drag on the airfoil, D_f=skin friction drag, D_p=pressure drag due to flow separation, and D_w=wave drag (present only at transonic and supersonic speeds; zero for subsonic speeds below the drag-divergence Mach number).

In terms of the drag coefficients, we can write

$$c_d = c_{d,f} + c_{d,p} + c_{d,w},$$

where c_d, $c_{d,f}$, $c_{d,p}$, and $c_{d,w}$ are the total drag, skin friction drag, pressure drag, and wave drag coefficients, respectively. The sum $c_{d,f} + c_{d,p}$ is called the *profile drag coefficient*; this is the quantity that is given by the data in Fig. 10. The profile drag coefficient is relatively constant with M_∞ at subsonic speeds.

The variation of c_d with M_∞ from incompressible to supersonic speeds is sketched in Fig. 20. It is important to note the qualitative variation of this curve. For M_∞ ranging from zero to drag divergence, c_d is relatively constant; it consists entirely of profile drag. For M_∞ from drag divergence to slightly above 1, the value of c_d skyrockets; indeed, the peak value of c_d around $M_\infty = 1$ can be an order of magnitude larger than the profile drag itself. This large increase in c_d is due to wave drag associated with the presence of shock waves. For supersonic Mach numbers, c_d decreases approximately as $(M_\infty^2 - 1)^{-1/2}$.

The large increase in the drag coefficient near Mach 1 gave rise to the term "sound barrier" in the 1940s. There was a camp of professionals who at that time felt that the sound barrier could not be pierced, that we could not fly faster than the speed of sound. Certainly, a glance at Eq. (8) for wave drag in supersonic flow would hint that the drag coefficient might become infinitely large as M_∞ approaches 1. However, such reasoning is an example of a common pitfall in science and engineering, namely, the application of equations outside their ranges of validity. Equation (8) is not valid in the transonic range near $M_\infty = 1$. Moreover, remember that nature abhors infinities. In real life, c_d does not become infinitely large. To get past the sound barrier, all that is needed (in principle) is an engine with enough thrust to overcome the high (but finite) drag.

1.3 Finite Wing Properties: Induced Drag

The airfoil properties discussed in the previous section apply to a wing which stretches to infinity along the span direction, i.e., there are no wingtips. Hence, airfoil data is frequently called *infinite wing* data. On the other hand, all real airplanes have wings that are finite in extent—so-called *finite wings*. The most important geometric parameter for a finite wing is the *aspect ratio*, AR, defined as

$$\text{Aspect ratio} = \text{AR} \equiv b^2/S,$$

where b is the *wing span*, i.e., the distance between the two wingtips, and S is the planform area (projected top-view area) of the wing.

The flow field about a finite wing is three-dimensional and is therefore inherently different from the two-dimensional flow about an infinite wing. As a result, the lift, drag, and moment coefficients for a finite wing with a given airfoil shape at a given α are different from the lift, drag, and moment coefficients for an infinite wing with the same airfoil shape at the same α. For this reason, the aerodynamic coefficients for a finite wing are designated by capital letters, C_L, C_D, C_M; this is in contrast to those for an infinite wing, which we have been designating as c_l, c_d, and c_m. Note that the data in Figs. 9 and 10 are for infinite (two-dimensional) wings, i.e., the data for c_l, c_d, and c_m.

The fundamental difference between flows over finite wings as opposed to infinite wings can be seen as follows. Consider the front view of a finite wing as sketched in Fig. 21(a). If the wing has lift, then obviously the average pressure over the bottom surface is greater than that over the top surface. Consequently, there is some tendency for the air to

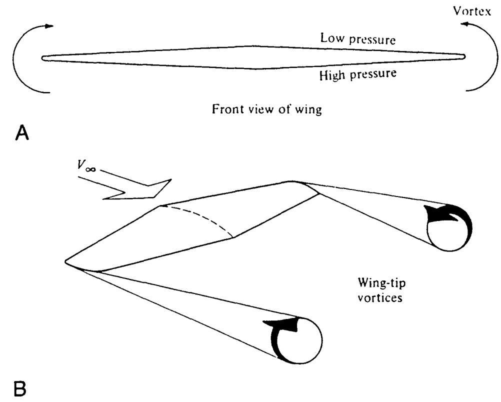

FIG. 21. Origin of wingtip vortices on a finite wing. [From Anderson (1989).]

"leak," or flow, around the wingtips from the high- to the low-pressure sides, as shown in Fig. 21(a). This flow establishes a circulatory motion which trails downstream of the wing. The trailing circular motion is called a *vortex.* There is a major trailing vortex from each wingtip, as sketched in Fig. 21(b).

These wingtip vortices downstream of the wing induce a small downward component of air velocity in the neighborhood of the wing itself. This can be seen intuitively from Fig. 21(b); the two wingtip vortices tend to drag the surrounding air around with them, and this secondary movement induces a small velocity component in the downward direction at the wing. This downward component is called *downwash,* given by the symbol w.

An effect of downwash can be seen in Fig. 22. As usual, V_∞ designates the relative wind. However, in the immediate vicinity of the wing, V_∞ and w add vectorally to produce a "local" relative wind which is canted downward from the original direction of V_∞. This has a couple of consequences:

1. The angle of attack of the airfoil sections of the wing is effectively reduced in comparison to the angle of attack of the wing referenced to V_∞.
2. There is an increase in the drag. The increase is called *induced drag,* which has at least three physical interpretations. First, the wingtip vortices simply alter the flow field about the wing in such a fashion as to change the surface pressure distributions in the direction of increased drag. An alternative explanation is that, because the local relative wind is canted downward (see Fig. 22), the lift vector itself is "tilted back"; hence it contributes a certain component of force parallel to V_∞, that is, a drag force. A third physical explanation of the source of induced drag is that the wingtip vortices contain a certain amount of rotational kinetic energy. This energy has to come from somewhere; indeed, it is supplied by the aircraft propulsion system, where extra power has to be added to overcome the extra increment in drag due to induced drag. All three of these outlooks of the physical mechanism of induced drag are synonymous.

The induced drag coefficient is defined as

$$C_{D,i}=D_i/q_\infty S,$$

where D_i is the induced drag. In turn, $C_{D,i}$ is related to the lift coefficient as

$$C_{D,i}=C_L^2/\pi e\mathrm{AR}. \tag{9}$$

The induced drag is the cost that is paid for the generation of lift; when the lift is zero, then D_i is zero. In Eq. (9), AR is the aspect ra-

FIG. 22. The origin of downwash. [From Anderson (1989).]

tio, and e is the span efficiency factor determined by the way that lift is distributed over the span, which depends on the planform shape of the wing and is usually less than unity; at best it is equal to unity. A value of e for a typical wing is about 0.9. Note that AR plays a strong role in the induced drag; a higher AR leads to lower $C_{D,i}$.

The lift slope for a finite wing is lower than that for the airfoil section of the wing. If a_0 represents the airfoil lift slope,

$$a_0 = dc_l/d\alpha,$$

and a represents the lift slope of the finite wing,

$$a = dC_L/d\alpha,$$

then

$$a = \frac{a_0}{1 + 57.3a_0/\pi e_1 \mathrm{AR}},$$

where a is given in terms of the change in lift coefficient *per degree*, and e_1 is an efficiency factor slight less than unity; the value of e_1 depends on the planform shape of the wing, and is usually about the same in value as e given in Eq. (9).

The total drag coefficient for a finite wing, C_D, is the sum of the skin friction drag as well as pressure drag due to flow separation, both represented by the *profile drag*, c_d, and the induced drag, C_{D_i}. Hence,

$$C_D = c_d + C_L^2/\pi e \mathrm{AR}. \tag{10}$$

If the wing is in a freestream near Mach one, then c_d also contains the wave drag.

1.4 Swept Wings

Many high-speed aircraft, both subsonic and supersonic, have swept wings. The reason for the swept wing is the same in both cases, namely, to reduce drag. However, the aerodynamic means for reducing drag is slightly different for the subsonic as compared to the supersonic cases.

We will first consider subsonic flight. Consider the planview of a straight wing, as sketched in Fig. 23(a). Assume this wing has an airfoil cross section with a critical Mach number $M_{cr} = 0.7$. (Remember from our previous discussions that for M_∞ slightly above M_{cr}, there is a large increase in drag. Hence, it is desirable to increase M_{cr} as much as possible in high-speed subsonic airplane design.) Now assume that we sweep the wing back through an angle of, say, 30°, as shown in Fig. 23(b). The airfoil, which still has a value of $M_{cr} = 0.7$, now "sees" essentially only the component of the flow normal to the leading edge of the wing; i.e., the aerodynamic properties of the local section of the swept wing are governed mainly by the flow normal to the leading edge. Hence, if M_∞ is the freestream Mach number, the airfoil in Fig. 23(b) is effectively seeing a smaller Mach number, M_∞ cos 30°. As a result, the actual freestream Mach number can be increased *above* 0.7 before critical phenomena on the airfoil are encountered. In fact, we could expect that the critical Mach number for the *swept wing itself* would be as high as 0.7/cos 30° = 0.808. Therefore, we see the main function of a swept wing. *By sweeping the wings of subsonic aircraft, drag divergence is delayed to higher Mach numbers.*

Airfoil section with M_{cr} = 0.7
B

FIG. 23. Effect of a swept wing on critical Mach number. [From Anderson (1989).]

In real life, the flow over the swept wing sketched in Fig. 23(b) is a fairly complex three-dimensional flow, and to say that the airfoil sees only the component normal to the leading edge is a sweeping simplification. However, it leads to a good rule of thumb. If Ω is the sweep angle, as shown in Fig. 23(b), the actual critical Mach number for the swept wing is bracketed by

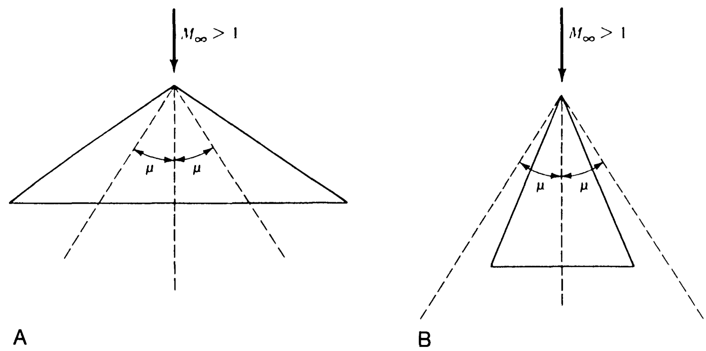

FIG. 24. Swept wings for supersonic flow. (a) Wing swept outside the Mach cone. (b) Wing swept inside the Mach cone. [From Anderson (1989).]

$$\begin{aligned}M_{\text{cr}} &\text{ for airfoil}\\ &< \text{actual } M_{\text{cr}} \text{ for swept wing}\\ &< (M_{\text{cr}} \text{ for airfoil})/\cos\Omega\,.\end{aligned}$$

For supersonic flight, swept wings are also advantageous, but not quite from the same point of view as described above for subsonic flow. Consider the two swept wings sketched in Fig. 24. For a given $M_\infty > 1$, there is a Mach cone with vertex angle μ, equal to the Mach angle. If the leading edge of a swept wing is *outside* the Mach cone, as shown in Fig. 24(a), the component of the Mach number normal to the leading edge is supersonic. As a result, a fairly strong oblique shock wave will be created by the wing itself, with an attendant large wave drag. On the other hand, if the leading edge of the swept wing is inside the Mach cone, as shown in Fig. 24(b), the component of the Mach number normal to the leading edge is subsonic. As a result, the wave drag produced by the wing is less. Therefore, the advantage of sweeping the wings for supersonic flow is in general to obtain a decrease in wave drag, and if the wing is swept inside the Mach cone, a considerable decrease can be obtained.

The quantitative effects of maximum thickness and wing sweep on wave-drag coefficient are shown in Fig. 25(a) and 25(b), respectively. For all cases, the wing aspect ratio is 3.5 and the taper ratio (tip to root chord) is 0.2. Clearly, thin wings with large angles of sweepback have the smallest wave drag. The effect of wing sweep on the lift-to-drag ratio is shown in Fig. 26. Note that for a subsonic airplane, sweeping the wing reduces C_L more than C_D and hence gives a lower L/D ratio. In contrast, for a supersonic airplane at Mach 2.2, sweeping the wing reduces both C_L and C_D correspondingly and has virtually no effect on L/D.

As a final note, we might observe that not all supersonic aircraft have swept wings. In supersonic flight, wave drag can also be reduced by using stubby, very *low*-aspect-ratio, straight wings with thin, sharp airfoils (such as on the Lockheed F-104). In supersonic

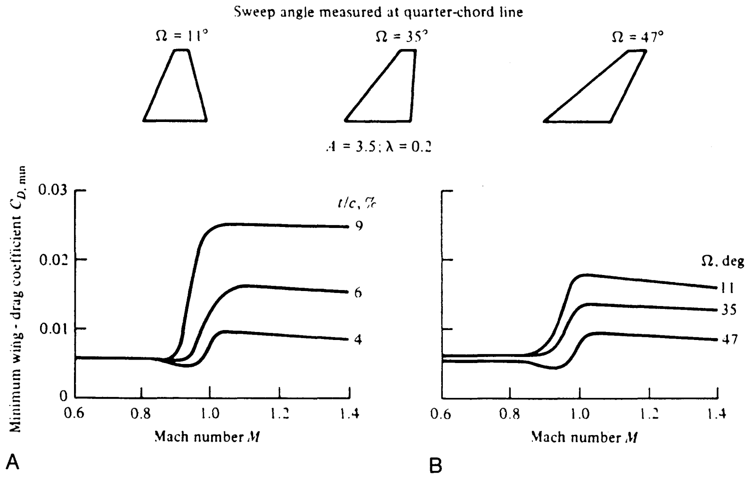

FIG. 25. Sketch of the variation of minimum wing-drag coefficient vs Mach number with (a) wing thickness as a parameter (Ω=47°) and (b) wing sweepback angle as a parameter (t/c=4%). [From Loftin (1985).]

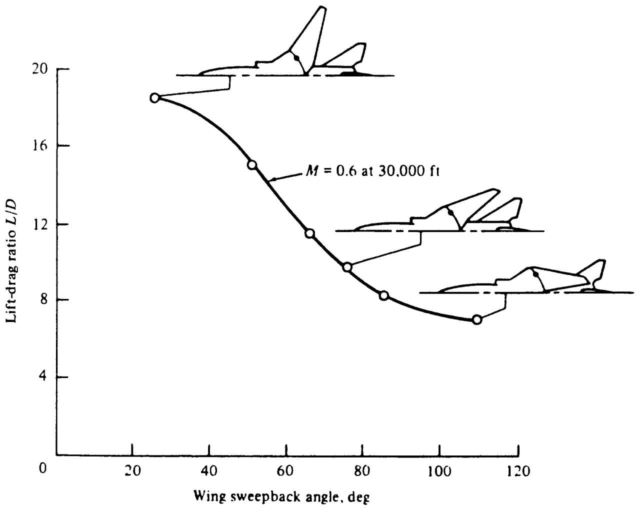

FIG. 26. Variation of lift-to-drag ratio with wing sweep. Wind-tunnel measurements at the NASA Langley Research Center. [From Loftin (1985).]

flight, wave drag is generally much larger, hence much more important, than induced drag. Thus, low-aspect-ratio wings for supersonic aircraft reduce wave drag much more than they increase induced drag. This results in a net decrease in total drag. Thus, low-aspect-ratio wings are efficient for supersonic flight, whereas high-aspect-ratio wings are efficient for subsonic flight.

1.5 Flaps—A Mechanism for High Lift

An airplane normally encounters its lowest flight velocities at takeoff or landing, two periods that are most critical for aircraft safety. The slowest speed at which an airplane can fly in straight and level flight is defined as the *stalling speed* V_{stall}. Hence, the calculation of V_{stall}, as well as aerodynamic methods of making V_{stall} as small as possible, are of vital importance.

The stalling velocity is readily obtained in terms of the maximum lift coefficient, as follows. From the definition of C_L,

$$L=q_\infty SC_L=\tfrac{1}{2}\rho_\infty V_\infty^2 SC_L.$$

Thus

$$V_\infty=\sqrt{2L/\rho_\infty SC_L}.$$

In steady, level flight, the lift is just sufficient to support the weight W of the aircraft, that is, $L=W$. Thus

$$V_\infty=\sqrt{2W/\rho_\infty SC_L}.$$

Examining this equation, for an airplane of given weight and size at a given altitude, we find the only recourse to minimize V_∞ is to maximize C_L. Hence, stalling speed corresponds to the angle of attack that produces $C_{L,\max}$:

$$V_{\text{stall}}=\sqrt{2W/\rho_\infty SC_{L,\max}}\,.$$

In order to decrease V_{stall}, $C_{L,\max}$ must be increased. However, for a wing with a given shape, $C_{L,\max}$ is fixed by nature, i.e., the lift properties of an airfoil, including maximum lift, depend on the physics of the flow over the airfoil. In order to assist nature, the lifting properties of a given airfoil can be greatly enhanced by the use of "artificial" high-lift devices. The most common of these devices is the simple flap at the trailing edge of the wing, as sketched in Fig. 27. When the flap is rotated downward, the camber of the airfoil is effectively increased, with a consequent increase in $C_{L,\max}$ for the wing. At the same time, the zero-lift angle of attack is shifted to a more negative value. These trends are illustrated in Fig. 28, which compares the variation of C_L with α for a wing with and without flaps.

The increase in $C_{L,\max}$ due to flaps can be dramatic. If the flap is designed not only to

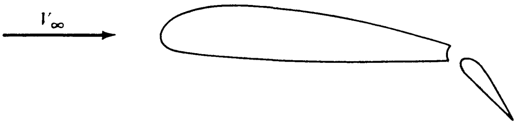

FIG. 27. Illustration of a single flap. [From Anderson (1989).]

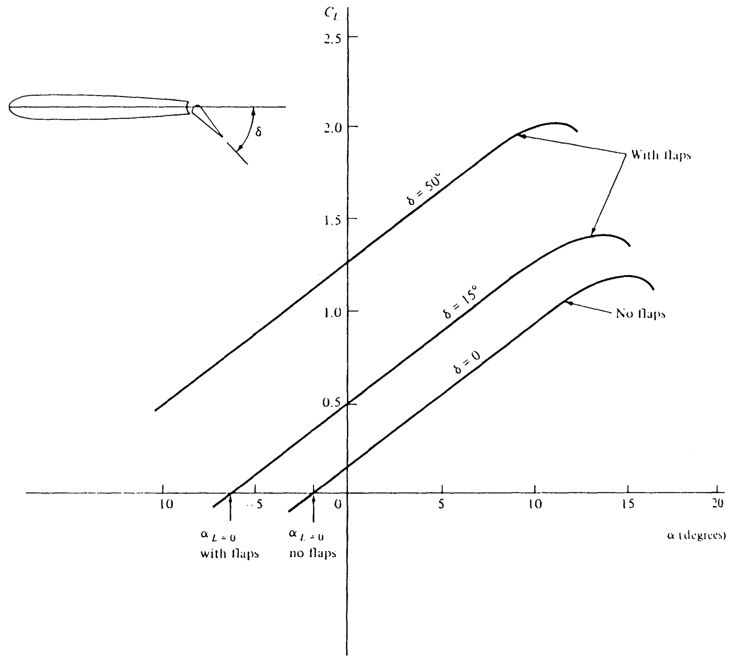

FIG. 28. Illustration of the effect of flaps on the lift curve. The numbers shown are typical of a modern medium-range jet transport. [From Anderson (1989).]

rotate downward, but also to translate rearward so as to increase the effective wing area, $C_{L,\max}$ can be increased by approximately a factor of 2. If additional high-lift devices are used, such as slats at the leading edge, slots in the surface, or mechanical means of boundary layer control, then $C_{L,\max}$ can sometimes be increased by a factor of 3 or more, as shown in Fig. 29.

2. AIRPLANE PERFORMANCE

Airplane performance is the study of such questions as: How fast can the airplane fly? How high can it fly? How long can it stay in the air starting with a full fuel load (endurance)? How far can it fly starting with a full fuel load (range)? To answer all these questions, the basic aerodynamics of the airplane are reflected through one important relation, similar to that developed in Sec. 1.3 for a finite wing, namely, the *drag polar* given by

$$C_D = C_{D,0} + C_L^2/\pi e \mathrm{AR},$$

where C_D and C_L are the total drag and lift coefficients, respectively, for the entire airplane, $C_{D,0}$ is the *zero-lift* drag coefficient (sometimes called *parasite drag at zero lift*) due to skin friction and pressure drag due to flow separation (sometimes called "form drag") acting over the entire airplane when the airplane is at zero lift, and $C_L^2/\pi e \mathrm{AR}$ is the *drag due to lift*, which is composed of the induced drag

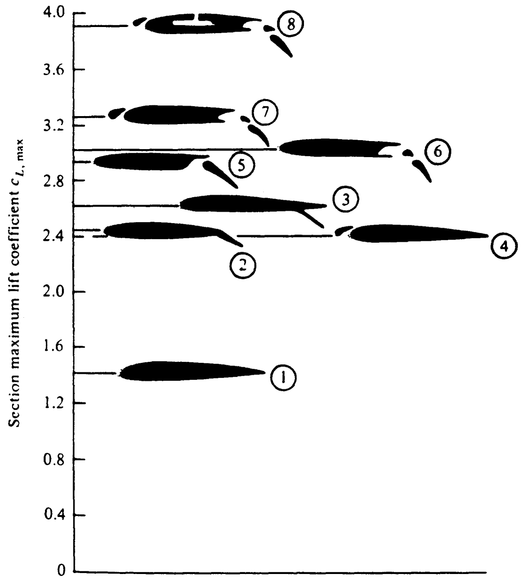

FIG. 29. Typical values of airfoil maximum lift coefficient for various types of high-lift devices: (1) airfoil only, (2) plain flap, (3) split flap, (4) leading edge slat, (5) single-slotted flap, (6) double slotted flap, (7) double-slotted flap in combination with a leading-edge slat, (8) addition of boundary-layer suction at the top of the airfoil. FIG. 30. Force diagram for an airplane in flight. [From Anderson (1989).]

plus the increased parasite drag when the airplane is at the higher angles of attack necessary to generate the required lift. In the above drag polar, AR is the conventional aspect ratio defined in Sec. 1.3, and e now represents the Oswald efficiency factor, different from the span efficiency factor defined in Sec. 1.3. A value of e for a typical airplane is about 0.6.

2.1 Equations of Motion

Consider an airplane in flight, as sketched in Fig. 30. The flight path (direction of motion of the airplane) is included at an angle θ with respect to the horizontal. The flight path direction and the relative wind are along the same line. The mean chord line is at a geometric angle of attack α with respect to the flight path direction. There are four physical forces acting on the airplane:

1. Lift L, which is perpendicular to the flight path direction.
2. Drag D, which is parallel to the flight path direction.
3. Weight W, which acts vertically toward the center of the earth (and hence is inclined at the angle θ with respect to the lift direction).
4. Thrust T, which in general is inclined at the angle α_T with respect to the flight path direction.

The flight path shown in Fig. 30 is drawn as a straight line. This is the picture we see by focusing locally on the airplane itself. However, if we stand back and take a wider view of the space in which the airplane is traveling, the flight path is generally curved. This is obviously true if the airplane is maneuvering; even if the airplane is flying "straight and level" with respect to the ground, it is still executing a curved flight path with a radius of curvature equal to the altitude h plus the radius of the Earth.

Summing forces parallel and perpendicular to the flight path in Fig. 30, and applying Newton's second law, we obtain

$$T \cos\alpha_T - D - W \sin\theta = m(dV/dt),$$

$$L + T \sin\alpha_T - W \cos\theta = m(V^2/r_c).$$

These are the *equations of motion* for an airplane in translational flight.

The above equations describe the general two-dimensional translational motion of an airplane in accelerated flight. However, in this discussion we are interested in a specialized application of these equations, namely, the case where the acceleration is zero. The performance of an airplane for such unaccelerated flight conditions is called *static performance.* This may, at first thought, seem unduly restrictive; however, static performance analyses lead to reasonable calculations of maximum velocity, maximum rate of climb, maximum range, etc.— parameters of vital interest in airplane design and operation.

With this in mind, consider level, unaccelerated flight. Referring to Fig. 30, level flight means that the flight path is along the horizontal; that is, $\theta = 0$. Unaccelerated flight means that the right-hand sides of the above equations are zero. Therefore, these equations reduce to

$$T \cos\alpha_T = D,$$

$$L + T \sin\alpha_T = W.$$

Furthermore, for most conventional airplanes, α_T is small enough that $\cos\alpha_T \approx 0$. Thus,

$$T = D,$$

$$L = W.$$

These are the equations of motion for level, unaccelerated flight. They can also be obtained directly from Fig. 30, by inspection. In level, unaccelerated flight, the aerodynamic drag is balanced by the thrust of the engine, and the aerodynamic lift is balanced by the weight of the airplane.

2.2 Maximum Velocity

The maximum velocity of an airplane at a given altitude occurs when the maximum thrust of the engine (called maximum thrust available) equals the thrust required to overcome the drag of the airplane at the maximum velocity. The thrust required (which is simply associated with the drag of the airframe) is

$$T_R = D = q_\infty S C_D.$$

The calculation of T_R for a given airplane at a given altitude is made as follows:

1. Choose a value of V_∞.
2. Calculate C_L from
   $$C_L = W/\tfrac{1}{2}\rho_\infty V_\infty^2 S,$$
   where W, ρ_∞ and S are known.
3. Calculate C_D from the drag polar
   $$C_D = C_{D,0} + C_L^2/\pi e \mathrm{AR}$$
   where $C_{D,0}$, e, and AR are known.
4. Calculate T_R from
   $$T_R = q_\infty S C_D.$$

The thrust required will vary with velocity. It can easily be shown that minimum T_R occurs when the airplane is flying at a velocity such that the lift-to-drag ratio, L/D, is a maximum. A typical variation of T_R versus velocity for a light, general aviation airplane is shown in Fig. 31. The velocity at which T_R equals the maximum thrust available (T_A) from the engine is the maximum velocity of the airplane.

A related concept is that of power required and power available, defined respectively as

$$P_R = T_R V_\infty,$$

$$P_A = T_A V_\infty.$$

The variation of P_R versus velocity is qualitatively similar to the T_R curve shown in Fig. 31.

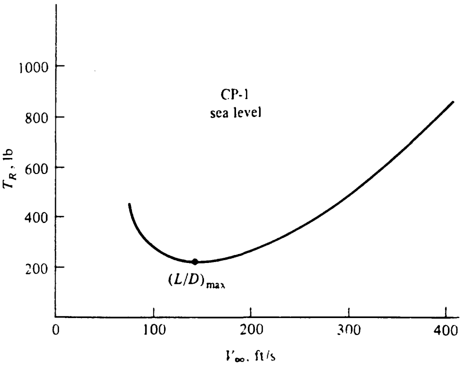

FIG. 31. Thrust-required curve. [From Anderson (1989).]

2.3 Rate of Climb

Returning to Fig. 30, when the airplane is in a steady, unaccelerated climb, the equations of motion become

$$T = D + W\cos\theta,$$

$$L = W\cos\theta.$$

Multiplying the first of these two equations by V_∞, we have

$$(TV_\infty - DV_\infty)/W = V_\infty \sin\theta.$$

However, $TV_\infty - DV_\infty = P_A - P_R$, which is the difference between maximum power available and power required. This difference is called *excess power*. Also, geometrically, $V_\infty \sin\theta$ is the *vertical* velocity of the airplane, called the *rate of climb*, *R/C*. Hence, from the above equation,

$$R/C = (\text{excess power})/W.$$

2.4 Gliding Flight

An airplane in powerless, steady, gliding flight is shown in Fig. 32. The equations of motion reduce for this case to

$$D = W\sin\theta,$$

$$L = W\cos\theta.$$

Hence

$$\tan\theta = \frac{1}{L/D}.$$

The equilibrium glide angle, θ, given by the above equation, is inversely proportional to the lift-to-drag ratio.

2.5 Maximum Altitude

As the altitude of an airplane increases, at the same velocity the drag decreases and the engine thrust generally decreases (both because ρ_∞ decreases with altitude). At some altitude, the maximum excess power will become at best zero, or negative, depending on the velocity. This altitude is the maximum altitude of the airplane. It is defined as the *absolute ceiling*. A more practical index is the *service ceiling*, defined as that altitude where the maximum rate of climb is 100 feet per minute.

2.6 Range and Endurance

Range is technically defined as the total distance (measured with respect to the ground) traversed by the airplane on a tank of fuel. A related quantity is endurance, which is defined as the total time that an airplane stays in the air on a tank of fuel. In different applications, it may be desirable to maximize one or the other of these characteristics. The parameters which maximize range are different from those which maximize endurance; they are also different for propeller- and jet-powered aircraft. Let us first consider the propeller-driven airplane, as discussed below.

One of the critical factors influencing range and endurance is the *specific fuel consumption*, a characteristic of the engine. For a reciprocating engine, specific fuel consumption (commonly abbreviated as SFC) is defined as the *weight of fuel consumed per unit power per unit time*. As mentioned earlier, reciprocating engines are rated in terms of horsepower, and the common units (although inconsistent) of specific fuel consumption are

$$\text{SFC}=\frac{\text{lb of fuel}}{(\text{bhp})(\text{h})},$$

where bhp signifies shaft brake horsepower.

First, consider endurance. On a qualitative basis, in order to stay in the air for the longest period of time, common sense says that we must use the *minimum* number of pounds of fuel per hour. On a dimensional basis this quantity is proportional to the horsepower required by the airplane and to the SFC:

$$(\text{lb of fuel})/\text{h} \propto (\text{SFC})(\text{hp}_R).$$

Therefore, minimum pounds of fuel per hour is obtained with minimum hp_R. Since minimum pounds of fuel per hour gives maximum endurance, we quickly conclude that *Maximum endurance for a propeller-driven airplane occurs when the airplane is flying at minimum power required.* It can be shown that this condition also corresponds to flying such that $C_L^{3/2}/C_D$ is maximum.

Now, consider range. In order to cover the longest distance (say, in miles), common sense says that we must use the minimum number of pounds of fuel per mile. On a dimensional basis, we can state the proprotionality

$$\frac{\text{lb of fuel}}{\text{mi}} \propto \frac{(\text{SFC})(\text{hp}_R)}{V_\infty}.$$

As a result, minimum pounds of fuel per mile is obtained with a minimum hp_R/V_∞. This minimum value of hp_R/V_∞ precisely corresponds to maximum L/D. Thus, *maximum range for a propeller-driven airplane occurs when the airplane is flying at a velocity such that C_L/C_D is maximum.*

Approximate expressions for the range and endurance of a propeller driven airplane are as follows:

range,

$$R=\frac{\eta}{c}\frac{C_L}{C_D}\ln\frac{W_0}{W_1};$$

endurance,

$$E=\frac{\eta}{c}\frac{C_L^{3/2}}{C_D}(2\rho_\infty S)^{1/2}(W_1^{1/2}-W_0^{1/2}),$$

where η is the propeller efficiency, c is the specific fuel consumption, W_1 is the weight of the airplane with empty fuel tanks, and W_0 is the full gross weight of the airplane. The units in the above equations must be consistent units, such as the SI system or the British engineering system.

Let us now consider a jet-propelled airplane. For a jet airplane, the specific fuel consumption is defined as the *weight of fuel consumed per unit thrust per unit time*. Note that *thrust* is used here, in contradistinction to power as in the previous case for a reciprocating-engine-propeller combination. The fuel consumption of a jet engine physically depends on the thrust produced by the engine, whereas the fuel consumption of a re-

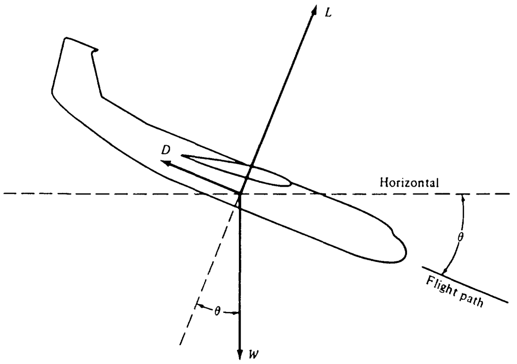

FIG. 32. Airplane in power-off gliding flight. [From Anderson (1989).]

ciprocating engine physically depends on the brake power produced. It is this simple difference which leads to different range and endurance formulas for a jet airplane. In the literature, thrust-specific fuel consumption (TSFC) for jet engines is commonly given as

$$\text{TSFC}=\frac{\text{lb of fuel}}{(\text{lb of thrust})(\text{h})}.$$

(Note the inconsistent unit of time.)

The maximum endurance of a jet airplane occurs for minimum pounds of fuel per hour, the same as for propeller-driven aircraft. However, for a jet,

$$(\text{lb of fuel})/\text{h}=(\text{TSFC})T_A,$$

where T_A is the thrust available produced by the jet engine. Recall that in steady, level, unaccelerated flight, the pilot has adjusted the throttle such that thrust available T_A just equals the thrust required T_R: $T_A=T_R$. Therefore, minimum pounds of fuel per hour corresponds to minimum thrust required. Hence, we conclude that *maximum endurance for a jet engine occurs when the airplane is flying at minimum thrust required.* We have already seen that minimum thrust required corresponds to flying at maximum L/D.

Now, consider range. As before, maximum range occurs for a minimum pounds of fuel per mile. For a jet, on a dimensional basis,

$$(\text{lb of fuel})/\text{mi}=(\text{TSFC})T_A/V_\infty.$$

Recalling that for steady, level flight, $T_A=T_R$, we note that minimum pounds of fuel per mile corresponds to a minimum T_R/V_∞. In turn, T_R/V_∞ is the slope of a line through the origin and intersecting the thrust-required curve; its minimum value occurs when the line becomes tangent to the thrust-required curve. The aerodynamic condition holding at this tangent point is obtained as follows. Recalling that for steady, level flight, $T_R=D$, then

$$\frac{T_R}{V_\infty}=\frac{D}{V_\infty}=\frac{\frac{1}{2}\rho_\infty V_\infty^2 S C_D}{V_\infty}=\frac{1}{2}\rho_\infty V_\infty S C_D.$$

Since $V_\infty=\sqrt{2W/\rho_\infty S C_L}$, we have

$$\frac{T_R}{V_\infty}=\frac{1}{2}\rho_\infty S\sqrt{\frac{2W}{\rho_\infty S C_L}}\,C_D\propto\frac{1}{C_L^{1/2}/C_D}.$$

Hence, minimum T_R/V_∞ corresponds to maximum $C_L^{1/2}/C_D$. In turn, we conclude that *maximum range for a jet airplane occurs when the airplane is flying at a velocity such that $C_L^{1/2}/C_D$ is maximum.*

Approximate relations for range and endurance for a jet airplane are as follows:

range,

$$R=2\sqrt{\frac{2}{\rho_\infty S}}\,\frac{1}{c_t}\,\frac{C_L^{1/2}}{C_D}\,(W_0^{1/2}-W_1^{1/2});$$

endurance,

$$E=\frac{1}{c_t}\,\frac{C_L}{C_D}\,\ln\frac{W_0}{W_1},$$

where c_t is the thrust-specific fuel consumption.

2.7 Turning Flight

A level turn is illustrated in Fig. 33. Here, the wings of the airplane are banked through the angle ϕ; hence the lift vector is inclined at the angle ϕ to the vertical. The bank angle ϕ and the lift L are such that the component of the lift in the vertical direction exactly equals the weight:

$$L\cos\phi=W$$

and therefore the airplane maintains a constant altitude, moving in the same horizontal plane. However, the resultant of L and W leads to a resultant force F_r, which acts in the horizontal plane. This resultant force is perpendicular to the flight path, causing the airplane to turn in a circular path with a radius of curvature equal to R. We wish to study this turn radius R, as well as the turn rate $d\theta/dt$.

From the force diagram in Fig. 33, the magnitude of the resultant force is

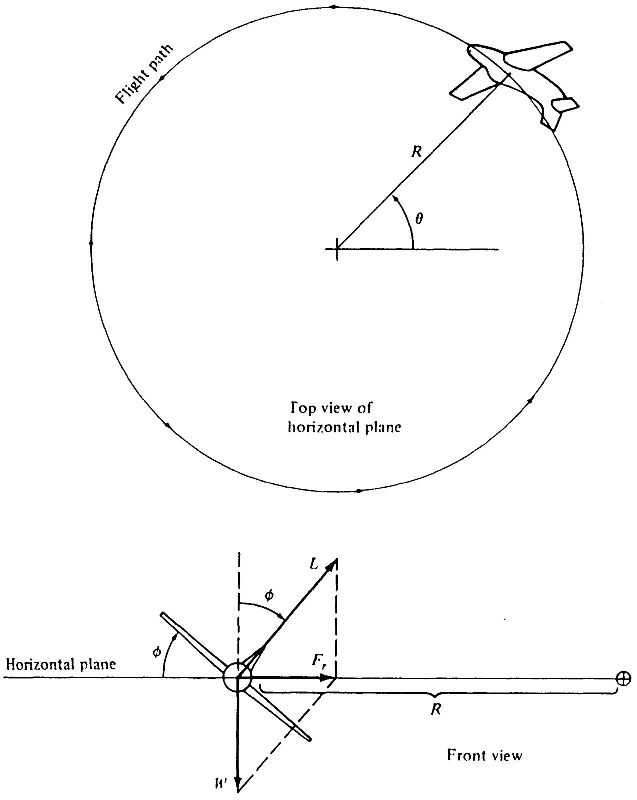

FIG. 33. An airplane in a level turn. [From Anderson (1989).]

$$F_r = \sqrt{L^2 - W^2}.$$

We introduce the *load factor n*, defined as

$$n \equiv L/W.$$

The load factor is usually quoted in terms of "*g*'s"; for example, an airplane with lift equal to five times the weight is said to be experiencing a load factor of 5*g*'s. Hence,

$$F_r = W\sqrt{n^2 - 1}.$$

The airplane is moving in a circular path at the velocity V_∞. Therefore, the radial acceleration is given by V_∞^2/R. From Newton's second law

$$F_r = m\frac{V_\infty^2}{R} = \frac{W}{g}\frac{V_\infty^2}{R}.$$

Combining, we have

$$R = V_\infty^2/g\sqrt{n^2 - 1}.$$

The angular velocity, denoted by $\omega = d\theta/dt$, is called the turn rate and is given by V_∞/R. Thus,

$$\omega = g\sqrt{n^2 - 1}/V_\infty.$$

For the maneuvering performance of an airplane, both military and civil, it is frequently advantageous to have the smallest possible R and the largest possible ω. The above equations show that to obtain both a small turn radius and a large turn rate, we want

1. the highest possible load factor (i.e., the highest possible L/W);
2. the lowest possible velocity.

3. AIRPLANE STABILITY AND CONTROL

3.1 Definition of Stability and Control

Airplane performance, as discussed in Sec. 2, is governed by forces (along and perpendicular to the flight path), with the translational motion of the airplane as a response to these forces. In contrast, airplane stability and control, discussed in the present section, are governed by moments about the center of gravity, with the rotational motion of the airplane as a response to these moments. Therefore, moments and rotational motion are the main focus of this section.

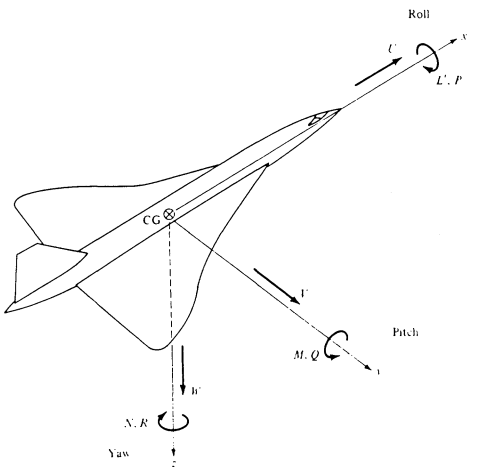

FIG. 34. Definition of the airplane's axes along with the translational and rotational motion along and about these axes. [From Anderson (1989).]

Consider an airplane in flight, as sketched in Fig. 34. The center of gravity (the point through which the weight of the complete airplane effectively acts) is denoted as cg. The *xyz* orthogonal axis system is fixed relative to the airplane; the *x* axis is along the fuselage, the *y* axis is along the wingspan perpendicular to the *x* axis, and the *z* axis is directed downward, perpendicular to the *xy* plane. The origin is at the center of gravity. The translational motion of the airplane is given by the velocity components, U, V, and W along the *x*, *y*, and *z* directions, respectively. (Note that the resultant freestream velocity V_∞ is the vector sum of U, V, and W.) The rotational motion is given by the angular velocity components P, Q, and R about the *x*, *y*, and *z* axes, respectively. These rotational velocities are due to the moments L', M, and N about the *x*, *y*, and *z* axes, respectively. (The prime is put over the symbol L so that the reader avoids confusing it with lift.) Rotational motion about the *x* axis is called *roll*; L' and P are the *rolling* moment and velocity, respectively. Rotational motion about the *y* axis is called *pitch*; M and Q are the *pitching* moment and velocity, respectively. Rotational motion about the *z* axis is called *yaw*; N and R are the *yawing* moment and velocity, respectively.

There are three basic controls on an airplane—the ailerons, elevator, and rudder—which are designed to change and control the moments about the *x*, *y*, and *z* axes. These control surfaces are shown in Fig. 35; they are flaplike surfaces that can be deflected back and forth at the command of the pilot. The ailerons are mounted at the trailing edge of the wing, near the wingtips. The elevators are located on the horizontal stabilizer. In some modern aircraft, the complete horizontal stabilizer is rotated instead of just the elevator (so-called flying tails). The rudder is located on the vertical stabilizer, at the trailing edge. Just as in the case of wing flaps discussed in Sec. 1.5, a downward deflection of the control surface will increase the lift of the wing or tail. In turn, the moments will be changed, as sketched in Fig. 36. Consider Fig. 36(a). One aileron is deflected up, the other down, creating a differential lifting force on the wings, thus contributing to the rolling moment L'. In Fig. 36(b), the elevator is deflected upward, creating a negative lift at the tail, thus contributing to the pitching moment M. In Fig. 36(c), the rudder is deflected to the right, creating a leftward aerodynamic force on the tail, thus contributing to the yawing moment N.

Rolling (about the *x* axis) is also called *lateral motion*. Referring to Fig. 36(a), we see that ailerons control roll; hence they are known as *lateral controls*. Pitching (about the *y* axis) is also called *longitudinal motion*. In Fig. 36(b), we see that elevators control pitch; hence they are known as *longitudinal con-*

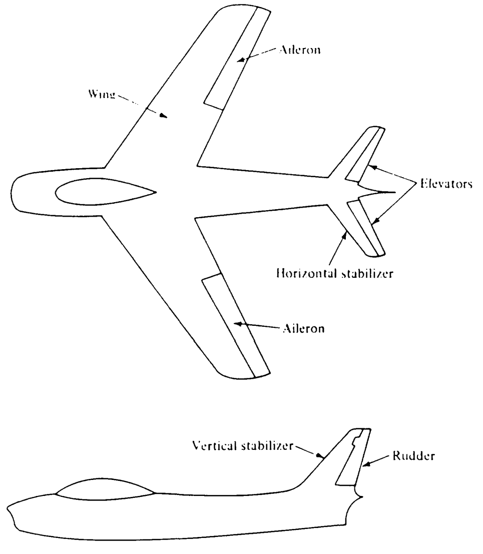

FIG. 35. Some airplane nomenclature. [From Anderson (1989).]

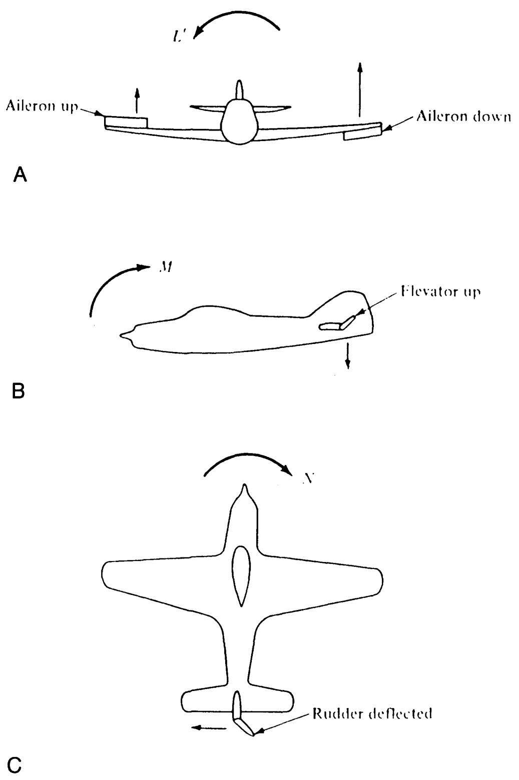

FIG. 36. Effect of control deflections on roll, pitch, and yaw. (a) Effect of aileron deflection; lateral control. (b) Effect of elevator deflection; longitudinal control. (c) Effect of rudder deflection; directional control. [From Anderson (1989).]

trols. Yawing (about the z axis) is also called *directional motion.* Figure 36(c) shows that the rudder controls yaw; hence it is known as the *directional control.*

There are two types of stability; static and dynamic. They can be visualized as follows. First, consider static stability. Consider a marble on a curved surface, such as a bowl. Imagine that the bowl is upright and the marble is resting inside, as shown in Fig. 37(a). The marble is stationary; it is in a state of *equilibrium,* which means that the moments acting on the marble are zero. If the marble is now disturbed [moved to one side, as shown by the dotted circle in Fig. 37(a)] and then released, it will roll back toward the bottom of the bowl, i.e., toward its original equilibrium position. Such a system is *statically* stable. In general, we can state that *if the forces and moments on the body caused by a disturbance tend initially to return the body toward its equilibrium position, the body is statically stable. The body has positive static stability.*

Now, imagine the bowl is upside-down, with the marble at the crest, as shown in Fig. 37(b). If the marble is placed precisely at the crest, the moments will be zero and the marble will be in equilibrium. However, if the marble is now disturbed [as shown by the dotted circle in Fig. 37(b)], it will tend to roll down the side, away from its equilibrium position. Such a system is *statically unstable.* In general, we can state that *if the forces and moments are such that the body continues to move away from its equilibrium position after being disturbed, the body is statically unstable. The body has negative static stability.*

Finally, imagine the marble on a flat horizontal surface, as shown in Fig. 37(c). Its moments are zero; it is in equilibrium. If the marble is now disturbed to another location, the moments will still be zero, and it will still be in equilibrium. Such a system is *neutrally stable.* This situation is rare in flight vehicles, and we will not be concerned with it here.

Emphasis is made that static stability (or the lack of it) deals with the *initial* tendency of a vehicle to return to equilibrium (or to diverge from equilibrium) after being disturbed. It says nothing about whether it ever reaches its equilibrium position, nor how it gets there. Such matters are the realm of dynamic stability, as follows.

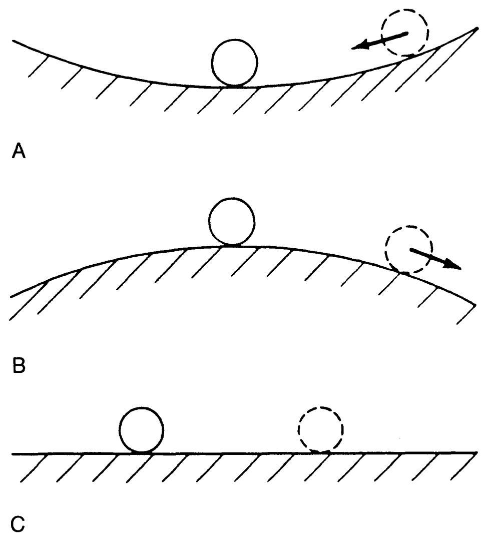

FIG. 37. Illustration of static stability. (a) Statically stable system. (b) Statically unstable system. (c) Statically neutral system. [From Anderson (1989).]

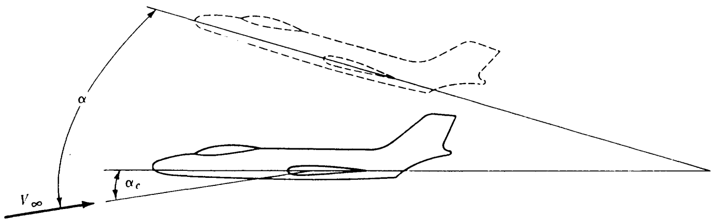

FIG. 38. Disturbance from the equilibrium angle of attack.

Dynamic stability deals with the *time history* of the vehicle's motion after it initially responds to its static stability. For example, consider an airplane flying at an angle of attack α_e such that its moments about the center of gravity are zero. The airplane is therefore in equilibrium at α_e; in this situation, it is *trimmed*, and α_e is called the trim angle of attack. Now assume that the airplane is disturbed (say, by encountering a wind gust) to a new angle of attack α as shown in Fig. 38. The airplane has been pitched through a *displacement* $\alpha-\alpha_e$. Now, let us observe the subsequent pitching motion after the airplane has been disturbed by the gust. We can describe this motion by plotting the instantaneous displacement versus time, as shown in Fig. 39. Here $\alpha-\alpha_e$ is given as a function of time t. At $t=0$, the displacement is equal to that produced by the gust. If the airplane is statically stable, it will *initially* tend to move back towards its equilibrium position, that is, $\alpha-\alpha_e$ will initially decrease. Over a lapse of time, the vehicle may monotonically "home-in" to its equilibrium position, as shown in Fig. 39(a). Such motion is called aperiodic. Alternately, it may first overshoot the equilibrium position and approach α_e after a series of oscillations with decreasing amplitude, as shown in Fig. 39(b). Such motion is described as damped oscillations. In both situations, the airplane eventually returns to its equilibrium position after some interval of time. These two situations are examples of *dynamic stability* in an airplane. Thus, we can state that *a body is dynamically stable if, out of its own accord, it eventually returns to and remains at its equilibrium position over a period of time.*

On the other hand, after initially responding to its static stability, the airplane may oscillate with increasing amplitude, as shown in Fig. 40. Here, the equilibrium position is never maintained for any period of time; the airplane in this case is *dynamically unstable* (even though it is statically stable). Also, it is theoretically possible for the airplane to pitch back and forth with constant-amplitude oscillations. This is an example of a *dynamically neutral* body; such a case is of little practical interest here.

It is important to observe from the above examples that a dynamically stable airplane must always be statically stable. On the other hand, static stability is *not* sufficient to ensure dynamic stability. Nevertheless, static stability is usually the first stability characteristic to be designed into an airplane. (There are some exceptions, to be discussed later.)

The conventional control surfaces (elevators, ailerons, and rudder) on an airplane were sketched in Figs. 35 and 36. Their function is usually to change the airplane from one equilibrium position to another and to produce nonequilibrium accelerated motions such as maneuvers. The study of the *deflection* of the ailerons, elevators, and rudder necessary to make the airplane do what we want and of the amount of *force* that must be exerted by the pilot (or the hydraulic boost system) to deflect these controls is part of a discipline called "airplane control."

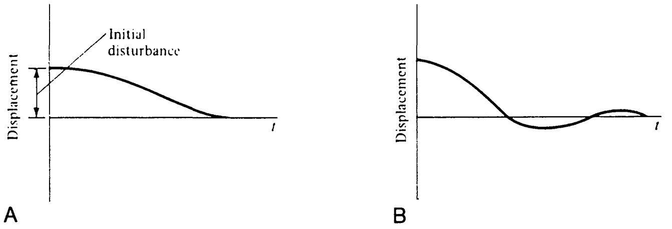

FIG. 39. Examples of dynamic stability: (a) Aperiodic; (b) Damped oscillations. [From Anderson (1989).]

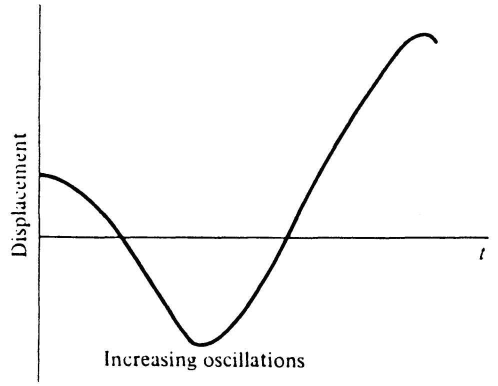

FIG. 40. An example of dynamic instability. [From Anderson (1989).]

3.2 Moments on the Airplane

A study of stability and control is focused on moments: moments on the airplane and moments on the control surfaces. Recall that the pressure and shear stress distributions over a wing produce a pitching moment. This moment can be taken about any arbitrary point (the leading edge, the trailing edge, the quarter chord, etc.).

Now consider the complete airplane, as sketched in Fig. 41. Here, we are most concerned with the pitching moment about the center of gravity of the airplane, M_{cg}. Clearly, by examination of Fig. 41, M_{cg} is created by L, D, and M_{ac} of the wing; lift of the tail; thrust; and aerodynamic forces and moments on other parts of the airplane, such as the fuselage and engine nacelles. (Note that weight does not contribute, since it acts through the center of gravity.)

The moment coefficient about the center of gravity is defined as

$$C_{M,\text{cg}}=M_{\text{cg}}/q_{\infty}Sc.$$

An airplane is in equilibrium (in pitch) when the moment about the center of gravity is zero; i.e., when $M_{\text{cg}} = C_{M,\text{cg}}=0$, the airplane is said to be *trimmed*.

3.3 Criteria for Longitudinal Static Stability

Static stability and control about all three axes shown in Fig. 34 is usually a necessity in the design of conventional airplanes. However, a complete description of all three types—lateral, longitudinal, and directional static stability and control—is beyond the scope of this article. Rather, the intent here is to provide only the flavor of stability and control concepts, and to this end only the airplane's longitudinal motion (pitching motion about the y axis) will be considered. This pitching motion is illustrated in Fig. 36(b). It takes place in the plane of symmetry of the airplane. Longitudinal stability is also the most important static stability mode; in airplane design, wind-tunnel testing, and flight research, it usually earns more attention than lateral or directional stability.

Consider a rigid airplane with fixed controls, e.g., the elevator in some fixed position. Assume the airplane has been tested in a wind tunnel or free flight and that its variation of M_{cg} with angle of attack has been measured. This variation is illustrated in Fig. 42, where $C_{M,\text{cg}}$ is sketched versus α. For many conventional airplanes, the curve is nearly linear, as shown in Fig. 42. The value of $C_{M,\text{cg}}$ at zero lift is denoted by $C_{M,0}$. The value of α where $M_{\text{cg}}=0$ is denoted by α_e; this is the equilibrium, or trim, angle of attack.

Consider the airplane in steady, equilibrium flight at its trim angle of attack α_e as shown in Fig. 43(a). Suddenly, the airplane is disturbed by hitting a wind gust, and the angle of attack is momentarily changed. There are two possibilities: an increase or a decrease in α. If the airplane is pitched upward, as shown in Fig. 43(b), then $\alpha > \alpha_e$. From Fig. 42, if $\alpha > \alpha_e$, the moment about the center of

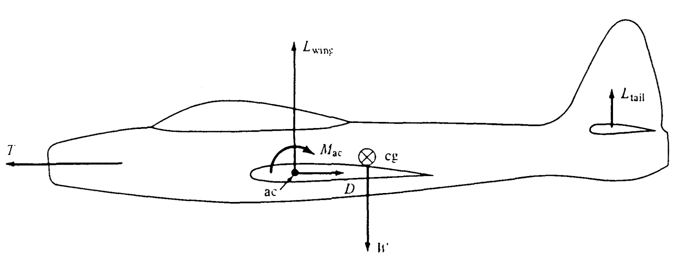

FIG. 41. Contributions to the moment about the center of gravity of the airplane. [From Anderson (1989).]

gravity is negative. A negative moment (by convention) is counterclockwise, tending to pitch the nose downward. Hence, in Fig. 43(b), the airplane will initially tend to move back toward its equilibrium position after being disturbed. On the other hand, if the plane is pitched downward by the gust, as shown in Fig. 43(c), then $\alpha < \alpha_e$. From Fig. 42, the resulting moment about the center of gravity will be positive (clockwise) and will tend to pitch the nose upward. Thus, again we have the situation where the airplane will initially tend to move back toward its equilibrium position after being disturbed. This is precisely the definition of static stability. Therefore, we conclude that an airplane which has a $C_{M,\text{cg}}$ vs α variation like that shown in Fig. 42 is *statically stable.* Note that from Fig. 42 that $C_{M,0}$ is positive and that the slope of the curve, $\partial C_{M,\text{cg}}/\partial \alpha_a$, is negative. Here, the partial derivative is used for the slope of the moment coefficient curve. This is because $C_{M,\text{cg}}$ depends on a number of other variables in addition to α, and therefore it is mathematically proper to use $\partial C_{M,\text{cg}}/\partial \alpha_a$ rather than $dC_{M,\text{cg}}/d\alpha_a$ to represent the slope of the line in Fig. 42.

Consider now a different airplane, with a measured $C_{M,\text{cg}}$ variation as shown in Fig. 44. Imagine the airplane is flying at its trim angle of attack α_e as shown in Fig. 45(a). If it is disturbed by a gust, pitching the nose upward, as shown in Fig. 45(b), then $\alpha > \alpha_e$. From Fig. 44 this results in a positive (clockwise) moment, which tends to pitch the nose even further away from its equilibrium position. Similarly, if the gust pitches the nose downward [Fig. 45(c)], a negative (counterclockwise) moment results, which also tends to pitch the nose further away from its equilibrium position. Therefore, because the airplane tends to diverge from equilibrium when disturbed, it is *statically unstable.* Note from Fig. 42 that $C_{M,0}$ is negative and $\partial C_{M,\text{cg}}/\partial \alpha_a$ is positive for this airplane.

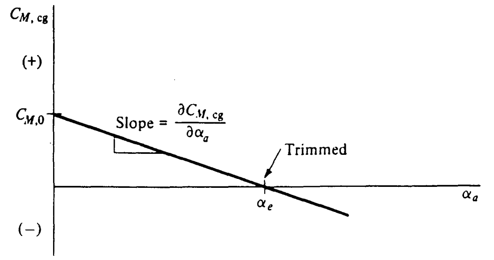

FIG. 42. Moment coefficient curve with a negative slope. [From Anderson (1989).]

For both airplanes, Figs. 42 and 44 show a positive value of α_e. An airplane moves through a range of angle of attack as it flies through its velocity range from V_{stall} (where α

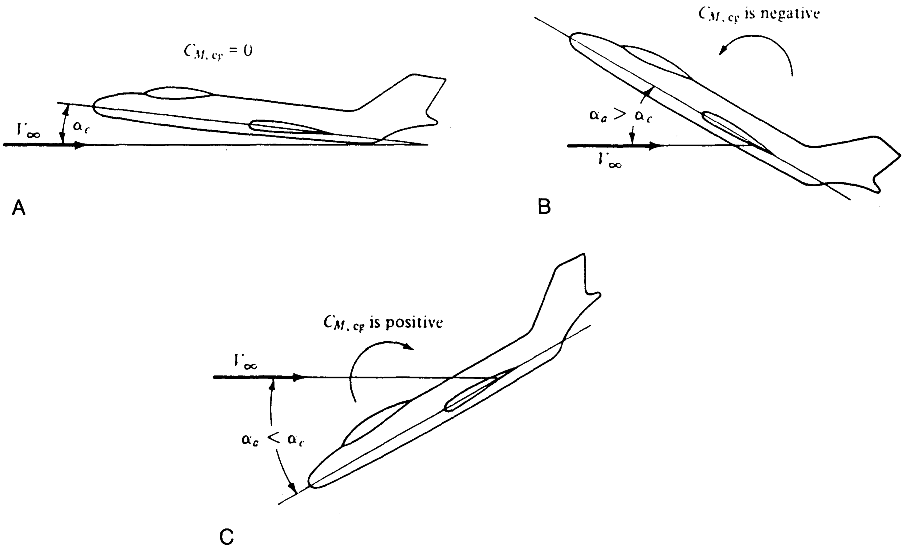

FIG. 43. Illustration of static stability: (a) Equilibrium position (trimmed). (b) Pitched upward by disturbance. (c) Pitched downward by disturbance. In both (b) and (c), the airplane has the initial tendency to return to its equilibrium position. [From Anderson (1989).]

is the largest) to $V_{\max}$ (where α is the smallest). The value of α_e must fall within this flight range of angle of attack, or else the airplane cannot be trimmed for steady flight. (Remember that we are assuming a fixed elevator position; we are discussing "stick-fixed" stability.) When α_e does fall within this range, the airplane is *longitudinally balanced.*

From the above considerations, we conclude the following. The necessary criteria for longitudinal balance and static stability are as follows:

1. $C_{M,0}$ must be positive.
2. $\partial C_{M,\mathrm{cg}}/\partial \alpha_a$ must be negative.

That is, the $C_{M,\mathrm{cg}}$ curve must look like Fig. 42. Of course, implicit in the above criteria is that α_e must also fall within the flight range of angle of attack for the airplane.

We are now in a position to explain why a conventional airplane has a horizontal tail (the horizontal stabilizer is shown in Fig. 35). First consider, an ordinary wing (by itself) with a conventional airfoil, say an NACA 2412 section. Note from the airfoil data in Figs. 9 and 10 that the moment coefficient about aerodynamic center is negative. This is characteristic of all airfoils with positive camber. Now, assume that the wing is at zero lift. In this case, the only moment on the wing is a pure couple; hence, at zero lift the moment about one point is equal to the moment about any other point. In particular,

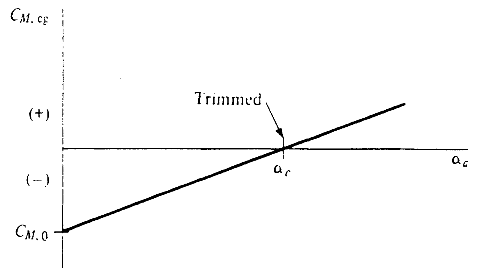

FIG. 44. Moment coefficient curve with a positive slope. [From Anderson (1989).]

$$C_{M,\mathrm{ac}} = C_{M,\mathrm{cg}} \text{ for zero lift (wing only).}$$

On the other hand, examination of Fig. 42 shows that $C_{M,0}$ is by definition the moment coefficient about the center of gravity at zero lift (when $\alpha = 0$). Hence,

$$C_{M,0} = C_{M,\mathrm{ac}} \text{ (wing only).}$$

This equation demonstrates that, for a wing with positive camber ($C_{M,\mathrm{ac}}$ negative) $C_{M,0}$ is also negative. Hence, such a wing by itself is *unbalanced.* To rectify this situation, a horizontal tail must be added to the airplane, as shown in Figs. 46(a) and 46(b). If the tail is mounted behind the wing, as shown in Fig.

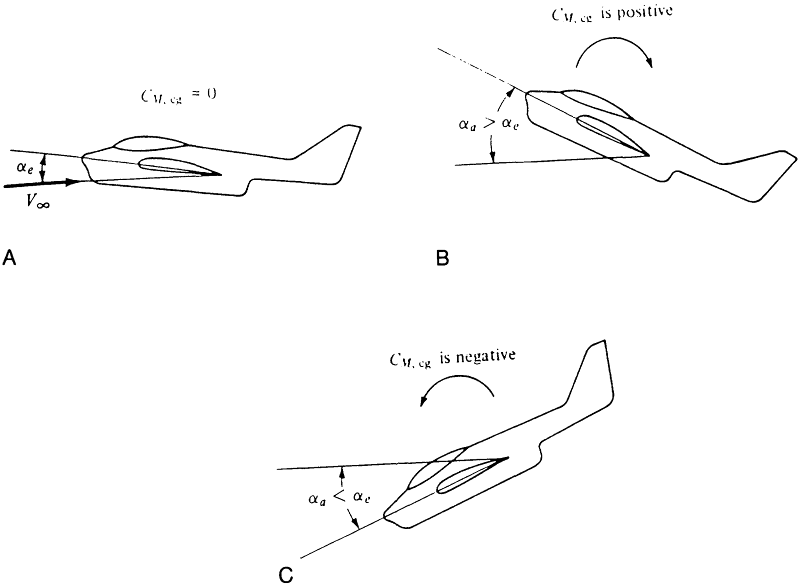

FIG. 45. Illustration of static instability. (a) Equilibrium position (trimmed). (b) Pitched upward by disturbance. (c) Pitched downward by disturbance. In both (b) and (c), the airplane has the initial tendency to diverge farther away from its equilibrium position. [From Anderson (1989).]

46(a), and if it is inclined downward to produce a negative tail lift as shown, then a clockwise moment about the center of gravity will be created. If this clockwise moment is strong enough, it will overcome the negative $C_{M,\text{ac}}$ and $C_{M,0}$ for the wing-tail combination will become positive. The airplane will then be balanced.

The arrangement shown in Fig. 46(a) is characteristic of most conventional airplanes. However, the tail can also be placed ahead of the wing, as shown in Fig. 46(b); this is called a *canard configuration*. For a canard, the tail is inclined upward to produce a positive lift, hence creating a clockwise moment about the center of gravity. If this moment is strong enough, $C_{M,0}$ for the wing-tail combination will become positive and again the airplane will be balanced.

3.3.1 The Neutral Point and Static Margin. An airplane will be statically stable in longitudinal motion if the slope of the moment coefficient curve is negative, as explained above. The location of the center of gravity plays a strong role in the value of this slope. The slope can be made more or less negative by moving the center of gravity forward or backward, respectively. There is some rearward location of the center of gravity at which the moment coefficient slope goes to zero, and hence the airplane becomes neutrally stable. This location is called the *neutral point*; it is a fixed point on the airplane. Hence, another criterion for stability is that the *center of gravity must be forward of the neutral point*. Basically, the neutral point is the *aerodynamic center* of the complete airplane; the moment coefficient about this point is independent of angle of attack.

The static margin is defined as the *distance* between the center of gravity and the neutral point, divided by the mean chord of the wing. When the center of gravity is forward of the neutral point, the static margin is positive. For static stability, the static margin must be positive.

It is interesting to note that the Wright brothers intentionally designed their airplanes to be statically unstable, i.e., with a negative static margin. This was to make the airplane immediately responsive to the controls. In contrast, a highly statically stable airplane naturally resists perturbations to its motion, and is therefore sluggish at the controls. On the other hand, the Wright airplanes were, as a result of the static instability, hard to fly. Virtually all conventional airplane designs since the Wright brothers were statically stable aircraft. However, with the advent of computer driven controls, modern military fighter aircraft such as the General Dynamics F-16 are once again being designed with a certain amount of negative static margin in order to enhance maneuverability.

4. HYPERSONIC FLIGHT

Flight in the 21st century will include airplanes which fly at many times the speed of sound—hypersonic flight. As a "rule-of-thumb" definition, hypersonic flight is that above a Mach number of five. However, hypersonic flow is best defined as that high-Mach number regime where certain physical flow phenomena become progressively more important, that are not important at lower supersonic or subsonic speeds. Among these are:

1. Thin shock layers. The shock waves lie very close to the body, and may even interact with the viscous boundary layer growing along the surface.
2. Very thick boundary layers, which can strongly interact with the outer inviscid flow. This is called *viscous interaction* problem.
3. High temperatures. The amount of kinetic energy is extremely large in a hypersonic flow. In regions on a body where the flow is slowed to low speeds, such as in the nose and leading-edge regions, and within a viscous boundary layer, the original kinetic energy is converted to internal energy in the gas, hence causing very high temperatures to occur in these regions. In such cases, the oxygen and nitrogen molecules in air will dissociate, and even ionization can occur. That is, the air can become a partially ionized plasma, and the flowfield over the body is a chemically reacting flow.

These effects distinguish hypersonic flight as a special regime in aeronautics.

Figure 47 shows a three-view diagram of a conceptual hypersonic cruise aircraft, e.g., a hypersonic transport. This NASA concept, in existence since the early 1970's, is a typical

example of a hypersonic airplane configuration. The solid lines show the wing-body combination, which was tested in a hypersonic wind tunnel; the dashed lines show the propulsion module and vertical tail surface, which are part of the airplane design but were not included in the wind-tunnel model.

As a final note in this section, we mention an important characteristic of any hypersonic-airplane design, namely, the necessity to integrate the propulsion system fully with the airframe. For subsonic airplane design, some attention is always paid to the aerodynamic interaction between the engine

(a) Supersonic transport ($M=3$), ram drag=54 500 lb, gross thrust=123 000 lb; (b) hypersonic transport ($M=6$), ram drag=220 000 lb, gross thrust=330 000 lb; (c) hypersonic cruise vehicle ($M=12$), ram drag=1950 000 lb, gross thrust=2100 000 lb. (Courtesy of NASA.)

nacelles and the rest of the airframe. However, this is not a driving aspect of airplane design, and in most subsonic airplanes the location of the engines is distinctly obvious. In contrast, at hypersonic speeds, extreme care must be taken to ensure that shock waves from one portion of the airplane, including the propulsion system, do not adversely impinge upon, and interact with, other portions of the airplane. Moreover, the flow that goes through the supersonic combustion ramjet engines has first passed through one or more shock-wave systems from the forward portion of the vehicle, and it is necessary to tailor the aerodynamic properties of this air so that they encourage the most efficient engine performance. Therefore, for a hypersonic airplane, the propulsion system and the airframe must be highly integrated. As an example, three typical generic configurations are compared in Fig. 48: a Mach 3 supersonic transport, a Mach 6 hypersonic transport, and a Mach 12 hypersonic cruise vehicle. Note that the supersonic airplane [Fig. 48(a)] still has fairly distinct propulsion nacelles and that none of the engine exhaust is designed to touch the airframe. In contrast, the Mach 6 hypersonic transport [Fig. 48(b)] has a more fully integrated propulsion system, where the rear part of the airframe acts as part of the engine nozzle expansion. Also, the wing and fuselage are more fully integrated, the wings being less distinct than for the Mach 3 airplane; i.e., the Mach 6 airplane is more of a blended wing-body configuration than the supersonic airplane. At Mach 12 [Fig. 48(c)] these features are even more pronounced; the undersurface area of the airframe exposed to the engine exhaust is much greater, and the engine is much more an integral part of the airframe. Since the wings have become much smaller, the Mach 12 vehicle is more like a *lifting body* than a wing-body combination. Clearly, the design of hypersonic vehicles is a marked departure from conventional airplane design, and this will pose many interesting challenges for the aerospace engineers of the future.

GLOSSARY

For the most part, all terms are defined within the text as appropriate. Here are a few of the important terms.

Aerodynamic Center: That point on an aerodynamic body about which the moments are independent of angle of attack.

Airfoil: A cross section of an airplane wing in the flow direction.

Angle of Attack: Angle between the chord line and the relative wind.

Aspect Ratio: Square of the wing span divided by the wing planform area.

Chord: Distance between the leading and trailing edges of an airfoil.

Critical Mach Number: That freestream Mach number at which sonic flow is first encountered at a point on the aircraft.

Drag: Component of the aerodynamic force parallel to the flight direction.

Lift: Component of the aerodynamic force perpendicular to the flight direction.

Planform Area: Projected area you see by looking down on the wing.

Relative Wind: The velocity and direction of the relative motion between the airplane and the atmosphere.

Span: Distance from one wing tip to the other.

Static Performance: Unaccelerated motion of the airplane.

Subsonic Flight: Mach number at every point the flow over the airplane is less than one.

Supersonic Flight: Mach number at almost every point in the flow over the airplane is greater than one.

Transonic Flight: The flowfield around the aircraft has mixed regions of both subsonic and supersonic speeds.

Trimmed: The condition when the moments about the center of gravity of the airplane are zero.

Wave Drag: Drag at transonic and supersonic speeds due to the presence of shock waves.

INTRODUCTION

Small solid or liquid particles suspended in a gas have found numerous scientific and technical applications. Such gas-borne dispersions are usually referred to as aerosols and treated in a branch of study known as aerosol science.

Aerosol is one of three types of dispersed systems found in nature and in various technological applications: aerosol (solid or liquid particles dispersed in a gas), hydrosol (solid or liquid particles suspended in a liquid), and foam (small gas bubbles dispersed in a solid or liquid). Although the most common aerosol systems are those with air as the suspending medium, other gaseous media are also important. The term aerosol is now used to denote any gas-borne particulate suspensions, including those in nitrogen, argon, helium, etc., and various complex gas mixtures, such as products of combustion from rockets, internal combustion engines, and coal or oil fired power plants, among others.

The importance of aerosols stems primarily from two facts: some particles are harmful and must be controlled, while others can be put to good practical use. Aerosols due to air pollution, for example, lead to visibility degradation and may be injurious to human health. Airborne lead, asbestos, and other harmful substances can lead to serious health consequences when inhaled and must be controlled to prevent overexposure. Atmospheric dust particles ingested by an engine, a gas turbine, or other power generating equipment can cause wear and the premature failure of the equipment. Particles depositing on semiconductor wafers during manufacturing of large-scale integrated circuit chips can cause defects, leading to device failure and loss of product yield. Beneficial applications of aerosols include production of useful materials such as carbon black, ceramic powders, glass fibers, etc., and use of aerosols for medical therapy or diagnosis. Understanding aerosol behavior and properties is important for such applications.

1. AEROSOL PROPERTY AND BEHAVIOR

The size range of interest in aerosol studies is approximately 0.002–100 μm. The lower limit of 2 nm (0.002 μm) is an operational limit, based on the size of the smallest particle that can be detected by an aerosol measuring instrument, viz., the condensation nucleus counter. Smaller particles do exist, but are usually in the form of molecular clusters, and normally not considered in aerosol studies. Particles larger than 100 μm will fall out quickly and are of less interest in aerosol science.

1.1 Mechanical Properties

The mechanical behavior of an aerosol particle is governed by the Stokes law (see FLUID DYNAMICS, EQUILIBRIUM), modified by the inclusion of a "slip correction," C, to account for the effect of gas slip due to the finite mean free path λ_g of the gas molecules:

$$F_d = 6\pi\mu aV/C\,. \tag{1}$$

In Eq. (1), F_d is the drag force exerted by the gas on the particle, V is the velocity of the particle relative to the gas, μ is the gas viscosity, and a is the particle (assumed spherical) radius. The slip correction is a function of the Knudsen number, $\mathrm{Kn} = \lambda_g/a$,

$$C = 1 + 1.246\,\mathrm{Kn} + 0.42\,\mathrm{Kn}\,e^{-0.87/\mathrm{Kn}}. \tag{2}$$

When subjected to a constant force F, an aerosol particle will achieve a terminal velocity V relative to the gas. The ratio V/F is known as the dynamic mobility:

$$B = V/F = C/6\pi\mu a\,. \tag{3}$$

The electrical mobility Z_p of a charged particle is the ratio of the terminal particle velocity to the applied electric field E,

$$Z_p = V/E = n_p eC/6\pi\mu a\,, \tag{4}$$

where n_p is the number of elementary units of charge on the particle, and e is the elementary unit of charge. The time period in which the particle will respond to the applied force to achieve the terminal velocity is of the order of the particle relaxation time,

$$\tau = 2a^2\rho_p C/9\mu\,, \tag{5}$$

where ρ_p is the particle density. Small particles also undergo Brownian motion due to molecular impact by the surrounding gas molecules. This leads to diffusion (see VISCOSITY AND DIFFUSION), described by a particle diffusion coefficient, which is related to the dynamic particle mobility B by Einstein's equation,

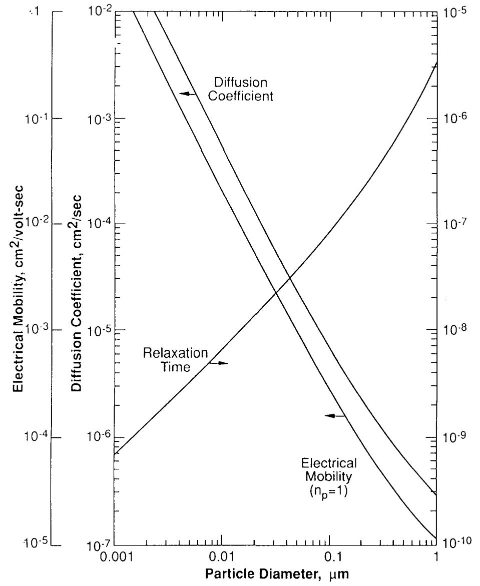

FIG. 1. Relaxation time, diffusion coefficient, and electrical mobility of submicrometer aerosols.

$$D = kTB = kTC/6\pi\mu a\,, \tag{6}$$

where k is Boltzmann's constant, and T is the absolute temperature. For large particles, gravitational settling is important. The settling speed of a particle in the Stokes law regime is given by

$$V_s = \tau g = 2a^2\rho_p Cg/9\mu\,, \tag{7}$$

where g is the acceleration of gravity. Figure 1 shows the relaxation time, electrical mobility, and diffusion coefficient of submicrometer particles and Fig. 2 shows the settling speed of particles in the >0.1 μm diameter range.

1.2 Electrical Properties

Aerosol particles found in the ambient air or generated in the laboratory are often charged. Important charging mechanisms include ion diffusion, ion drift in an electric field, and contact electrification. A high-voltage corona discharge will produce unipolar ions which can be used to charge the par-

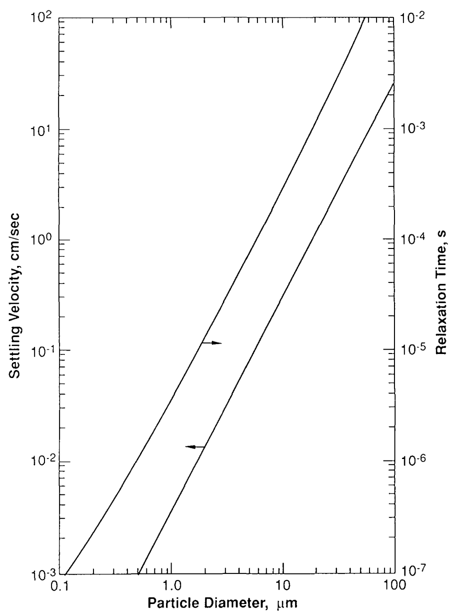

FIG. 2. Relaxation time and settling velocity of aerosols.

ticles by diffusion or ion drift, while surface contact is necessary for charging by contact electrification. Thus, particles reentrained from a solid surface or an aerosol formed by dispersing a powder into air are often charged due to contact electrification.

In the presence of ionizing radiation, the gaseous medium surrounding the particles may be ionized, leading to the appearance of positive and negative ions of approximately equal concentration in the gas. These ions will collide with the particles, causing the aerosol cloud to develop a bipolar charge. The steady-state bipolar charge distribution on the particles is given by the Boltzmann law and shown in Table 1.

Other mechanisms of charging include thermionic emission (*q.v.*) at high temperatures, photoelectric emission in the presence of light, gamma rays, or x rays, and induction charging when liquid sprays are formed in the presence of an electric field. The last mechanism is particularly important in industrial spray painting where charged paint droplets are produced by induction to increase the efficiency of paint utilization.

Figure 3 shows the aerosol charge levels for some of the charging mechanisms described above. Included in the figure is the Rayleigh limit for liquid droplets, which is the limiting charge at which the repulsive force due to the surface charge on the drop is just sufficient to overcome the surface tension to cause drop disintegration and, therefore, is the maximum charge a liquid drop can carry. The charge on atomized drops shown is based on the theory of Smoluchowski (Whitby and

Liu, 1966) for droplet charge resulting from the random fluctuation of ions in the liquid at the time of droplet formation during atomization.

1.3 Optical Properties and Light Scattering

The optical properties of aerosol particles depend on the sizes of the particles and the wavelength of light (see ELECTROMAGNETIC RADIATION). Light scattering by aerosol particles is responsible for many spectacular effects seen in the atmosphere. Colored sunsets, coronae, halos, and rainbows are all due to light scattering by atmospheric particles or water droplets. Calculations of light scattering by small spherical particles can be made by the Mie theory (Kerker, 1969). For small particles with radius a much smaller than the wavelength of light λ, the theory of Rayleigh scattering applies:

$$I_1 = \frac{8 I_0 \pi^4 a^6}{R^2 \lambda^4} \left(\frac{m^2 - 1}{m^2 + 2} \right)^2, \tag{8}$$

$$I_2 = \frac{8 I_0 \pi^4 a^6}{R^2 \lambda^4} \left(\frac{m^2 - 1}{m^2 + 2} \right)^2 \cos^2\theta, \tag{9}$$

for scattered intensities I_1 and I_2 polarized perpendicular and parallel to the scattering plane and for a receiver at the distance R from the scatterer and in the direction θ from the incident beam, where m is the refractive index of the particle. The light scattering by small particles is strongly dependent on light wavelength and particle size. The total scattering cross section of a particle increases as the sixth power of particle size and inversely as the fourth power of wavelength.

2. INSTRUMENTATION FOR AEROSOL STUDIES

Devices needed for aerosol studies include those for the generation, measuring, sampling, and analysis of airborne particles. Many such devices were developed in the 1970s and 1980s, in response to the need in air pollution studies. Figure 4 summarizes the principal devices used in aerosol studies. A comprehensive review of the topic has been given in two recent papers by Liu and Pui (1987) and Pui and Liu (1988). In this article, only selected instruments in each category will be briefly discussed to illustrate their operating principles and performance characteristics.

2.1 Aerosol Generators

The ability to generate an aerosol in a controlled and reproducible manner is an important requirement for laboratory aerosol studies. As shown in Fig. 4, a variety of aerosol generators have been developed to produce monodisperse (particles of the same size) or polydisperse (nonuniform sized) aerosols for experimental purposes. Two such devices are particularly important in basic aerosol science because they are used as standards of calibration for aerosol measuring instruments and for different experimental purposes.

The vibrating orifice monodisperse aerosol generator, described by Berglund and Liu (1973), and shown schematically in Fig. 5, is based on the controlled disintegration of a liquid jet through a small vibrating orifice to produce uniform droplets. The jet is formed

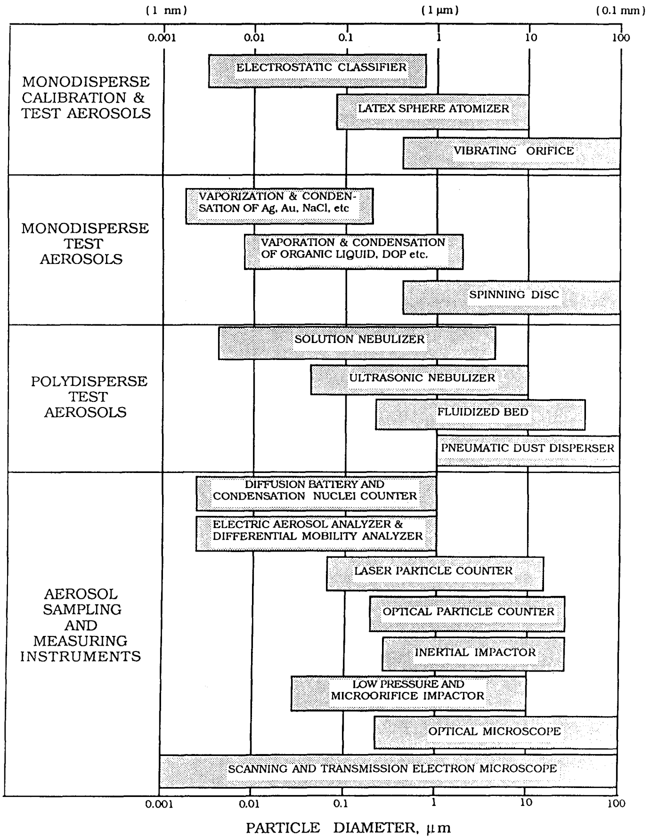

FIG. 4. Size range of aerosol generating, measuring, and sampling instruments.

by means of a syringe pump which forces the liquid through the small orifice which is vibrated at a suitable frequency by a piezoelectric ceramic. The jet is broken up into uniform droplets by the vibration. To prevent plugging of the orifice, which is usually quite small (5–20 μm), the upstream passage of the orifice must be flushed with pure solvent by removing the plug before the start of the jet.

The vibrating orifice generator produces uniform droplets of a known volume V_d, which is related to the vibrating frequency f and the liquid flow rate Q by the equation $V_d = Q/f$. By atomizing a solution of the aero-

sol material in a volatile solvent, and allowing the solvent to evaporate from the droplets, a monodisperse aerosol of diameter $D_p = (6QC/\pi f)^{1/3}$, is obtained, where C is the volumetric concentration of the dissolved material in the solution. The particle diameter can thus be determined accurately by measuring the quantities Q, f, and C. Some solid and liquid particles produced by the device are shown in Fig. 6. The device is capable of generating monodisperse aerosols from less than 1 μm to about 30 μm in diameter. With simple modifications, particles as large as several hundred micrometers have been generated by the principle. The device is particularly useful for generating aerosols of a known size for calibrating optical particle counters, inertial impactors, and other particle measuring instruments, and for fundamental studies such as those concerning turbulent deposition, electrical charging, and neutralization, etc.

To produce submicrometer aerosols, the electrostatic classification method of Liu and Pui (1974) shown in Fig. 7 is widely used. The system includes an atomizer to produce a polydisperse aerosol which is then classified electrically according to mobility to produce a monodisperse aerosol. The particle size can be calculated from the known electrical mobility of the particles, and the particle concentration can be measured by collecting the charged particles by filtration and measuring the resulting current flow with an electrometer. Making use of the fact that the particles are singly charged, the aerosol concentration can be determined by the equation $N = I/eq$, where I is the electrometer current, e is the elementary unit of charge, and q is the volumetric flow rate of the aerosol. The device has been used for generating monodisperse aerosols in the 0.008 to 1 μm diameter range to calibrate condensation nucleus counters, diffusion batteries, the electrical aerosol analyzer, etc., and for various experimental aerosol studies.

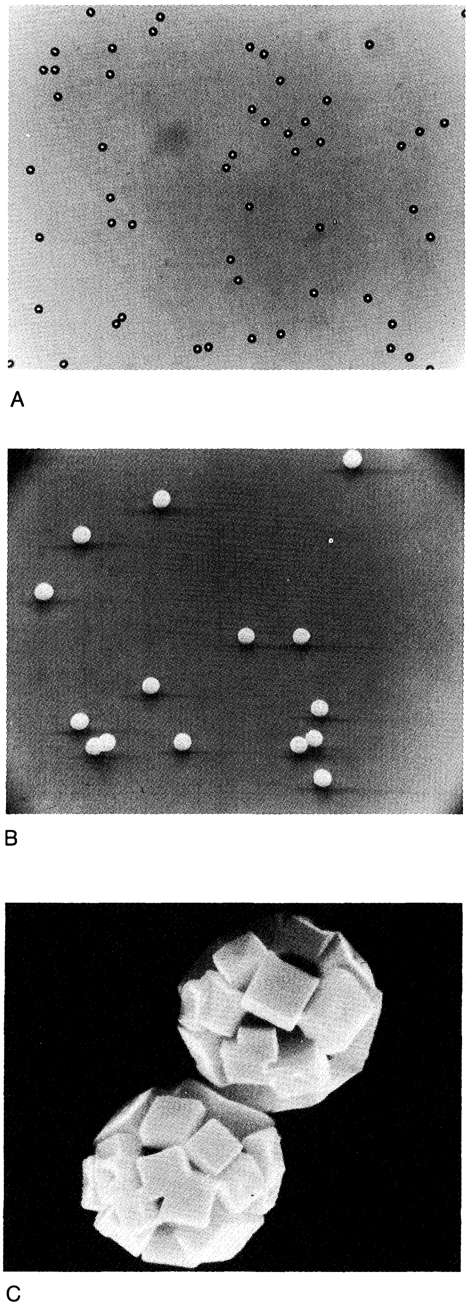

FIG. 6. Particles generated by the Berglund–Liu generator; particles are approximately 4, 5, and 10 μm in diameter (top to bottom).

2.2 Aerosol Measuring Instruments

Automatic instruments for concentration and size distribution measurement of aerosols are available to cover a wide range of particle sizes from 0.002 to approximately 50 μm. These instruments have fast time response and can follow rapid changes in both particle size and concentration. Good counting statistics can usually be obtained with automatic instruments because repeated measurements on a large number of particles will yield statistically accurate results. On the other hand, automatic instruments usually

rely on indirect sensing techniques and more calibration effort is usually required.

The optical particle counter, shown schematically in Fig. 8, is widely used for particle measurement in both the indoor—as in a cleanroom—and outdoor environments. Single, individual particles are carried by an airstream into the instrument and passed through an illuminated viewing volume where light is scattered by the particle as it traverses the volume. The scattered light is then sensed by a photomultiplier or a solid-state photodetector. The output of the sensor is in the form of a voltage pulse corresponding to the passage of the particle through the viewing volume. By counting the number of pulses and measuring the corresponding pulse amplitude, both the number and size of particles can be determined. Traditional counters using an incandescent light source can measure particles to approximately 0.3 μm in diameter. Counters using gas or solid-state laser sources can measure smaller particles—to approximately 0.05 μm in diameter. The upper size limit of the instrument is usually about 10 μm due to sampling limitations—particles much larger than 10 μm usually do not follow the streamlines faithfully into the sensing volume of the instrument for them to be counted. Calibration studies by Liu *et al.* (1974, 1985, 1986b), Szymanski and Liu (1986), and others show that

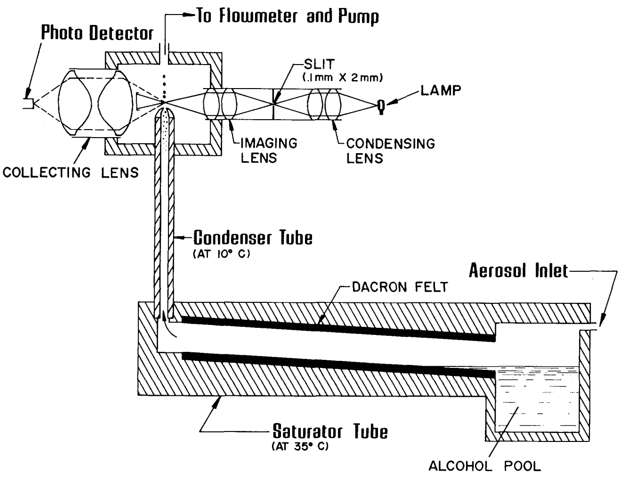

FIG. 9. Schematic diagram of the continuous flow condensation nucleus counter.

the influence of refractive index and particle size on counter response can be predicted accurately by Mie scattering calculations.

The principal instrument for counting particles smaller than 0.1 μm is the condensation nucleus counter (CNC). A schematic diagram of a commercially available CNC, described by Agarwal and Sem (1980), is shown in Fig. 9. The aerosol to be measured is first saturated with alcohol vapor by passing through a heated butyl alcohol saturator maintained at 35 °C, and then cooled in a thermoelectrically cooled condenser to 10 °C. This causes the vapor to become supersaturated and condense on the particles. Particles that are too small to be detectable by direct light scattering can then be detected by measuring the grown drops, which are usually about 12 μm in diameter. Either the particles can be counted individually or, in the case of high aerosol concentrations, the light scattering from the entire droplet cloud in the viewing volume can be measured in a "photometric mode" to determine the droplet concentration. Particle concentration in the range of <0.01 to more than 10^6 particles/cm^3 can be measured. The lower detection limit of the standard commercially available instruments is in the range of 0.005–0.01 μm. Recent advances in instrument design (Stolzenburg and McMurry, 1984) have led to instruments capable of measuring small, ultrafine particles to as small as 0.003 μm in diameter.

Since the CNC measures only the particle concentration, a different approach is needed to measure particle size. This is often done by combining the CNC with a size-selective filter in the form of a diffusion battery. By passing aerosols through metal screens of different sizes, particles with sizes below a selectable limit can be removed. Using a series of such diffusion screens and the CNC, the size distribution of the aerosol can be measured.

Another approach to sizing submicrometer aerosols is the electrical aerosol analyzer (EAA) described by Liu and Pui (1975) and shown schematically in Fig. 10. The instrument operates by first charging the aerosol particles, using unipolar ions produced by a corona discharge, and then measuring the electrical mobility of the charged particles. From the measured electrical mobility distribution and knowing the relationship between particle size and mobility by calibration, the size distribution of the particles can be determined. The instrument has been used for air pollution studies and for measuring the characteristics of pollution control devices, such as the electrostatic precipitator, bag-house filter, etc.

2.3 Aerosol Samplers

Sampling instruments for aerosols are particularly useful when particles are to be collected for subsequent analysis. The collection can be done with a simple filter to give an integrated sample for time-averaged mass or chemical measurement, or with an impactor or cyclone to give size-fractionated samples for mass concentration and chemical composition studies as a function of particle size. Analysis of a collected sample can be done by weighing with a microbalance, wet-chemical

analysis following sample extraction, or various nondestructive chemical analysis techniques, such as energy disperse x-ray (EDX), x-ray fluorescence (XRF), and proton induced x-ray emission (PIXE) analysis, among others.

The cascade impactor, shown schematically in Fig. 11, is particularly useful and widely used for size fractionating of airborne particles. A single-stage impactor, consisting of a nozzle directing a high-velocity jet against a solid surface, will cause particles above the stage "cut size" to impact on the surface while allowing smaller particles to pass through. This occurs because large particles traveling towards the impaction plate will have sufficient momentum to impact on the plate as the airflow is deflected sideways by the plate. In the meantime, small particles with insufficient momentum will follow the air flow and be carried by the airstream around the plate, thus avoiding impaction. The critical particle size at which this occurs is known as the stage cut size.

The stage cut size of an impactor can be varied by varying the nozzle diameter and the airflow velocity. By arranging several of these impactor stages in series with progressively smaller nozzles and higher jet velocities, progressively smaller particles can be removed by impaction. By this means, a polydisperse aerosol composed of particles covering a wide range of sizes can be size-fractionated into samples each covering only a narrow size range. The size-fractionated samples can then be analyzed by weighing to determine their mass, or by x-ray fluorescence, atomic

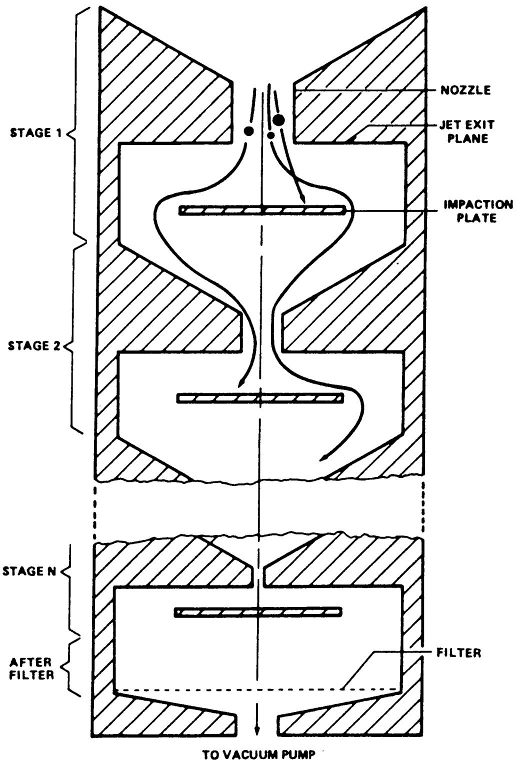

FIG. 11. Schematic diagram of cascade impactor.

absorption, etc., to determine their elemental chemical composition.

The lower size limit of the conventional impactor is about 0.3 μm. Smaller particles can be impacted by means of small nozzle diameters, or high jet velocities, or both. A recent development by Marple *et al.* (1981), using micro-orifice nozzles, allows the cut size to be extended to 0.05 μm. A typical micro-orifice impactor will have six to eight impactor stages and a final filter stage. The filter collects all particles below the smallest cutoff size of the impactor stage. A picture of the Micro-Orifice Uniform Deposit impactor described by Marple *et al.* is shown in Fig. 12.

Impactor samplers require particles to adhere to the surface upon impact. Since this may not occur for dry solid particles, the surface usually must be coated with an adhesive layer to prevent particle bounce. Another approach involves using a virtual impactor (Loo *et al.*, 1979), shown schematically in Fig. 13. In the virtual impactor, the particle-bearing airstream exiting the nozzle is directed at the void space of a receiving tube. Only a small fraction (about 10%) of the airflow is allowed to flow through the receiving tube, while the remainder is deflected through a side passage as shown. Particles larger than the cut size of the virtual impactor stage will not follow the major airflow into the side passage, but will impact into the receiving tube as a result of their momentum. These particles are then carried by the small airflow to a filter located downstream. Particle bounce therefore can be avoided. A single virtual impactor will separate particles into two size fractions, each fraction being collected on a separate filter. By arranging several of these virtual impactor stages in series, size-fractionated samples can be obtained.

3. SCIENTIFIC AND TECHNICAL APPLICATIONS

3.1 Lung Deposition and Respiratory Protection

Small airborne particles can be inhaled into, and be deposited in, the lung to cause damage or produce harmful health effects. The ability of an aerosol to enter the human respiratory system is governed by the aerodynamic particle size, defined as the size of a unit-density sphere having the same settling

velocity as the particle in question. The entire human respiratory system can be divided into three regions: the head airways region, the tracheobronchial region, and the alveolar region (Hinds, 1982). Particles smaller than 100 μm will enter the nose during breathing, but most will deposit in the head region. Only those smaller than 10 μm can enter the trachea and those smaller than about 3.5 μm can reach the deep, gas exchange region of the lung. The ACGIH (American Conference of Governmental Industrial Hygienists) Air Sampling Procedures Committee (Phalen *et al.*, 1986) has established the size-dependent respiratory penetration curves shown in Fig. 14 to describe particle penetration into the human respiratory system, and has recommended measuring three mass fractions for assessing airborne inhalation hazard: the inspirable particulate mass (IPM) for materials which may be hazardous anywhere in the respiratory tract, thoracic particulate mass (TPM) for materials which may be hazardous anywhere within the lung airways and the gas exchange region, and respiratory particulate mass (RPM) for materials which may be hazardous in the gas exchange region of the lung. The U.S. Environmental Protection Agency has recently promulgated a PM-10 standard (particulate matter, 10 μm cut) for the thoracic particle concentration in the revised particulate air quality standard for ambient air. Devices for ambient PM-10 sampling have been described by Liu and Pui (1986) and McFarland *et al.* (1984).

In the workplace environment where airborne particulate concentration can reach unhealthy levels, respirators are often used to protect workers against particulate exposure. One of the earliest aerosol studies was in connection with developing respirators to protect miners and firemen. Early pioneers, such as Robert Brown in 1827 and John Tyndall in 1870, developed respirators using aerosol technologies. However, the most rapid advances made in respirator design were during World War I to develop respirators to protect personnel against chemical warfare agents (Pritchard, 1976).

Modern respirators come in a variety of shapes and configurations to protect the wearer against inhalation of harmful substances, including particles, gas, and vapors. Figure 15 shows the general classification of respirators according to whether they are atmosphere supplying or air purifying. The former is further divided into two major subcategories, self-contained breathing apparatus and air supplied respirator; and the latter into powered and nonpowered. There are further subclassifications according to their specific design, intended applications, or ability to remove gas, vapor, and/or particles.

An increasingly popular form of respirator for the workplace environment and for general use is the disposable mask made of fine

organic or glass fiber mats. A recent development is the dielectric fibers carrying a permanent dipole electric charge. The charge density is much higher than in the classical resin-impregnated wool fibers and gives stable performance at high temperature and in humid environments. On account of their high efficiency and low breathing resistance, the filters have found increasing use as the respirator filter media. A fundamental study of disposable respirators has been reported by Fardi and Liu (1989). A photograph of a disposable respirator face mask and a cartridge-type full face mask is shown in Fig. 16.

3.2 Atmospheric Aerosols and Air Pollution

Aerosols in the ambient atmosphere are complex mixtures of particles from a variety of sources. The principal sources include those that are natural, such as windblown dust, sea salt sprays, etc., and those that are man-made, such as direct emission from industrial plants and vehicular emissions. Gaseous emissions from both natural and man-made sources can also be converted into particles in the atmosphere through photochemical reactions. H_2S, NH_3, and other organic and inorganic species produced by decaying vegetation and hydrocarbon emissions from industrial plants and motor vehicles can react in the atmosphere under sunlight to form condensable species and aerosol particles (see AIR POLLUTION). Table 2 shows the typical atmospheric concentrations of particles in urban and rural areas (Seinfeld, 1986).

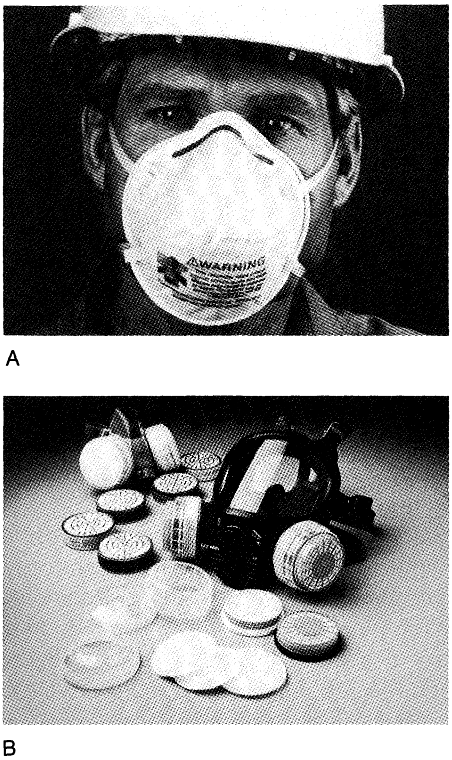

FIG. 16. Disposable and cartridge-type respirators (courtesy 3M Co.).

The size distribution of atmospheric aerosols is usually bimodal in shape with particles in the coarse (>2.5 μm) mode being primarily of soil origin, such as oxides of aluminum, iron, and silicon, and those in the fine particle mode consisting of products of com-

bustion or photochemical reaction. This bimodal size distribution is shown in Fig. 17 and illustrated in Fig. 18 for the distribution of pollutant species in the aerosol (Whitby, 1978).

3.3 Industrial Gas Cleaning

Particles suspended in a gas often need to be removed for purposes of product recovery, equipment protection, or emission control to meet environmental regulations. Important equipment used for industrial gas cleaning includes fibrous and fabric filters and electrostatic precipitators.

Fibrous and fabric filters remove particles by capturing the particles by adhesion when the particles are brought into physical contact with the fiber by the airflow. The overall efficiency of a fibrous filter is shown schematically in Fig. 19. For small particles, the diffusion mechanism is important, whereas for large particles, the interception and impaction mechanisms dominate. The minimum in the curve of filter efficiency versus particle size corresponds to the transition from the diffusion dominated regime to the interception and inertial impaction dominated filtration regimes. This minimum usually occurs in the 0.1 to 0.3 μm diameter range. Figure 20 (Liu *et al.*, 1985) shows the penetration (1 – efficiency) of the aerosol through a HEPA (high efficiency particulate air) filter and an ULPA (ultralow penetration air) filter. These filters are used extensively for cleanroom air filtration and they have efficiencies in excess of 99.99% in the most penetrating particle size range.

A popular form of industrial gas filter is the pulse-cleaned cartridge dust collector shown schematically in Fig. 21. The filter is in the form of a pleated paper element made into a cylindrical cartridge. A number of these cartridges are placed in the collector to provide the required flow rate. Particles are collected on the outside of the cylindrical cartridges as the airflow passes through them and these particles can be dislodged from the outside surface by a pulse of high-pressure air and drop into a dust bin below. The cartridge filters have efficiencies in excess of 99.999% for dry dust particles. Table 3 shows the performance of nine industrial dust collectors (Bergin *et al.*, 1989). The high efficiencies of these filters have made it possible to recirculate the treated air into the workplace environment for energy conservation and other purposes.

For high volume gas filtration requiring low pressure drop, the electrostatic precipitator invented by F. G. Cottrell (White, 1963) is widely used. A typical single stage electrostatic precipitator is shown in Fig. 22. It consists of a discharge electrode to produce unipolar negative ions, which charge the particle as they flow through the corona discharge region. The charged particles are then precipi-

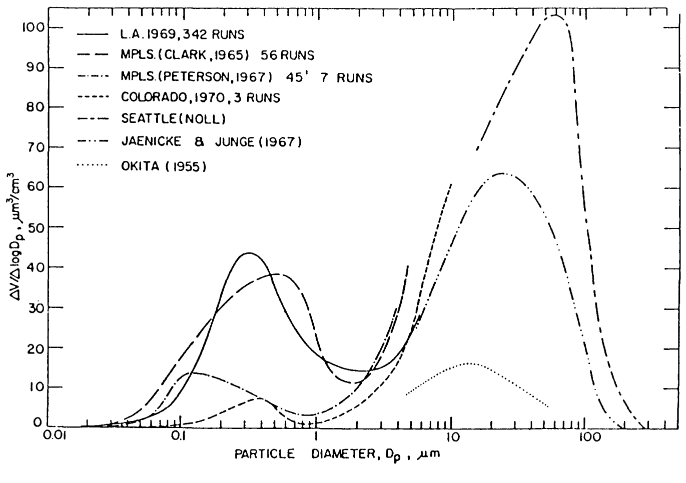

FIG. 17. The bimodal size distribution of atmospheric aerosols (Whitby, 1978).

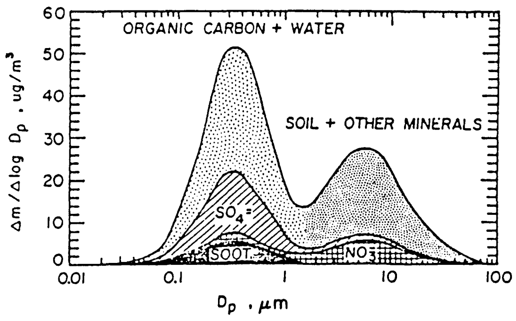

FIG. 18. Distribution of pollutant chemical species in the aerosol modes.

tated onto the outer electrode by the electric field. Electrostatic precipitators are used extensively for fly ash removal from coal-fired power plants and for various industrial applications. Theory of particle charging due to ion drift in the corona discharge region has been developed by Liu and Kapadia (1978).

Other important industrial gas cleaning devices include cyclones and Venturi scrubbers (Strauss, 1966). Cyclones operate by imparting a rotational motion to the gas to cause the particles to be separated by centrifugal force. The rotational gas motion can be created by a set of turning vanes or by introducing the gas into the cylindrical cyclone body in a tangential direction. Venturi scrubbers operate by accelerating the gas flow in a Venturi tube to a high velocity in the Venturi throat, to atomize water and cause particle impaction on the atomized drops. The water drops are then removed along with the collected particles by a cyclone or a mist eliminator.

3.4 Cleanrooms and Microelectronics

Clean manufacturing technologies for microelectronics constitutes a fast growing area for the application of aerosol science. The manufacturing of integrated circuit chips and data storage devices, such as those based on magnetic thin films, is a multibillion dollar industry that requires particulate contamination control, including the control of airborne contaminants in the form of aerosols (see SEMICONDUCTOR DEVICE PROCESSING). The yield and reliability of the manufactured products depend critically on contamination control and the avoidance of particulate contamination due to people, machinery, and process generated contaminants.

Due to device miniaturization, the critical contaminant size causing device failure also becomes smaller. Figure 23 (Larrabee, 1985) shows a sequence of photos comparing the semiconductor wafer, the integrated circuit chips on the wafer, and typical device feature size, to an insect—a ladybug. The state-of-the-art 1-megabit DRAM (dynamic random access memory) chip capable of storing one million bits of data has typical device feature sizes of approximately 0.9 μm (Cooper, 1986). The next-generation 4-megabit chips will have feature sizes of the order of 0.7 μm. Contaminant particles down to 1/10 of the characteristic device feature size are usually consid-

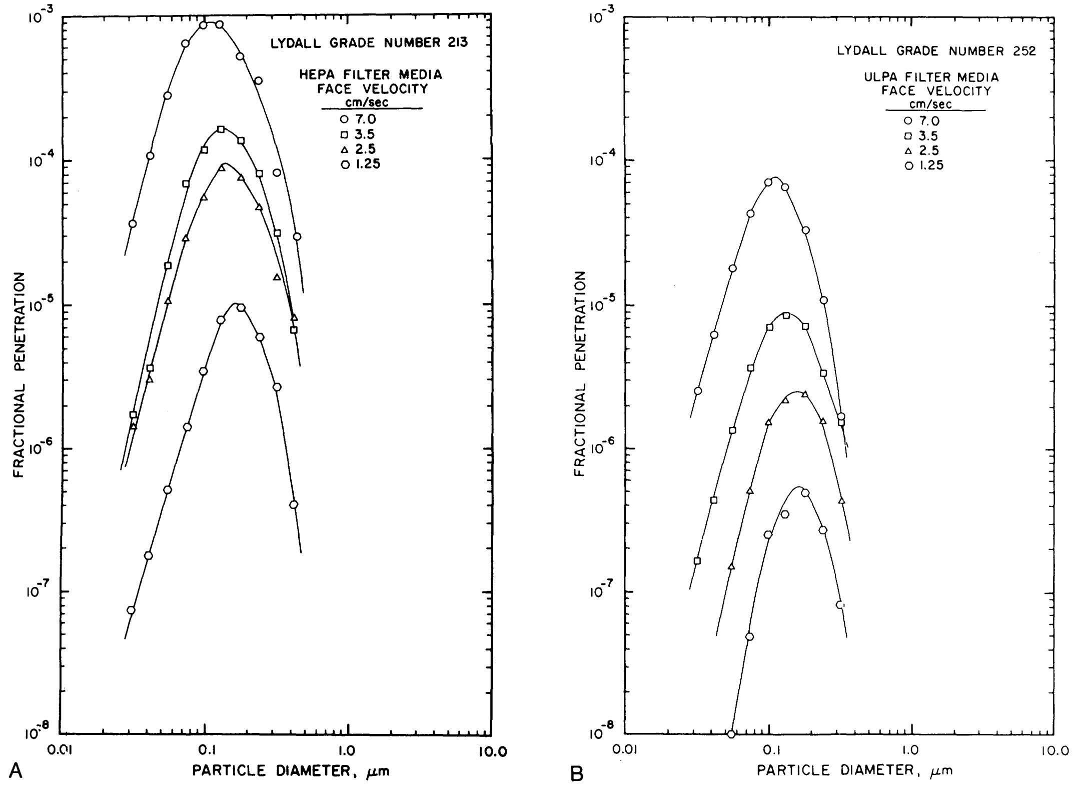

FIG. 20. Aerosol penetration through HEAP (high efficiency particulate air) and ULPA (ultralow penetration air) filters (Liu *et al.*, 1985).

ered harmful and must be avoided. The present concern is for particles down to approximately 0.1 μm. Future generations of integrated circuit chips will require the control of particles of all sizes down to the lower size limit of aerosol science, viz., 2 nm.

For magnetic storage disk drives, the read-write head is supported on a thin air film above a rotating disk. The spacing between the head and the rotating disk surface is currently about 0.2–0.3 μm. Figure 24 shows the flying height of the head as compared to the

sizes of some typical particles. Particles larger than the "flying height" of the head can cause damage or the destruction of the device in a "head crash."

To control airborne contaminants, microelectronic manufacturing is usually done in a cleanroom. Figure 25 is a schematic diagram of a typical vertical laminar-flow (VLF) cleanroom (Larrabee, 1985). Air is introduced through HEPA (high efficiency particulate air) or ULPA (ultralow penetration air) filters covering the entire ceiling into the clean-

room. Although the airflow in a VLF cleanroom is vertical, it is seldom laminar. As Fig. 25 shows, various factors can cause the airflow in a VLF cleanroom to become turbulent. Other types of cleanrooms include the horizontal flow cleanroom in which air flows horizontally from one end of the room to the other, and the mixed flow cleanroom in which the airflow is vertical, but different velocities are maintained across the ceiling filter to reduce airflow requirement and conserve energy.

Cleanrooms are usually categorized into classes in accordance with Federal Standard 209D (FED-STD-209D, 1988). A Class 100 cleanroom is one in which there are fewer than 100 particles per cubic foot >0.5 μm, Class 10, fewer than 10 particles per cubic feet >0.5 μm, etc. Since normal ambient air contains approximately 1 million particles

per cubic foot >0.5 μm, a Class 100 cleanroom is 10 000 times cleaner than the normal ambient; a Class 10 cleanroom, 100 000 times cleaner. Current cleanrooms are being constructed in the Class 1 to Class 10 level for the state-of-the-art semiconductor manufacturing.

Deposition of aerosol particles on semiconductor wafers has been studied theoretically (Liu and Ahn, 1987) and by experiments (Pui *et al.*, 1990). Figure 26 shows the particle deposition velocity, the ratio of particle flux to airborne particle concentration, as a function of particle diameter. Particles larger than 0.2 μm are deposited by gravitational sedimentation and those below by Brownian diffusion.

3.5 Material Synthesis and Processing

Aerosol technology has played an important role in modern material processing. Aerosols are used in material synthesis to produce powders and bulk materials (Bowen, 1980), and for coating optical and microwave waveguides (Schober, 1987). Due to their simplicity and freedom from contamination, aerosol processes are used in the production of a variety of modern materials, such as advanced ceramics, carbon black, paint pigments, and high-temperature superconductors, and for coating waveguides, refractories, gas sensors, and semiconductors.

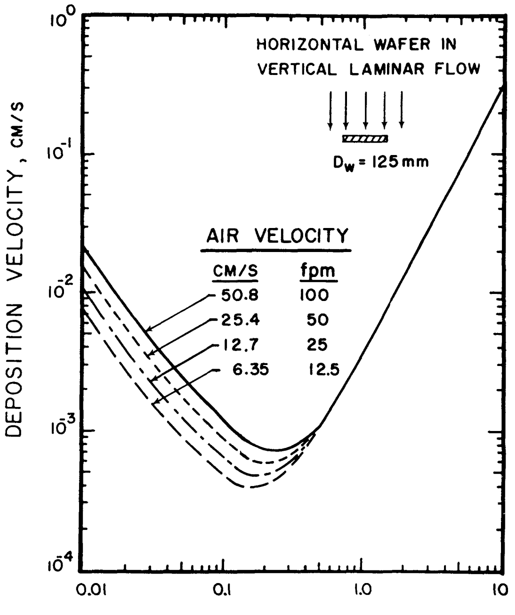

FIG. 26. Deposition velocity of aerosol particle on semiconductor wafers.

Table 4 summarizes the applications of aerosol processing of materials (Flagan, 1989). The largest commercial aerosol processes are flame synthesis reactors that are used in the production of carbon black, TiO_2 powder, and fume silica. Ceramics are produced by a number of aerosol processes including flame synthesis to produce oxides and carbides, plasma synthesis to produce oxides, carbides, nitrides, and borides, laser synthesis to produce SiC and Si_3N_4, and thermal reactors to produce Si, Si_3N_4, oxides, etc. Combustion processes are also used in a number of film growth technologies including the modified chemical vapor deposition process (see CHEMICAL VAPOR DEPOSITION) that is used to fabricate optical waveguide preforms (Nagel *et al.*, 1982). Lasers (Flint *et al.*, 1982) and plasmas (Pfender and Young, 1985) are also used to drive the chemistry in aerosol processes for powder synthesis or film growth.

Figure 27 shows a schematic diagram of a vapor-phase reactor developed for producing ultrafine MgO powder (Sheppard, 1987). The 99.98% ultrafine MgO can be used for such applications as sintering aids, electronics, catalysts, and rubber or plastic additions. To produce the powder, Mg is heated in an inert

gas atmosphere above its boiling point by an electric furnace. The Mg vapor is then injected by argon into the oxidation region through the cylindrical nozzle, A. The oxidizing air is carried into the oxidation region through an annular nozzle B outside of nozzle A. A diffusion flame is formed as a result of reaction between the Mg vapor and the oxidizing air, which oxidizes the vapor to form MgO powder.

A second example involves the fabrication of a gas sensor using ultrafine tin dioxide particles. Figure 28 shows the schematic diagram of an ultrafine tin dioxide particle generator developed by Adachi *et al.* (1988). High-purity tin wire in a ceramic boat is heated in a nitrogen gas stream. The tin vapor is subsequently oxidized by oxygen gas in a mixing section to produce a supersaturated tin dioxide vapor. At a sufficient level of supersaturation, ultrafine tin oxide clusters are formed by homogeneous nucleation and by heterogeneous condensation of vapor molecules on the clusters. These tin dioxide particles are then impacted onto a glass substrate between two silver-plated electrodes to produce a deposit 2×3 mm in size and 0.01 to 0.2 mm in thickness. The gas sensor was found to be a sensitive leak detector for hydrogen in air.

3.6 Radioactive Aerosols and Nuclear Safety

Radioactive aerosols have received considerable attention by aerosol scientists because of safety concerns relating to nuclear power and fuel reprocessing plants. Radioactive aerosols also occur naturally as decay products of radon emanation from the soil attach to airborne particles. Current nuclear research has focused on three areas, namely, characterization of sources of nuclear aerosols, aerosol transport and deposition in confined systems, and air cleaning and nuclear aerosols. A summary of nuclear aerosol research can be found in the two international aerosol conference proceedings (Liu, Pui, and Fissan, 1984; GAeF and AAAR, 1986). Extensive research has been performed in the above three areas for fast breeder (LMFBR), light-water reactor (LWR), and reprocessing plant (RP).

In a nuclear power plant accident, the most severe form of which is the loss of all coolant to the reactor cores, the core would melt and vaporize, leading to the formation of highly radioactive aerosols. These aerosols would first be released into the containment vessel, and in the case of containment failure, escape to the ambient atmosphere. The source terms describing radioactive aerosol release can be classified as primary or secondary. The primary source terms are those due to the melting and vaporization of major parts of the core inventory, and the secondary, those in the form of delayed emissions such as hot sodium in LMFBR carrying fission and activation products which are released into the containment space (Schikarski, 1984). Brockmann and Tarbell (1984) have demonstrated that the pressurized ejec-

tion of molten core material from the vessel can lead to the formation of fine aerosols.

Computer codes for predicting aerosol transport and deposition in confined systems have been developed for nuclear safety studies beginning about 1965. Schikarski (1983) summarized the experimental programs and corresponding code development. Aerosol processes and properties, such as coagulation, sedimentation, diffusion, thermophoresis, diffusiophoresis, turbulent deposition, dynamic shape factor, and coagulation shape factor, all need to be considered in order to understand the behavior of nuclear aerosol in confined systems.

Air cleaning requirements in a nuclear facility are stringent. In addition to high removal efficiency, cleaning devices are required to handle high temperature and chemically aggressive nuclear aerosols. It is known that sodium aerosols together with high humidity can degrade ordinary HEPA filters rapidly. Alternative systems, such as granular bed filters, Venturi scrubbers, and electrostatic precipitators, are also investigated for the removal of nuclear aerosols (Schikarski, 1984).

Recent concerns about radon gas and its short-lived progeny in indoor environments and mine shafts have advanced significantly the measurement technology in radioactive aerosols and thus nuclear aerosols. Knutson *et al.* (1986) performed an intercomparison program for radon progeny measurement.

3.7 Atmospheric Science and Weather Modification

Clouds are formed when rising currents of air containing water vapor are cooled as they expand (see ATMOSPHERIC PHYSICS). Condensation of water vapor in the air requires aerosol particles to serve as nuclei of condensation. In the atmosphere, a particle of 0.1-μm diameter will serve as a nucleus of condensation for a cloud droplet at a supersaturation level of 1%. NaCl and other hygroscopic particles are particularly effective in serving as cloud nuclei due to their hygroscopic nature and their ability to absorb water vapor from the ambient atmosphere and grow before the relative humidity reaches 100%. The presence of aerosol particles in the ambient atmosphere therefore contributes to the cloud formation process. An important source of cloud nuclei over the ocean surface or in the coastal area is the dry sea salt particles resulting from the bursting of bubbles from breaking of waves on the ocean surface.

When clouds rise to a sufficiently high altitude, the temperature drops below 0 °C. However, the cloud droplets may remain in a supercooled liquid state due to the absence of freezing nuclei in the droplet. Very pure water droplets, only a few micrometers in diameter, may be supercooled to −40 °C without freezing and cloud droplets commonly exist in the supercooled state to −20 °C and, on occasion, down to −35 °C (Mason, 1975). The most important source of terrestrial ice nuclei appears to be soil particles, including clay minerals such as kaolinite, montmorillonite, and other closely related forms.

The possibility of seeding supercooled clouds by introducing artificial ice nuclei to form snow and initiate precipitation was foreseen in the 1930s, but cloud seeding experiments did not start in earnest until 1946, when Vincent J. Shaefer of the General Electric Company dropped dry ice into a supercooled cloud, precipitating snow that fell for 2000 ft before evaporating in the dry air. The discovery by B. Vonnegut in the same year that silver iodide crystals served as efficient ice nuclei further stimulated work on artificial rainmaking experiments in the U.S. and elsewhere. Cloud seeding is now done commercially, although only to a limited extent.

Atmospheric aerosols are often referred to as Aitken nuclei in honor of John Aitken, who in 1880 developed the first aerosol counter based on the adiabatic expansion of saturated air to condense water vapor on the invisible particles to form visible droplets, which are then counted. Atmospheric aerosols cover a wide range of sizes, from a few nanometers to as large as 100 μm. Atmospheric aerosols reflect sunlight back to space, and those with absorption characteristics will absorb solar radiation, causing a heating effect on the atmosphere. The climatic impact of air pollution is a subject of considerable contemporary interest, but the effect is not precisely quantified. When combined with the heating effect due to the "greenhouse gases," principally CO_2, which is also emitted by fossil fuel combustion, the net effect of air pollution on global climate remains to be determined. In the event of large scale nuclear war, very large amounts of aerosol material may be injected into the atmosphere to cause a significant cooling of the atmosphere and the onset of "nuclear winter." Both the nature and the extent of the nuclear winter effect are of some controversy and not universally accepted.

GLOSSARY

Aerosol: Solid or liquid particles suspended in a gas.

Aerodynamic Equivalent Diameter: Diameter of a unit-density sphere having the same settling speed as the particle in question; the particle itself may have a density different from one and be irregular in shape.

Aitken Nuclei: Aerosol particles measured by the Aitken type of condensation nucleus counter; generally refers to particles that can serve as nuclei of condensation in high vapor supersaturation, typically in the (2–5)% range.

Cascade Impactor: An aerosol size fractionation device whereby a polydisperse (nonuniform) aerosol is separated into discrete size-fractionated samples each covering a narrower size interval. Cascade impactor operates by the principle of inertial impaction onto a solid surface (inertial impactor) or into a void space (virtual impactor).

Cloud Condensation Nuclei: Aerosol particles that can serve as nuclei of condensation in cloud formation processes involving low water vapor supersaturation (usually $<1\%$).

Condensation Nuclei: Small particles that can serve as nuclei of condensation in a supersaturated vapor atmosphere.

Condensation Nucleus Counter: An aerosol particle counter based on the condensation of a vapor on the particle and subsequent growth of the particle to a large enough size for optical detection by light scattering or attenuation.

Corona Discharge: High-voltage electrical discharge maintained from the tip of a needle or a fine wire in a gas.

Diffusion Battery: An aerosol size distribution measuring device based on the diffusive collection of particles by metal screens, capillary tubes, or rectangular flow channels. The decrease in particle concentration is taken as a measure of particle diffusion coefficient, which is then converted to a particle size by Einstein's equation.

Dispersions: Solid or liquid particles dispersed in a gaseous or a liquid medium.

Drag Force: Force exerted by the fluid medium on a suspended particle during motion of particle through the medium.

Electrical Aerosol Analyzer: An aerosol concentration and size distribution measuring device based on the charging of particles by unipolar ions and subsequent measurement of the mobility distribution of the charged aerosol by an electrical condenser and an electrometer detector.

Electrostatic Precipitator: An aerosol particle removal device based on the charging of the particles by unipolar ions generated by a corona discharge and precipitating the charged particles in an electric field.

Energy Disperse X-Ray (EDX) Analysis: A particle analysis method based on irradiating a single particle or a small sample of particles by electrons and measuring the energy distribution of the emitted x rays by a solid-state detector.

Foam: Small gas bubbles dispersed in a solid or liquid matrix.

HEPA Filter: A high efficiency particulate air filter with efficiencies $>99.97\%$ for 0.3-μm-diam particles.

Hydrosol: Solid or liquid particles suspended in a liquid.

Ice Nuclei: Small particles that can serve as nuclei for ice formation in a subcooled cloud.

Knudsen Number: Ratio of mean free path of molecules to particle radius.

Inspirable Particles: Particles capable of entering the human nose or mouth during breathing; usually <100 μm in aerodynamic equivalent diameter.

Mie Scattering: Light scattering by particles with radius comparable to the wavelength of light as originally studied by Gustav Mie in 1908.

Mobility: Dynamic mobility is the ratio of the terminal velocity of the particle to the applied force; electrical mobility is the ratio of the terminal velocity of a charged particle in an electric field to the electric field intensity.

Molecular Clusters: Clusters of molecules consisting of two to several thousand molecules which are often unstable and may grow by collision with other molecules or disintegrate as a result of thermal energy or collision. Molecular clusters are usually smaller than an aerosol particle and larger than a single molecule.

Optical Particle Counter: A particle counting and sizing instrument based on the scattering of light by particles.

PM-10, or Particulate Matter, 10-μm Cut: Aerosol particles with aerodynamic equivalent diameter of 10 μm or smaller measured by a method approved by the U.S. Environmental Protection Agency for air pollution control regulations.

Particulate Matter or Particulates: Small, microscopic pieces of material from a few nanometers to several hundred micrometers in size. Particulate matter can exist in the form of an aerosol (solid or liquid particles suspended in a gas), a hydrosol (solid or liquid particles suspended in a liquid), or a powder (solid particles).

Proton Induced X-Ray Emission (PIXE) Analysis: A particle analysis method whereby a small sample of particles is irradiated by energetic protons from an accelerator to cause x-ray emission from the sample for elemental analysis.

Rayleigh Limit: Limiting charge on a liquid drop determined by the balance between the electrical repulsion between the charges on the drop and surface tension. Rayleigh limit is the maximum charge a liquid drop can carry without disintegration.

Rayleigh Scattering: Light scattering by particles much smaller than the wavelength of light.

Respirable Particles: Aerosol particles capable of reaching the gas-exchange, alveolar (pulmonary) region of the human lung; usually <3.5 μm in aerodynamic equivalent diameter.

Settling Speed: Terminal velocity of a particle in a gas or liquid under the action of gravity.

Terminal Velocity: The steady velocity of a particle in a gas or liquid under the action of a constant force such as gravity, electrical, etc.

Thoracic Particles: Particles capable of penetrating into the trachea in the human thorax; usually <10 μm in aerodynamic equivalent diameter.

ULPA Filter: An ultralow penetration air filter with 99.999% or higher efficiency when tested with particles in the 0.1 to 0.3 μm diameter range.

Ultrafine Particles: In aerosol science, usually refers to particles in the 2–20 nm range.

VLF Cleanroom: A vertical laminar flow cleanroom with entire ceiling covered with HEPA or ULPA filters used for semiconductor or microelectronic manufacturing.

X-Ray Fluorescence (XRF) Analysis: A particle analysis method whereby a small sample of collected particle is irradiated by x rays and the fluorescent x-ray emission of the sample is analyzed to determine its elemental composition.

INTRODUCTION

The human body has evolved in the Earth's gravitational field and is well adapted to this environmental stress. Extremely fast, highly maneuverable modern aircraft expose air crews to acceleration forces of exorbitant magnitude, whereas spacecraft within Earth's orbit subject crews to an acceleration force of virtually zero magnitude. This article summarizes the physics and physiology of high-magnitude, sustained acceleration on retinal and cerebral circulation and discusses the effects of aircraft maneuvers on arterial wall performance. Human physiological adaptation to the microgravity space environment is summarized and basic biological responses to weightlessness are discussed.

A countermeasure to microgravity, the rotating environment, is examined. This artificial-gravity environment should provide an effective countermeasure for the bone demineralization, muscle loss, motor coordination disturbance, and cardiovascular deconditioning experienced after long periods in the zero gravity of space. Such physiological deterioration if not compensated for could have a disastrous impact on an Earth-Mars-Earth mission with the propulsion systems currently available. A rotating artificial-gravity environment has inherent and unique characteristics that may have debilitating effects on humans and their performance. Here we review current knowledge about artificial gravity. Its unique characteristics are examined and its effects on human performance and vehicle habitability are discussed.

Many aircraft and spacecraft crew members experience illusory sensations of craft altitude and motion, or fail to detect changes in craft orientation at some time during their flights. These events are normal and are due to physiological limitations of the sensory mechanism. Human sensory organs are functionally adapted to terrestrial conditions in a stable 1*g* environment. In the aerial and space environment humans are exposed to motion stimuli that differ from those experienced on the ground, so that misperception of spatial orientation is not surprising.

The discussion of motion sickness is restricted to air and space motion sickness (SMS). The cardinal symptom of motion sickness is nausea and the cardinal signs are vomiting, pallor, and sweating. SMS affects, to some degree, about half of those exposed to 0*g* environment. Its onset is rapid—within 30 min of entry—and in nearly all cases adaptation and recession of signs and symptoms occur within 48 to 72 h. The visual and vestibular systems play significant roles in the genesis of both spatial disorientation and motion sickness.

In addition to microgravity conditions, the Earth's natural radiation environment poses a hazard to manned space activities directly through biological effects and indirectly through effects on materials and electronics.

Long-term manned space flight and missions involving the colonization of the Moon or Mars would expose humans to types and levels of ionizing radiation neither encountered on Earth nor experienced in near-space orbits. Characteristics of the radiation environment unique to manned space flight, both in near space and beyond the Earth's geomagnetic field, and biological effects of the radiation are summarized briefly.

1. BIODYNAMICS

1.1 Physics and Physiology of High-Magnitude Acceleration (Leverett and Whinnery 1985)

Acceleration is defined as the rate of change of velocity, and is a vector quantity. It can result from a change in *speed* along a straight line (linear acceleration), from a change in the *direction* of motion (radial acceleration), or from changes in both. If s is the distance and t is the time, then

$$\text{acceleration } (f) = d^2s/dt^2. \qquad (1)$$

Acceleration can be positive (increasing velocity) or negative (decreasing velocity). In the Système International d'Unités (SI), the units are m/s^2. In aviation, acceleration is generally expressed as a multiple of that due to the Earth's gravitational force. The Earth's gravitational acceleration, g, has the value 9.81 m/s^2. The ratio of an applied acceleration to the gravitational constant is known as the g value. For example, $3g$ represents an applied acceleration of 29.43 m/s^2. It is also standard practice to express the acceleration vector g in terms of three orthogonal components, g_x, g_y, and g_z, with the axes oriented to the human torso (Fig. 1). The symbols $\dot{r}_x$, $\dot{r}_y$, and $\dot{r}_z$ denote *angular* acceleration around these orthogonal axes.

The applied acceleration and the resultant inertial force always act in diametrically opposite directions, and this holds for the $0g$ and non-$0g$ environments. Thus, a headward acceleration tends to force blood towards the lower extremities. The resultant force is designated as $+g_z$. Figure 1 illustrates the standard terminology for indicating the *direction* of acceleration and the inertial forces that act on aircraft crews.

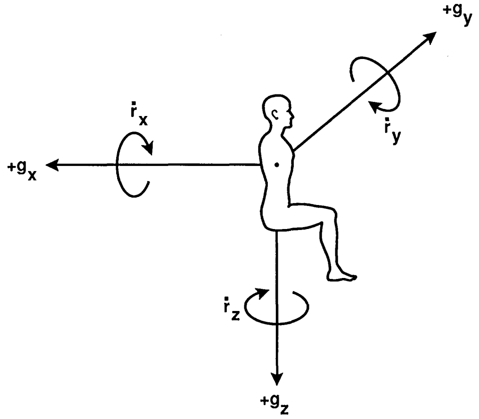

FIG. 1. Physiological acceleration system.

1.2 Physiological Effects of Sustained Acceleration

Crew members in high-performance aircraft are regularly exposed to sustained $+g_z$ acceleration. Accelerations of $(5–7)g$ for 10–40 s are common. Onset rates may be as high as $10g/s$. Even with the use of anti-g suits, human tolerance is the limiting factor in aircraft performance.

1.2.1 General Effects. With $+ g_z$ acceleration (Burton, Leverett, and Michaelson, 1974), the sequence of general effects as the g value rises is as follows:

$+g_z=2.0$: The subject is aware of an increase in weight of the trunk and limbs and increased pressure on the buttocks. The face and soft tissues of the body begin to sag.

$+g_z=2.5$: Difficulty in raising oneself from a sitting position is experienced.

$+g_z=3.0–4.0$: It is now impossible to raise oneself from a sitting position and difficult to raise the arms and legs. Progressive dimming of vision occurs after 3–4 s of exposure, progressing to tunnel vision.

The acceleration value at which a given loss of peripheral vision occurs varies among subjects. In one experimental series, the vision field was reduced to a cone with an angle of 45° at a mean value of $4.1g$ (standard deviation $+0.7g$). Blackout occurred at a mean value of $4.7g$ $(+0.8g)$.

g_z = 4.5–6.0: Diminution of vision continues and progresses to blackout after about 5 s. Loss of hearing and then loss of consciousness (LoC) occur if exposure continues. Mild to severe convulsions occur in about 50% of test subjects during or following LoC; subjects frequently experience bizarre dreams. LoC is accompanied by a loss of muscle tone, so the head and trunk slump. Recovery of consciousness is slow, with complete incapacitation for 15 s followed by a similar period of loss of orientation in time and space.

1.2.2 Negative-Acceleration Effects. Aircraft maneuvers that produce $-g_z$ are outside loops and spins and simple inverted flight. Tolerance of $-g_z$ is much less than $+g_z$. At $-g_z = 2.0–3.0$, severe facial congestion and a throbbing headache develop. Progressive blurring, graying, or reddening of vision ("redout") occurs after 5 s. The congestion resolves slowly and may leave petechial hemorrhages and edematous eyelids.

The limit of tolerance for $-g_z$ is 5.0 for 5 s—rarely reached by most subjects. Because of severe performance decrements and aircraft limitations (they are not usually stressed to withstand high $-g_z$), maneuvers involving $-g_z$ greater than $(1.0–1.5)g$ are seldom performed.

1.2.3 Cardiovascular Effects. The cardiovascular effects of acceleration are generally the most significant. Positive acceleration immediately changes the distribution of pressure in the arterial and venous systems, shifting blood toward the more dependent parts (heart and lungs) and away from the head. Reflex compensatory changes then occur.

1.2.4 Hydrostatic Effects. Positive acceleration increases the weight of the columns of blood above and below the heart, decreasing vascular pressure above the heart and increasing it below. The changes in intravascular pressure alter the lumen diameter of blood vessels. The lumen diameter is a function of transmural pressure, vessel distensibility, and volume of blood available to fill the vessel.

Alteration of vessel diameter, in turn, determines regional blood flow and blood content. As the increase in pressure is transmitted to the small arteries and arterioles (vascular "beds") below the heart, the peripheral resistance falls and local blood flow rises. Any major decrease in venous pressure above the heart can cause vessels to collapse and stop blood flow through them. The magnitude of the induced pressure change, ΔP, is proportional to the vertical distance (h) from the observation point to the heart and the acceleration level (ng). Thus,

Table 1. Pressure in the arterial tree of a seated subject.

Location	Arterial pressure (mm Hg) $+1g_z$	$+4.5g_z$
Heart	100	100
Cerebral artery (eye level, +30 cm)	78	1
Femoral artery (−60 cm)	144	300

$$\Delta P = \rho n g h, \tag{2}$$

where ρ is the density of blood.

Table 1 indicates the gauge pressures in the arterial tree of a seated subject at $+1.0g_z$ and $+4.5g_z$. The pressure in the right atrium of the heart (venous reference point) is approximately atmospheric (0 mm Hg) both at $+1.0g_z$ and $+4.5g_z$. At $+1.0g_z$ the pressure in the cerebral veins at eye level would be about −20 mm Hg. At $+4.5g_z$ one would expect it to be about −100 mm Hg. But, because of a compensatory change in diameter of the jugular veins in the neck, the pressure in the cerebral veins falls to about −50 mm Hg. Positive acceleration increases the pressure in veins below the heart; in the femoral vein it rises from about 40 mm Hg at $+1.0g_z$ to about 150-mm Hg at $+4.5g_z$.

1.3 Positive Acceleration and Its Effects on Retinal Circulation, Cerebral Circulation, and the Pulmonary System

1.3.1 Retinal Circulation. Visual disturbances are caused by ischemia of the retina. Internal pressure in the eye is 20 mm Hg. If the systolic arterial pressure in the eye falls below 20 mm Hg, blackout occurs. Once the arterial pressure falls below 20 mm Hg, loss of vision occurs in 4–6 s. The delay is caused by a small reserve of oxygen dissolved in the extravascular fluid of the retina. When the pressure in the central retinal artery is reduced by $+g_z$, the blood supply to the periphery of the retina fails first and produces loss of peripheral vision ("greyout").

1.3.2 Cerebral Circulation. Positive acceleration of $(3.4–4.0)g$ reduces the arterial pressure at the brain below that required to

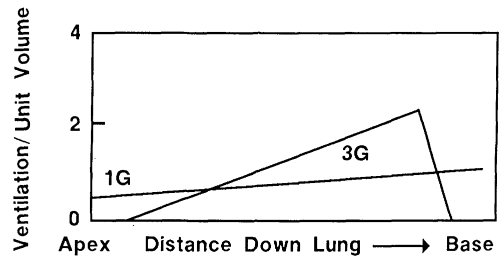

FIG. 2. Vertical distribution of alveolar ventilation.

maintain adequate cerebral blood flow. At 4.5*g* the cerebral arterial pressure is reduced to almost zero. The incidence of LoC with positive acceleration of (3.0–5.0)*g* is much lower than expected. Several mechanisms maintain an adequate flow of blood through the brain (even with arterial pressures of 0–20 mm Hg at head level).

First, the cerebrospinal fluid pressure falls so that the pressure differences across the walls of the intracranial vessels remain nearly normal. Second, active vasodilation of the cerebral arterioles reduces flow resistance. Third, the venous blood column in the neck sets off a siphon effect that maintains cerebral flow. The pressure difference between arterial and venous systems is maintained at 50–60 mm Hg at $+g_z$ of (4.0–5.0)*g* by a pressure in the jugular bulb of −50 mm Hg.

1.3.3 Pulmonary System (Glaister, 1970). Positive acceleration of up to +5.0*g* produces minimal respiratory difficulties. Total lung and vital capacities are unaffected at values up to +3.0*g* while exposure to +5.0*g* reduces them by about 15%. Positive acceleration causes the abdominal contents and diaphragm to descend, thereby increasing the functional residual volume by about 500 mL at $+3.0g_z$. The diaphragm descent is greatly reduced, and may be reversed by inflating the standard anti-*g* suit.

1.3.3.1 Regional Lung Ventilation. Positive acceleration increases regional differences in the distribution of ventilation in the lungs of an erect individual at $+1.0g_z$ (see Fig. 2). At $+5g_z$ the fluid pressure at the lung base is 30 cm water greater than at the apex. Alveoli at the apices are more distended and those at the bases are nearer to closure with respect to conditions at $+1g_z$. At minimum alveolar volume, the associated airways close. The lung volume at which airway closure can first be detected is termed the closing volume of the lung, and it increases linearly with acceleration (Fig. 3). Inflation of the abdominal bladder of an anti-*g* suit raises the diaphragm and reduces the functional residual capacity. Its use markedly increases the number of nonventilated alveoli in the lower part of the lung.

1.3.3.2 Regional Pulmonary Blood Flow. The distribution of blood flow in the lung is susceptible to $+g_z$, as pulmonary blood pressures are relatively low. The mean pulmonary artery pressure (15 mm Hg) at the junction of the middle and lower thirds of the lung is unaffected by $+g_z$. The vascular pressures above and below this level are determined by hydrostatic forces. Even at $+1g_z$ the mean arterial pressure (MAP) falls to zero 20 cm above this level (that is, near the apex). At $+4g_z$ the MAP is zero only 5 cm above this level. The proportion of the lung not perfused increases as $+g_z$ increases (Fig. 4).

1.4 Long-Duration Negative Acceleration

Tolerance to $-g_z$ is much lower than that for $+g_z$ and symptoms at even $-2.0g_z$ are unpleasant and alarming. Serious decrement in performance also occurs.

1.4.1 General Effects. A feeling of heaviness and interference with limb movements occurs as with $+g_z$. At $-1.0g_z$, a sense of fullness and pressure in the head occurs, which develops into a throbbing headache at

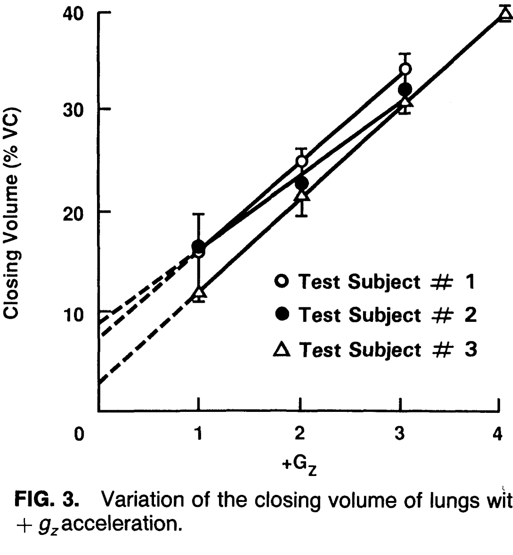

FIG. 3. Variation of the closing volume of lungs with $+g_z$ acceleration.

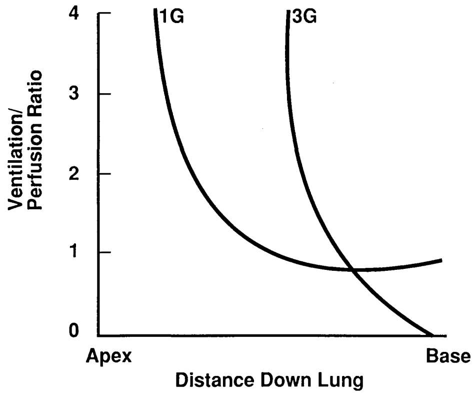

FIG. 4. Vertical distribution of ventilation/perfusion ratio for 1g and 3g accelerations.

$-2.0g_z$. At $-2.5g_z$, edema of the eyelids and petechial hemorrhages in the facial and neck skin occur. Nasal mucosal congestion may cause difficulty in breathing and lead to epistaxis. At $-(2.5\text{–}3.0)g_z$ the eyes feel as if they are about to pop out of their sockets, and excessive lachrymation causes blurring of vision. Exposure to more than $-4.0g_z$ for more than 6 s causes mental confusion and unconsciousness.

1.4.2 Cardiovascular Effects. The immediate hydrostatic effect of $-\ g_z$ is to increase vascular pressures in the regions above the heart and to decrease them below this level. The MAP at eye level increases by 20–25 mm Hg per g, so that it becomes 170 mm Hg at $-3g_z$. The *venous* pressures at eye level take several seconds to rise to a plateau, as there is a time delay involved in transcapillary flow. The venous pressure at eye level at $-3g_z$ rises to about 100 mm Hg.

1.4.3 Carotid Sinus and Cardiac Output. The increase in MAP in the neck stimulates the baroreceptors of the carotid sinus. The response is bradycardia and generalized arteriolar vasodilation. Cardiac arrhythmias usually occur on exposure to $-g_z$ over 1g. The arrhythmia reduces the cardiac output, and this effect and the dilation oppose the direct pressure rise due to the acceleration.

1.4.4 Cerebral Circulation. The increase in MAP produced by $-g_z$ is balanced internally by a similar increase in the pressure of the cerebrospinal fluid, so that there is no risk of rupture of vessels in the skull. The rise in MAP, venous engorgement, and the carotid sinus effect combine to reduce progressively the arteriovenous pressure differences across the cerebral vascular bed. The cerebral blood flow progressively slows and mental confusion and LoC result.

1.4.5 Pulmonary Effects. Negative acceleration produces a headward displacement of the diaphragm, and the vital capacity and residual capacity are reduced. Negative acceleration also reduces pulmonary ventilation. In $-g_z$ the apical region of the lung is better ventilated and perfused than the basal region. Indeed, most of the lung remains perfused under $-g_z$. Acceleration atelectasis induced by $-g_z$ occurs at the apices of the lung.

1.5 Effects of Acceleration on Arterial Wall Mechanical Properties

The viscoelastic behavior of arterial walls primarily reflects the properties of the fibrous components—smooth muscle, elastin, and collagen. Table 2 gives the amounts, quantitated by chemical, physiological, and histologic methods. The arterial wall has three layers—intima, media, and adventitia. The intima layer is formed by a single layer of endothelial cells, which holds the blood cells within the lumen and controls the passage of water and other substances from the plasma into the tissue.

A layer of elastic tissue—the internal elastic membrane—separates the intima from the media. The media is formed of smooth mus-

Table 2. Viscoelastic behavior of arterial walls.

	Arterial wall composition (% mass)		
Location	Elastin	Collagen	Smooth muscle
Arch of aorta	41	18	35
Main pulmonary artery	21	9	65

Table 3. Elastic moduli for elastin and collagen in carotid arteries.

Species	Elastin (dyne cm^{-2})	Collagen (dyne cm^{-2})
Dog	3.6×10^6	800×10^6
Rabbit	6.2×10^6	2400×10^6
Rat	5.6×10^6	1100×10^6
Human	4.5×10^6	1000×10^6

cle cells. The fibrous proteins—elastin and collagen—and the carbohydrates of the media are all secreted by smooth muscle cells.

The outer layer of the artery wall, the adventitia, is composed of fibroblast cells and their associated intercellular collagen and glycosaminoglycans. Table 3 summarizes the values of elastic moduli for elastin and collagen in carotid arteries for humans and three other species. The results of Roach and Burton (1957) indicate that the passive mechanics (no smooth muscle activity) of these vessels is closely related to the elastin content at low strain and to the collagen content at high strain (cf. BIORHEOLOGY).

In a published analysis of arterial wall mechanical properties by Westerhof and Noordergraff (1970), the incremental elastic modulus of arteries was assumed to be governed by an equation of the form

$$E=W_eE_e+f_cW_cE_c, \tag{3}$$

where E_e is the elastic modulus of elastin, E_c is the elastic modulus of collagen, W_e is the fractional mass content of elastin, W_c is the fractional mass content of collagen, and f_c is the fraction of collagen fibers supporting the wall load at a particular value of wall strain. The analysis assumes that at low strain, $f_c \to 0$ (i.e., no collagen supports the wall load), whereas at high strain, $f_c \to 1$ (i.e., all collagen fibers are recruited). Using Eq. (3), experimentally measured values for E_e and E_c, and the fractional tissue content, one can compute f_c for a range of arterial pressure (Fig. 5). Defining strain as

$$\epsilon=\text{strain}=(l_1-l_{10})/l_{10}, \tag{4}$$

where l_{10} is the unstretched (circumferential) length of wall element and l_1 is the stretched length, it is found that at low strains ($\epsilon<1.3$) the aortic wall behaves like smooth muscle, at intermediate strains ($1.3<\epsilon<1.7$) the aortic wall behaves like elastin, and at high strains ($\epsilon>1.8$) the aortic wall behaves like collagen.

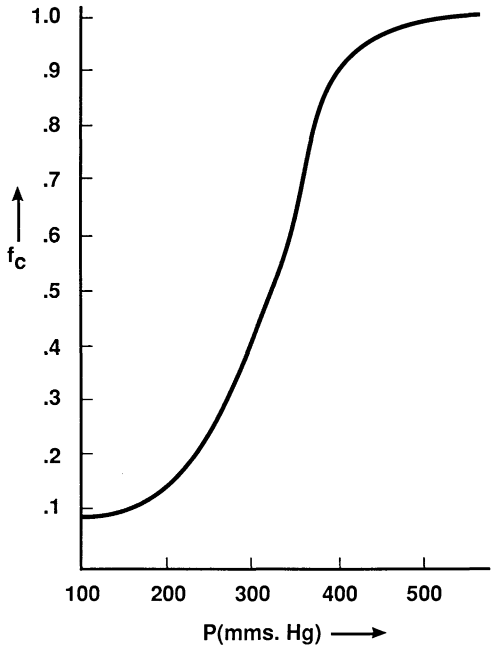

FIG. 5. Collagen recruitment fraction (f_c) versus arterial pressure *P*. [Redrawn from McCormack (1984).]

Gow and Taylor (1968) showed that for canines the aortic elastic modulus varied with MAP as

$$\text{modulus} \propto (\text{pressure})^{2.8}. \tag{5}$$

For the human femoral artery McCormack (1981) found a similar relation, namely,

$$\text{modulus} \propto (\text{pressure})^{2.6}. \tag{6}$$

For a $+g_z$ of 1, the MAP in the femoral is about 100 mm Hg, while at a $+g_z$ of 5, the pressure would be about 500 mm Hg. Using Eq. (3) for humans, the predicted modulus at $-5g_z$ would be 197×10^6 dyne cm^{-2}. This would imply a very stiff artery with the recruitment of many collagen fibers.

1.5.1 Arterial Wall Viscoelastic Properties. The arterial wall displays viscoelastic properties that differ from elastic material in that it exhibits the following.

Creep: The time-dependent deformation exhibited by an arterial strip subject to a constant stress or load. Figure 6 shows a general creep reference curve. Linear viscoelastic theory treats the total deformation, δ_1, as the sum of three components,

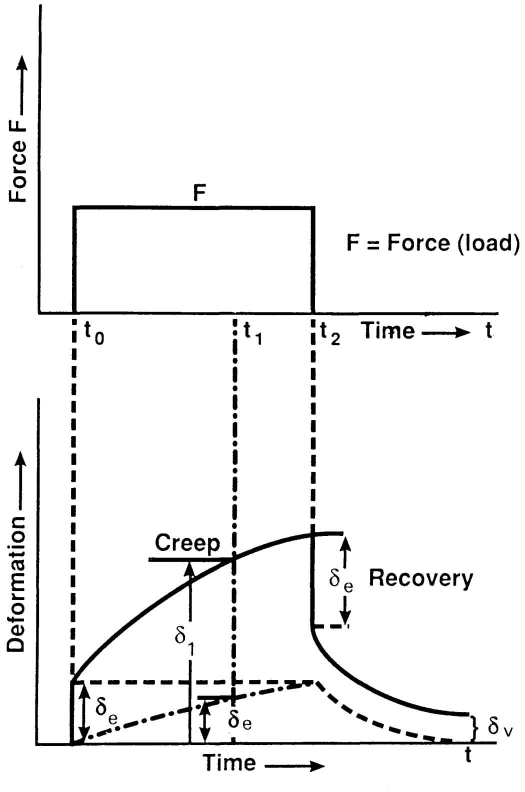

FIG. 6. General creep curve decomposed into different components; δ_e denotes elastic part of deformation, δ_{de} is the delayed part of deformation, δ_v represents the viscous component of deformation, and δ_1 the total deformation.

$$\delta_1=\delta_e+\delta_{de}+\delta_v, \qquad (7)$$

where δ_e is the *elastic* contribution, instantaneous and recoverable, δ_{de} is the *delayed* contribution, time dependent and recoverable, and δ_v is the *viscous* contribution, permanent and nonrecoverable.

Stress Relaxation: The time-dependent stress or load in an arterial strip subject to a constant *deformation.*

Hysteresis: This involves a nonelastic property of a material characterized by a particular stress-strain path during stress or load application, but taking a different path when the stress is removed (Fig. 7). The displacement remaining when the load is removed is called the "permanent set." Hysteresis can be related to creep or stress relaxation, depending on whether force or length is chosen as the independent variable.

1.5.2 Arterial Viscoelasticity—Complex Young's Modulus. The general definition of Young's modulus in the frequency domain is

$$E_c(s)=E_0 \prod_{l=1}^{M} b_l \prod_{n=1}^{N} (s+a_n) \times\left[\prod_{n=1}^{N} a_n \prod_{l=1}^{M} (s+b_l)\right]^{-1}, \qquad (8)$$

where $s=jw$; w is angular frequency; $E_c(s)$ is the complex Young's modulus; E_0 is the zero-frequency modulus ($s=0$); and N, M, a_n, and b_n are constants, still to be determined. The form of this expression is such that $E_c(s)$ reduces to E_0 at low frequencies.

For stress to be bounded, the condition $N \leqslant M$ must hold. For length to be bounded in creep experiments, the condition $M \leqslant N$ must hold, and, thus, $N=M$. Moreover, stress relaxation and creep measurements are nonoscillatory. Thus, a_n and b_n are greater than or equal to zero and are real.

1.5.3 Hysteresis. In high-performance aircraft maneuvers, the viscoelastic characteristic of prime interest is the hysteretic behavior of the arterial wall. In a typical maneuver, the stress builds to a maximum, re-

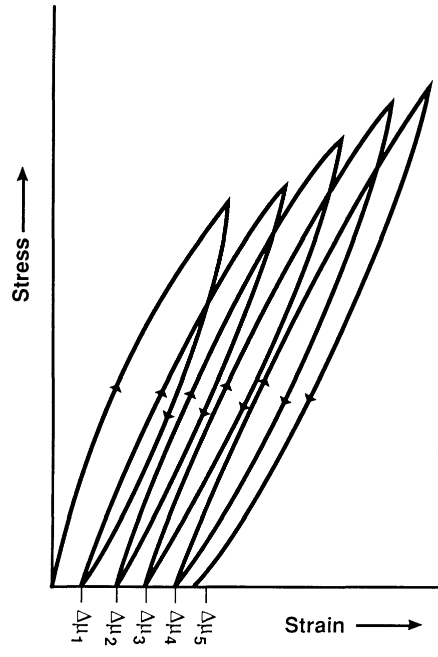

FIG. 7. Stress-strain hysteresis; $\Delta\mu_n$ denotes the permanent sets.

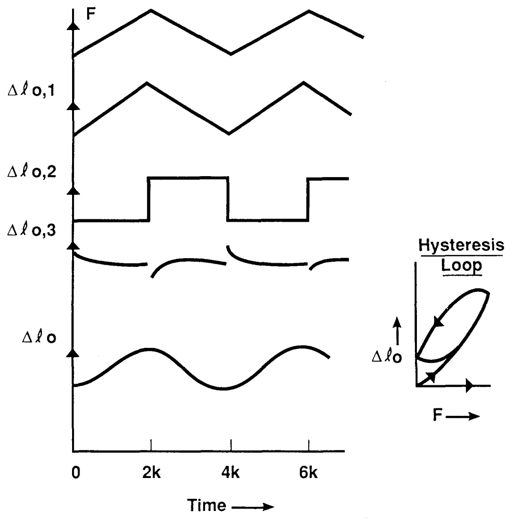

FIG. 8. Construction of hysteresis loop; $\Delta\ell_{0\ell}$, $\ell = 1,2,3$, are extension components versus time, $\Delta\ell_0$ is total extension versus time, and F is applied force versus time.

mains there for a finite time, and then falls to its initial value. The strain lags but follows the same pattern. Force, or length, can be used as the independent variable. One can use various shapes for the time variation of this variable—square wave, trapezoidal, triangular, etc. Consider an applied force that increases linearly with time up to $t=2k$ and then decreases linearly. At $t=4k$ the process then repeats. The applied force is thus

$$F(t)=F_0\left(tu(t)+2\sum_{m=1}^{\infty}(-1)^m(t-2mk)\times u(t-2mk)\right), \tag{9}$$

where $u(t)$ is a unit step function. Figure 8 illustrates the qualitative shape of $F(t)$ (upper curve), the resulting strain, Δl_0 (lower curve), and three components ($\Delta l_{0,j}$) thereof (middle three curves) versus time. The abscissas of each quantity at $t=0$ have been arbitrarily displaced from the origin for clarity and their magnitudes are arbitrary.

The Laplace transform of $F(t)$ is

$$F(s)=F_0 \tanh ks/s^2. \tag{10}$$

Using the basic definition for the complex Young's modulus $E_c(s)$ gives

$$E_c(\omega)=l_0F(\omega)/A\Delta l_0(\omega), \tag{11}$$

where $F(\omega)$ is the applied force, A is the initial cross-sectional area of the strip of material, and $\Delta l_0(\omega)$ is the change in length.

If a force of magnitude F_0 is suddenly applied to a strip of material (arterial wall), then it can be shown (McCormack, 1984) that in terms of the parametric constants used in Eq. (8), the change in length at $t=0$ is given by

$$\Delta l_0(0)=l_0F_0\prod_{n=1}^{N}a_n\left(AE_s\prod_{n=1}^{N}b_n\right)^{-1}, \tag{12}$$

whereas as for $t\to\infty$

$$\Delta l_0(t)=l_0F_0/AE_s. \tag{13}$$

Thus, Δl_0 jumps to the value given by Eq. (12) at $t=0$ and then creeps to the value given in Eq. (13). Inserting Eqs. (13) and (10) into Eq. (11) gives

$$\Delta l_0(s)=\frac{F_0l_0}{AE_s}\tanh ks\left(\frac{1}{s}-\frac{1}{s}\sum_{n=1}^{N}P_n+\sum_{n=1}^{N}\frac{P_n}{s+a_n}\right), \tag{14}$$

where P_n is constant.

Transforming this expression to the time domain yields

$$\begin{aligned}\Delta l_0(t)=\frac{F_0l_0}{AE_s}\Bigg[&\left(tu(t)+2\sum_{m=1}^{\infty}(-1)^m(t-2mk)u(t-2mk)\right)\\&-\left(\sum_{n=1}^{N}P_n\right)\left(u(t)+2\sum_{m=1}^{\infty}(-1)^mu(t-2mk)\right)\\&+\sum_{n-1}^{N}P_n\left(e^{-a_nt}u(t)+2\sum_{m=1}^{\infty}(-1)^me^{-a_n(t-2mk)}u(t-2mk)\right)\Bigg].\end{aligned} \tag{15}$$

Thus we can write the extension as a sum of three components,

$$\Delta l_0(t) = \Delta l_{0,1}(t) + \Delta l_{0,2}(t) + \Delta l_{0,3}(t). \qquad (16)$$

Figure 8 shows the graphical construction of $\Delta l_0(t)$ from its parts, $\Delta l_{0,1}$, $\Delta l_{0,2}$, and $\Delta l_{0,3}$. Δl_0 does not return to zero when the force returns to zero. The remaining extension in the absence of a net force is called the *permanent set*. It is not permanent in the true sense of the word, as it will decay with a time constant that is the same as the creep behavior of the material—a_1, for example, in a simple one–time-constant material. For this simplified case ($N=1$), $a_1 \neq b_1$ and $b_1 > a_1$, the above equations give at short times

$$\Delta l_0(t) = F_0 l_0 t / AE_s \qquad (17)$$

and at long times

$$\Delta l_0(t) = F_0 l_0 (t+D)/AE_s, \qquad (18)$$

where

$$D = [(b_1/a_1) - 1], \; a_1 \neq b_1. \qquad (19)$$

The permanent set after a hysteresis loop is, therefore, given by

$$\text{permanent set} = \frac{F_0 l_0 D}{AE_s} = \frac{F_0 l_0}{AE_s}\left(\frac{b_1}{a_1} - 1\right). \qquad (20)$$

Values of a_1 for the aortic wall have been calculated from the data of Hardnung (1953), Bergel (1961), Learoyd and Taylor (1966), and Tucker *et al.* (1969). The average of their values is 5.8 s^{-1}. For other arteries the data of Bergel (1961) and Learoyd and Taylor (1966) lead to a value for a_1 of 4.0 s^{-1}.

1.6 Calculation of Arterial Wall Performance in Aircraft Maneuvers

As stated previously, in aircraft maneuvers the viscoelastic characteristic of prime interest is the hysteretic behavior of the arterial wall. In typical maneuvers the stress builds to a maximum, remains there for a period, and then falls to its initial value. The strain lags, but follows the same temporal pattern.

It is usual procedure to enter the loop so that $+g_z$ is experienced. Below a fractional extension, or strain, ϵ of less than 1.3, it is the smooth muscle component in the arterial wall that is predominantly active. This is the situation at normal arterial pressures that produce strains in the region of $\epsilon \geqslant 0.3$. The smooth muscle is, of course, under autonomic nerve control.

As pointed out earlier, if the strain ϵ is over 1.7, collagen is predominant; the strain does *not* return to its initial value, and a permanent set is left. As noted above, the set is only quasipermanent because it decays slowly with a time constant of the order of 100 s.

McCormack (1984) predicted the number of sequential maneuvers (with less than 1 min separating the sequences) that would cause the complete failure of the collagen and rupture of the arterial wall. These are catastrophic events leading immediately to LoC (loss of consciousness). Step changes of 100% in collagen recruitment, at 6*g* for the external carotid and 5*g* for both the abdominal aorta and pulmonary arteries, will be considered. At these baseline *g* values, the elastic modulus is 400×10^6 dyne cm^{-2} and the number of sequential maneuvers to extend *all* the collagen by 20% can be computed. At 10*g* only 10 sequential maneuvers are required to cause catastrophic rupture of the pulmonary artery. The conclusion inferred from the above calculations is that in combat maneuvers in contemporary high-speed aircraft, significant damage to the collagen component in the arterial wall is quite likely.

2. PHYSIOLOGICAL AND BIOLOGICAL RESPONSES TO WEIGHTLESSNESS

2.1 Physiological Responses to Weightlessness

Figure 9 shows the time course of physiological changes observed in human adaptation to the microgravity environment for near-Earth orbit. It is assumed that all physiological systems are in a state of homeostatis in the 1*g* environment before entering orbit. While most systems appear to establish a new equilibrium at 0*g* steady state, calcium loss, loss of lean body mass, and the effects of exposure to ionizing radiation increase continually (Johnston, Dietlein, and Berry, 1975; Yorub'yer, Gazenko, and Shulzenko, 1986).

In readapting to the 1*g* environment, however, various physiological systems behave differently (Fig. 10). The variable value indicated as the clinical horizon is the value above which a clinically observable change occurs in the subject. The bone calcium re-

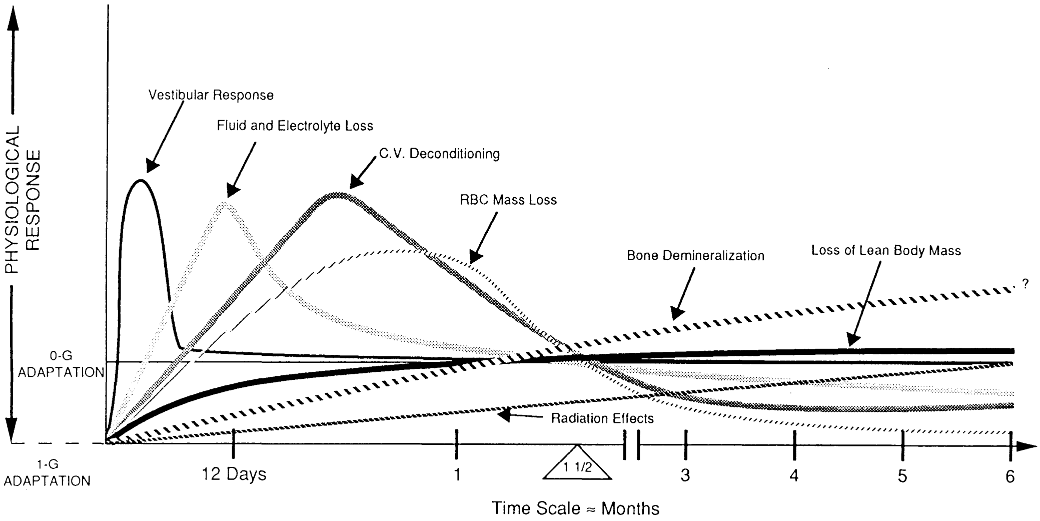

FIG. 9. Time course of adaptation to microgravity. RBC, red blood cells; C.V., cardiovascular.

covery curve is not shown because sufficient postflight data is not available. Evidence indicates that most of the bone loss is recovered (as indicated by bone density measurement), but the question of whether or not bone quality changes permanently (as measured by bone tensile strength, for example) has not been answered (Rambaut and Johnston, 1979).

Table 4 lists observations of selected systems from Skylab experiments. Three physiological systems are examined in some detail here, as they have been investigated extensively and are of significance operationally. A fourth system is considered in the context of significant potential change in 0*g*—the gastrointestinal system.

2.2 Cardiopulmonary System

Humans are a 1*g* species and the cardiopulmonary system has evolved an array of mechanisms to counter the stress of gravity. In adapting to the 0*g* of space flight, the cardiopulmonary system changes significantly. Probably the most overt symptom is the cephalad fluid shift.

2.2.1 Fluid Shifts. When the body experiences weightlessness, about 1.5–2.0 L of fluid move cephalad from the lower extremities. Visual evidence of this shift is evident in periorbital puffiness, facial edema, and thickening of the eyelids observed in astronauts and cosmonauts (Thornton, Hoffler, and

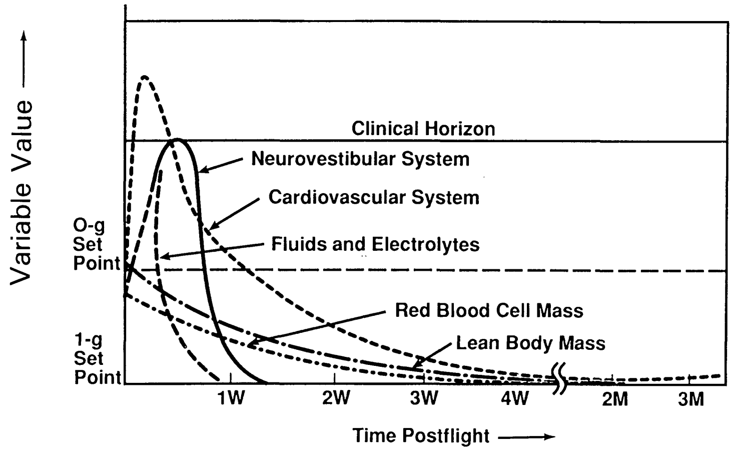

FIG. 10. Postflight time course (w=weeks; m=months) of physiological shifts during readaptation to 1*g* environment. Clinical horizon represents the level above which the variable produces a clinically observable change.

Table 4. List of effects on selected physiological systems from Skylab experiments.

Fluid-Electrolyte System
Rapid loss of water early in flight.
Much larger increase in leg fluid volume compared to bed rest.
Absence of measurable diuresis following headward fluid shifts.
Unusual combination of hormonal changes compared to bed rest and water immersion.
Presence of a hyponatremic plasma maintained throughout flight.
Increased water and sodium excretion throughout mission without continuous body losses.
Difference in ADH (anti-diuretic hormone) response between missions.
Decreased evaporative water loss in presence of hypobaric atmosphere.
Disproportionate losses of potassium and cell water.
Cardiovascular System
Acute cardiovascular disturbances expected from headward fluid shifts were not observed.
Decreased orthostatic tolerance as measured by lower-body negative pressure tests.
Maintained aerobic capacity during flight in spite of decreased blood volume and decreased orthostatic tolerance.
Decreased aerobic capacity immediately following flight.
Differences in aerobic capacity among the three crews.
Erythropoietic System
Inflight loss of red cell mass.
Delay in postflight recovery of red cell mass on shortest mission.
Significant differences in rates of red cell loss among the three crews.
Musculoskeletal System
Progressive loss of calcium from body.
Urinary calcium stabilizes at elevated level while focal calcium increases progressively with flight duration.
Changes in PTH (parathyroid hormone) during space flight not similar to changes in bed rest.
Rates of nitrogen losses appear to decrease as a function of flight duration and increasing levels of exercise.
Body Composition
Rates of water, muscle, and fat losses appear to be disproportionate to ratio in body tissues.
Body mass losses decrease with flight duration.
Water losses appear independent of flight duration.
Large differences in body composition changes between the three Skylab missions.
Energy requirements in 0g and 1g appear similar.

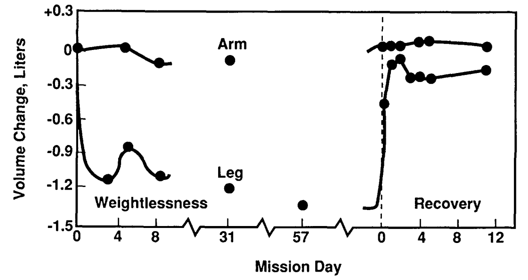

FIG. 11. Changes in left limb volumes of Skylab 4 Commander. [Redrawn from Thornton *et al.* (1977).]

Rummel, 1977). Efforts to quantify the shift have focused on measuring changes in calf girth and leg volume. In the Skylab and Apollo–Soyuz flights, circumferential measurements of the lower extremities were performed preflight, in flight, and postflight.

Figure 11, limb volume data (arm and leg) for the Skylab 4 commander, shows that the lower but not upper limb volumes decrease in flight and return to preflight values after returning to the 1*g* environment (Thornton, Hoffler, and Rummel, 1977). Observations in later flights showed that the major shift in fluid volume occurs rapidly upon entry into the 0*g* environment. The *rate* of this fluid shift appears to follow an exponential course, reaching a maximum in approximately 24 h and a new steady state in 3–5 days. Calf volume measurements performed in the Soviet Salyut-6 mission show similar behavior, with steady state achieved on the 12th day of the flight. For 140-, 175-, and 185-day missions, variations in leg volume follow an oscillatory time course of loss and recovery. The renal and endocrine systems are known to be involved in the adaptation process (Leach, 1983; 1984).

2.2.2 Decreased Orthostatic Tolerance. During the immediate postflight period, decreased orthostatic tolerance has been observed consistently. Symptoms range from a higher heart rate and decreased arterial pulse pressure to fainting (syncope). Tests commonly used to quantify this phenomenon are the tilt test, stand test, and lower body negative pressure (LBNP). The latter involves the application of a reduced pressure around the lower extremities. This will tend to reduce the cephalad fluid shift, thereby minimizing the loss of orthostatic tolerance on returning to a

1*g* environment. Figure 12 describes the protocols used for the stand and LBNP tests and the cardiovascular parameter measurements.

2.2.3 Lower Body Negative Pressure. This involves the application of negative pressure to the lower part of the body resulting in a footward displacement of body fluid. The response can be measured by such parameters as change in leg volume (ΔLV) and changes in heart rate. Figure 13 shows the change in the leg volume and heart rate during pre- and postflight conditions of the Apollo Commander using the LBNP protocol (Hoffler and Johnston, 1975). These and other observations, for both Soviet and U.S. missions, showed that during flight the LBNP presents greater stress to the cardiovascular system than the *same* levels of LBNP preflight. This is presumably due to change attending the large cephalad movement of body fluids in flight. The change in immediate postflight orthostatically stressed heart rates from preflight mean reference value, as a function of change in total blood volume, has also been studied (Nicogossian, Leach-Huntoon, and Pool, 1989). Results indicate that the depleted blood volume is at least one factor in the exaggerated cardiovascular response to LBNP observed postflight. These observations led to the countermeasure of fluid loading of shuttle crews before returning to Earth.

2.2.4 Venous Compliance. Measurements of venous compliance were performed for the crew of Skylab 4 preflight, in flight, and postflight (Fig. 14) (Thornton and Hoffler, 1977). Vascular compliance increased in flight (under microgravity conditions) but did not attain maximum value until 10 days inflight. After approximately six weeks compliance fell and rapidly returned to preflight val-

ues on return to ground. This change in mechanical properties of the venous walls in 0*g* has not yet been explained.

2.3 Bone and Calcium Metabolism

Reduction of gravitational forces acting on the weight-bearing structures of the body leads to a loss of calcium (Rambaut and Johnston, 1979) and other minerals essential for bone strength and integrity (Hattner and McMillan, 1968; Mack, 1971). Bone mineral losses are not observed from the distal compact radius, however. Soviet space flight measurements demonstrated that mineral loss occurs from the tubercle and plantar areas of the os calcis—mainly compact bone. Bone mineral loss increases approximately proportionally to mission length, varying from −0.9% to −19.8% over intervals from 75 days to 184 days (Stufakov, 1984). Calcaneal mineral recovery occurs gradually and at about the same rate as the mineral (Vogel and Whittle, 1976). The measured recovery was only partial in at least one Skylab 4 astronaut (50% replacement, 90 days postflight).

2.3.1 Calcium Balance Studies. Skylab studies showed that human exposure to microgravity is accompanied by increased excretion of calcium and phosphorus. Figure 15 illustrates the changes in urinary and fecal calcium content during Skylab 4. The calcium content of urine increased rapidly after entrance into a microgravity environment and plateaued after 30 days. Over the first 10 days in flight, preflight positive calcium balances decreased and eventually became negative. The rate of loss increased to almost 300 mg/day by the eightieth day of flight. For three Skylab 4 crewmen, the average loss (over 84 days) was 25 g of calcium from the overall body pool (about 1250 g). Rambaut and Johnston (1979) predicted, based on trends in calcium loss over the first 30 days in flight, that calcium loss for a 1-year mission might be sufficient to undermine bone strength.

The 4% loss observed in the os calcis after the 84-day mission represents a loss of about 100 mg of calcium. Thus, other weight-bearing skeletal sites account for most of the mineral loss. Unfortunately, bone mineral loss from nonweight-bearing bone structures has not yet been documented. Soviet experience with intensive exercise programs demonstrated that this countermeasure can reduce the bone mineral loss considerably (Gazenko, Grigor'yev, and Natochin, 1981). In recent 1-y flights, overall bone loss was kept to within 5%.

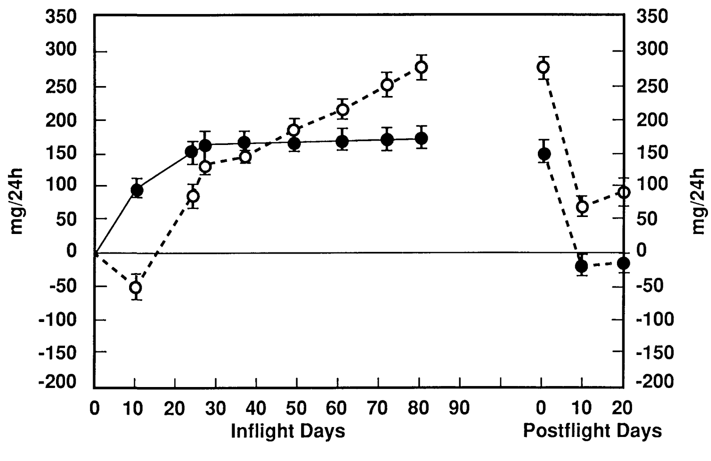

FIG. 15. Changes in urine (●—●) and fecal calcium (○---○) as a function of Skylab flight duration (mean ± SE). [Redrawn from Rambaut and Johnston (1979).]

Recovery of lost calcium began soon after returning to the $1g$ environment. Urinary calcium content decreased below the preflight baseline in 10 days postflight, but fecal calcium content remained elevated even after 20 days. Negative calcium balance also persisted for up to 20 days. Studies on the recovery of the os calcis mineral content postflight indicate that after several weeks (and sometimes up to months), the content returns to normal. This has been confirmed by bed rest studies.

2.3.2 Bed Rest Simulation. In bed rest the force of gravity on the longitudinal skeleton is reduced from $1g$ to $\frac{1}{6}\,g$. There are many uncontrollable variables involved in in-flight mineral balance studies. Bed rest studies, however, offer reliable and reproducible data. Such studies determined that calcium loss continues for at least 36 weeks with no evidence that a new steady state is being approached. Total body calcium decreases by 6 g per month after the first 30 days of bed rest, and by 9 months at least 50 g of calcium are lost.

The amount of mineral lost in bed rest subjects varies widely. This variability may be partially explained by two parameters: the *initial* os calcis mineral content, and the urinary hydroxyproline excretion rate. The most pronounced bone changes in $0g$ occur in weight-bearing bones. Mechanical stress apparently has a profound effect on bone metabolism and structure, as many studies involving bone strain measurement have shown (Hinsenkamp, 1981).

2.4 Biological Responses to Weightlessness

All life on Earth evolved in $1g$ environment. Hence, every cell and cell organelle has weight, however small. The basic question in gravitational biology is how nature has used weight to accomplish the objectives of life development.

All organisms must perceive the environment. The best-understood environment receptors are the chemoreceptors of the enteric bacteria, receptors that recognize a favorable chemical and ultimately enable the bacterium to swim toward the nutrient chemical. Many types of receptors have been investigated, including light, heat, moisture, osmolarity, and gravity. Unfortunately, gravity perception is one of the least-understood mechanisms.

2.4.1 Tropic Systems of Plants. Plants respond to both light and gravity. Light responses have been reviewed thoroughly elsewhere (Wareing, 1983). Compared to light receptors, there is considerably less information about the gravity-sensing component of plants (Bandurski and Schulze, 1983). It has, however, been shown that a plant can respond to gravity within minutes (Bandurski, Schulze, and Kaufman, 1984). In fact, the time period of the response in some cases is so rapid that it precludes the settling of a heavy organelle to the bottom of the plant cell. There is considerable literature on statoliths, which are formed by a heavy starchlike organelle. However, the time course of the response observed is so rapid as to make it unlikely that the statoliths are the major gravity sensing component in plants.

2.4.2 Gravitational Biodynamics. Many fundamental questions remain unanswered, including the following.

1. Is the perception of gravity a fundamental property of a cell ?
2. How does the absence of gravity or a reduction in gravity affect the molecular structure of the cell and hence the genome?
3. What happens to the mechanism of cell recognition under $0g$?
4. How is three-dimensional reaggregation of dissociated cells affected by $0g$?
5. Does $0g$ cause changes in the distribution of cell organelles during mitosis, meiosis, or budding?

The well-known law of universal gravitation in its simplest form states that every mass is attracted to every other mass. Hence, in response to the gravitational force, internal mechanical stress is produced in every biological system. In $0g$ this stress is zero. The question is, then, would a cell that has evolved in the presence of stress retain the same characteristics in a stress-free environment?

We note that, of the four types of forces in nature, only the electromagnetic and gravitational forces appear to play major roles in biological systems. Nuclear forces have no direct biological effects. Weak forces are responsible for beta decay and have no direct

Table 5. Comparison of thermal velocities for spherical particles executing Brownian motion in the absence of gravity at $T=300$ K with terminal velocities in a plasma using Stokes's law.

Radius (μm)	Thermal velocity ($\mathrm{m\ s^{-1}}$)	Terminal velocity ($\mathrm{m\ s^{-1}}$)
10^{-2}	1.4	10^{-10}
10^{-1}	4.5×10^{-2}	10^{-8}
1	1.4×10^{-3}	10^{-6}
10	4.5×10^{-5}	10^{-4}
100	1.4×10^{-6}	10^{-2}

biological effects. Electromagnetic forces are involved in molecular interactions, maintenance, and breakage of chemical bonds. Gravitational forces are the most pervasive, but the weakest of the fundamental forces.

The diffusion of molecules and very small particles is governed by random collisions with the local molecular constituents. It is a simple calculation to show the particle size at which the directional force of gravity overcomes this randomizing force. Molecular thermal motion is governed by the equation

$$\tfrac{1}{2}mv^2=\tfrac{3}{2}k_\mathrm{B}T, \tag{21}$$

where m is the particle mass (kg); T is the temperature (K); v is the particle velocity (m/s), and k_B is the Boltzmann constant, $1.380\,65\times10^{-16}$ ergs per kelvin.

Consider a sphere of plasma of radius r with density$=1.5\times10^3\ \mathrm{kg\ m^{-3}}$ at $T=300$ K (see Table 5). Under these conditions Eq. (21) implies that a ribosome has a thermal velocity of 1 m/s, a cell nucleus has a thermal velocity of 10 μm/s, and a free protist has a thermal velocity of only 1 μm/s. Using Stokes's law, the balance between a force of 1g and the viscous friction of a fluid allows one to calculate the terminal particle velocity (v)

$$\frac{4\pi r^3}{3}(\rho-\rho_a)g=6\pi\eta v r, \tag{22}$$

where η is the fluid viscosity, $\rho-\rho_a=0.5\times10^3\ \mathrm{kg\ m^{-3}}$, and ρ_a is the ambient mass density. For water at 20 °C, $\eta=10^{-3}\ \mathrm{kg\ m^{-1}\ s^{-1}}$; for blood at 37 °C, $\eta=3\times10^{-3}$. Comparisons given in Table 5 clearly demonstrate that gravitationally driven motion is insufficient to overcome the diffusional motion of a particle unless the particle diameter is over 10 μm, if the particle density is 50% greater than that of the surrounding medium.

2.5 Statistical Distribution of Particles under Gravitational Force

As noted above, random molecular motion competes with ordering produced by the force of gravity. If the average density in a cell is taken to be unity ($\rho_a=1$), and the density of a particulate unit is ρ, then for a volume v, the difference between the *downward* force of gravity and the buoyant *upward* force is $v(\rho-\rho_a)g$. At a temperature T the resulting statistical distribution is

$$n=n_0\exp[-v(\rho-\rho_a)gh/k_\mathrm{B}T], \tag{23}$$

where n_0 denotes the number of particulates per unit volume at a certain baseline level, and n is the number per unit volume at a height h above this baseline. For a bacterial cell with $h=1\ \mu$m at room temperature and taking the particulate to be the whole unit of DNA ($\rho=1.6\ \mathrm{g\ cm^{-3}}$ and $v=2\times10^{-5}\ \mathrm{cm^3}$), Eq. (22) gives

$$n/n_0=0.997.$$

Thus, the maximum intracellular difference in the statistical distribution produced by gravity for the largest and densest internal component of a cell is less than 0.3%. A similar calculation for ribosomes (volume$=4.2\times10^{-18}\ \mathrm{cm^{-3}}$, $\rho=1.5\ \mathrm{g\ cm^{-3}}$) gives an even smaller distribution gradient. One is forced to conclude that changes in the statistical distribution due to gravity for a single bacterial cell are insignificant. For a mammalian cell, however, 10 μm in diameter, the situation changes. For organelles, such as mitochondria, with a volume of approximately $10^{-12}\ \mathrm{cm^3}$ and a density of $1.1\ \mathrm{g\ cm^{-3}}$, Eq. (23) gives $n/n_0=0.09$ at room temperature. This is a significant difference and, hence, in this situation, the removal of the gravitational force could produce considerable intracellular changes.

The stratifying effect of gravity, however, is opposed by a second effect of gravity: convection, or streaming. This effect tends to mix material in a cell, distributing components equally. Nevertheless, it has been suggested that certain dynamic aspects of the cell may be exquisitely sensitive to the presence or absence of gravity.

The kinetics of transposable genes, the pairing and exchange of chromosome fragments, and the repair or misrepair of DNA could be influenced by gravity. The capacity for DNA to repair is intrinsically connected with life; in fact, life could not exist if DNA did not have a significant capacity to repair damage, because replication errors occur continually, as does radiation-induced damage. A basic property of a living system is self-assembly (Lima de Faria, 1986), as has been demonstrated experimentally (Fritz-Niggli, 1988). The process could be altered significantly in a weightless environment. In the D1 Spacelab Shuttle flight, a biostack experiment indicated synergy between gravity and radiation-induced cell damage (Bücker, Facius, and Horneck, 1986). A tentative explanation for this observation involves the effect of gravity on the DNA repair mechanism.

2.6 Effects of Gravitation on Membranes

All compartments of the body, both extracellular and intracellular, are delineated by biological membranes. The transport of all material (for example, enzymes, nutrients, and waste products) into and out of different compartments is controlled by membranes. Known physical properties of membranes include the basic unit, which is a pairing of lipid molecule; the electrical capacitance, the order of which is 1 μF/cm^2; the surface tension (values as low as 0.1 erg/cm^2 are known); and two intermolecular forces, *attraction* due to London dispersion force and *repulsion* due to electrostatic charges.

The London potential energy (in ergs) between "two cylinders" of lipids (Verwey and Overbeck, 1948) can be written as

$$U_a = 5\times 10^{-13} a/R, \tag{24}$$

where a is the radius of a cylinder (cm) and R is the surface separation (cm). The *repulsive* potential U_r can be written in the form (Verwey and Overbeck, 1948)

$$U_r = B \exp(-\kappa R), \tag{25}$$

where κ is the Debye–Hückel constant, and B is a constant (units of energy).

Calculations using these potentials, unfortunately, provide no direct information about the membrane behavior or the effects of gravity on membranes (Verwey and Overbeck, 1948).

2.6.1 Effects of Hydrostatic Stress on a Membrane. Hydrostatic stress caused by gravity does *distort* the cell's membrane integrity. For a cell 10 μm in diameter, pressure on the lower membrane due to gravity is about $10^{-3}g$, approximately 1 dyne/cm^2. The resulting strain in the membrane increases separation between molecules and may enhance membrane permeability. The increase in membrane permeability can be estimated as follows.

Consider a pressure of 1 dyne/cm^2 on a membrane 100 Å thick. This pressure causes the membrane to stretch and develop an elastic force. Weibull (1955) measured the changes in volume of a protoplast produced by changes in the concentration of sucrose. For a change in osmotic pressure (Δp) of 2×10^6 dyne/cm^2, the volume changes from 2.7×10^{-12} cm^3 to 2.0×10^{-12} cm^3. For a cell of radius 8.6×10^{-5} cm, this pressure causes the area to change by 1.54×10^{-8} cm^2. For 1 dyne/cm^2 pressure, the volume decreases by a factor of only 2.2×10^{-6}, corresponding to a volume change of roughly 3.5×10^{-14} cm^3 or to an area change of approximately 8.1×10^{-16} cm^2. This change is considered too small to have any significant effect. In comparison, we note that for a plant 1-m high the hydrostatic pressure on its lower membrane is about 10^5 dyne/cm^2. This pressure is significant and produces a relative change of approximately 0.1 in the cell's membrane area. In this case the average separation for a neighboring pair of molecules is increased by about 30%. Hence, the effect of gravity can be appreciable in plants of this size or larger.

2.6.2 Effects of Hydrostatic Stress on Active and Passive Transport through Semipermeable Membranes. The absorption of water and electrolyte occurs mostly in the jejunum and ileum across a semipermeable nonporous membrane with active transport. The absorption rates are a function of the osmolality of the intestinal contents. Vaughan (1960) showed that for a dog's intestine the absorption rates in the jejunum and ileum are linear functions of the osmolality (Fig. 16). Both sodium and water move against their concentration gradients, implying an active transport process. Figure 17 illustrates the most accepted mechanism for transport of sodium and water. Compartment 1 is the intestinal medium, 2 is the blood plasma, and 3 de-

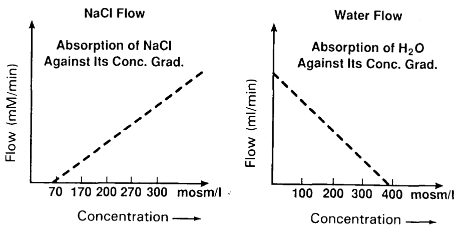

FIG. 16. Absorption flow of water (H_2O) and sodium (NaCl) versus intestinal osmolality. [Redrawn from Vaughan (1960).]

notes the epithelial layer of the intestinal wall (the membrane); A denotes a semipermeable nonporous membrane with active transport and B represents a passive (porous) and active membrane. It is assumed that no hydrostatic flow occurs across A, and no osmotic flow occurs across B.

The solution in compartment 3 would leak passively into compartment 2 under hydrostatic pressure. However, this process would not occur under 0*g* conditions. The balance equations for water and solute flows are as follows:

$$P_{AO}(C_3-C_1)=P_{BH}H+K_1, \quad (26)$$

$$T-P_{AS}(C_3-C_1)=P_{BH}HC_3+K_1C_3. \quad (27)$$

The corresponding 0*g* equations are as follows:

$$P_{AO}(C_3-C_1)=K_1, \quad (28)$$

$$T-P_{AS}(C_3-C_1)=K_1C_3, \quad (29)$$

where K_1 is the active transport of water (mosm s^{-1} cm^{-1}) (mosm is the abbreviation for milliosmole; see "Osmole" in the Glossary), H is the hydrostatic pressure (dyne cm^{-2}), T is the net active transport of solute (mosm^2 s^{-1} cm^{-1} L^{-1}), P_{AO} (L s^{-1} cm^{-1}) is the osmotic permeability of A to water, P_{AS} (mosm s^{-1} cm^{-1}) is the osmotic permeability of A to solute, P_{BH} (mosm cm s^{-1} dyne^{-1}) is the hydrostatic permeability of B to the solution, and C_i is the solute concentration in mosm L^{-1}. As Eqs. (26) and (27) differ from those in 0*g*, there could be significant differences in membrane transport (McCormack, 1989) in 0*g* (Gazanko, Grigor'yev, and Natochin, 1981) that have implications for organ processes ranging from the absorption of nutrients and medications to the function of the immune system. Unfortunately, no comparative experimental data exist on membrane transport characteristics in 0*g* and 1*g* environments. Furthermore, it is not known whether absence of gravity alters the osmotic permeability parameters.

3. ARTIFICIAL GRAVITY: A COUNTERMEASURE TO WEIGHTLESSNESS

3.1 Characteristics of the Rotating Environment

Several features of the rotating environment make artificial gravity different from the Earth's gravitational environment. These unique characteristics of artificial gravity fall into two categories—static and dynamic. The static characteristics include the magnitude of the artificial gravity, the gradient of the force in the radial direction, and the variation of the hydrostatic pressure in fluid systems caused by the gravitational gradient. The dynamic aspects include properties associated with motion: Coriolis acceleration, which occurs when a subject moves linearly with re-

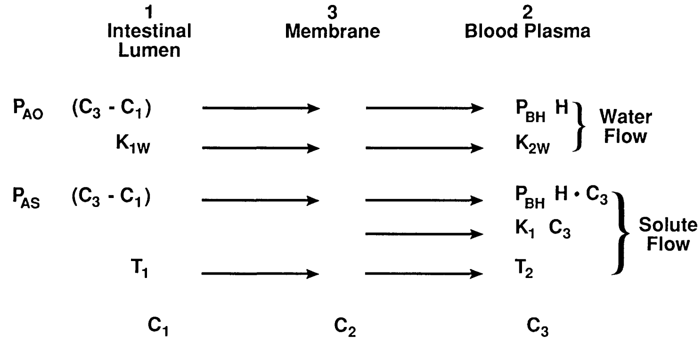

FIG. 17. Movement of sodium and water across a cellular membrane water. T denotes active transport flow of solute; P_{AO} and P_{AS} the osmotic permeability of A to water and solute, respectively; and P_{BH} is the hydrostatic permeability of B to solute.

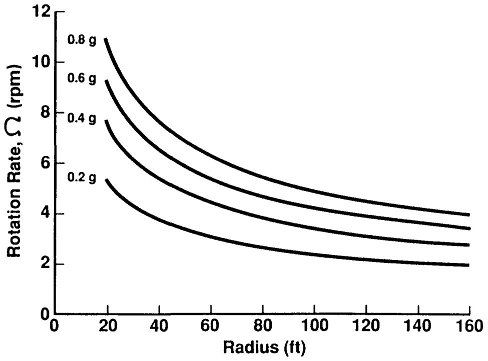

FIG. 18. Rotation rate [Ω (rpm)] versus radius (ft) for various *g* levels. [Redrawn from McCormack and Nicogossian (1987).]

spect to the rotating environment, and cross-coupled angular acceleration, which occurs when the subject rotates relative to the rotating environment. A major effect of rotation is that the apparent weight of an object is now a function of its position relative to the vehicle central axis of rotation. The object weight change is

$$\Delta W/W=(r_1-r_2)/r_2, \tag{30}$$

where subindices 1 and 2 imply two radial positions.

3.2 Artificial Gravity Level

Figure 18 shows the variation in rotation rate Ω (rpm) of the space habitat versus radius for a range of g levels. The curves tend to level off for radii greater than 70 ft. Adding 20 ft to a 90-ft-radius vehicle only reduces the rotation rate by about 0.3 rpm. At a vehicle rotation of 4 rpm and at g level of 1, a radius of 197 ft is required.

In the context of interplanetary travel, increasing vehicle size is expensive in terms of launch weight, inertia, momentum, and energy. It also introduces considerable difficulties in control, stabilization, and fuel requirements, to note but a few of the problems expected for large spacecraft. The variation in gravity gradient with vehicle radius also flattens as the radius increases. At $0.4g$ adding 20 ft to a 20-ft vehicle radius reduces the gravity gradient by $0.09g$/ft. Adding 20 ft to a 98-ft vehicle radius reduces the gradient by less than $0.007g$/ft.

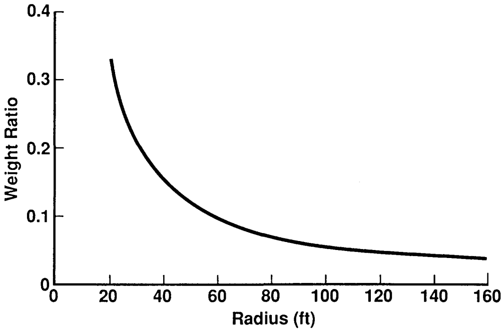

FIG. 19. Artificial weight change versus radius (6-ft change in radial position of object). [Redrawn from McCormack and Nicogossian (1987).]

Figure 19 illustrates the variation of the ratio of the weight of an object 6.6 ft off the floor to the weight when on the floor with vehicle radius. It is again evident that the advantage of increasing radius becomes insignificant for radii greater than 80 ft.

3.3 Coriolis Forces

This title is restricted to the force that is operative when *linear* motion is attempted in a rotating environment. When an angular motion is carried out in a rotating environment, cross-coupled angular acceleration occurs. This case is called the Coriolis effect.

When an object (animate or inanimate) moves tangentially or radially in a rotating environment, it experiences a force normal to the relative motion. Figure 20 shows the ratio of the tangential Coriolis acceleration to artificial gravity versus the radius of vehicle rotation for a range of artificial gravities. The

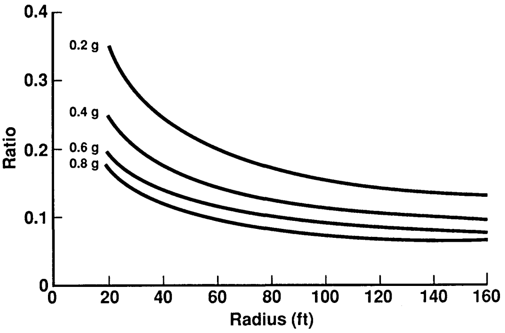

FIG. 20. Ratio of tangential Coriolis acceleration to artificial gravity versus radial position. [Redrawn from McCormack and Nicogossian (1987).]

Table 6. Potential criteria for artificial gravity.

Gravity level
  $g_{\max} \geqslant r\omega_1^2 + 2r\omega_1\omega_v + r\omega_v^2 \geqslant g_{\min}$
Coriolis forces
  Tangential movement
  $(1 + C_1)r\omega_v^2 \geqslant r\omega_1^2 + 2r\omega_1\omega_v + r\omega_v^2 \geqslant (1 - C_1)r\omega_v^2$
  Radial movement
  $2\dot{r}/r\omega_v \geqslant C_2$
  Dropped objects
  $r(\sqrt{r^2 - r_1^2}/r_1 - \tan^{-1}\sqrt{r^2 - r_1^2}/r_1) \leqslant C_3$
Gravity gradient
  Change in object ωeight $(r - r_1)/r \leqslant C_4$
  Along body $(r - r_h)/r \leqslant C_5$
  Hydrostatic pressure $(r_{\text{heart}} + r_h)/(r + r_h) \geqslant C_6$
Cross-coupled angular accelerations
  $\omega_v \leqslant C_7/\omega_h$

curves were computed for a subject having a radial velocity of 2 ft/s. Once again, a decrease in the effect as vehicle radius increases is obvious. At 0.4*g*, for example, adding 20 ft to a 20-ft radius vehicle reduces the ratio by just over 25%. Doubling a 98-ft radius vehicle, however, reduces the ratio by less than 10%. With tangential motion, changes in the radial force (weight) also occur. Similar graphs can be drawn for the ratio of radial Coriolis acceleration to artificial gravity versus vehicle radius. Again, a rapid reduction in change in the ratio with increasing radius occurs.

3.4 Human Performance in Artificial Gravity

The peculiar characteristics of the rotating environment would alter human performance and, in all likelihood, would degrade it to some extent. Over a period of exposure, adaptation may occur and performance could improve. Factors of concern are the radius and rate of rotation that allow effective performance and habitable conditions, and the cost of attaining this condition in terms of factors such as weight, moments of inertia, angular momentum, rotational energy, and stability.

The various aspects of human performance that may be influenced by artificial gravity are gross motor performance, including self-locomotion and material handling, and fine motor performance involved in dexterity and eye-hand coordination in the presence of head motion. Table 6 lists potential criteria for artificial gravity.

3.4.1 Self-Locomotion. Habitability of the space vehicle, with respect to orientation and arrangement of equipment in the vehicle, depends directly on self-locomotion capability. Figure 21 illustrates the influence of artificial gravity forces on a moving subject in a rotating spacecraft. In radial movement, both away from or toward the center of rotation, the tangential components of the Coriolis force operate. For tangential movement, both with and against the direction of rotation, changes in the radial forces (weight) occur.

Axial motion produces no Coriolis effect unless the limbs move laterally or the body sways. Figure 22 shows the four boundaries expected to limit tangential motion on the floor of a rotating vehicle. The 1*g* limit is shown for a walking speed of 3.3 ft/s (a reasonable upper walking speed). Tests on the Langley rotating Space Station simulator

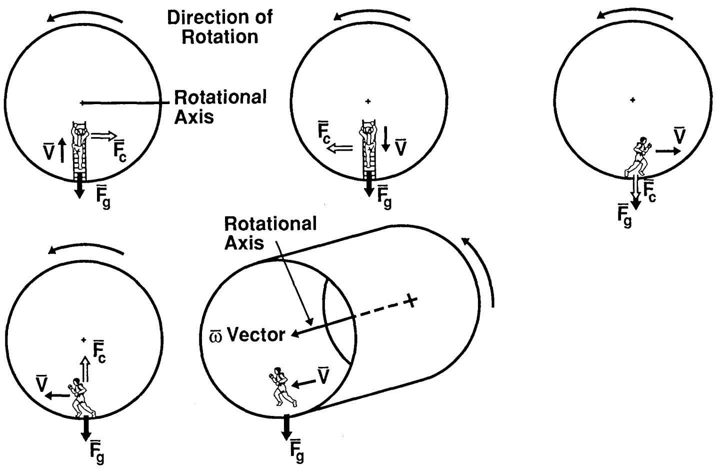

FIG. 21. Influences of artificial gravity on locomotion. $\overline{\omega}$ denotes rotation rate, $\overline{F}_g$ is the gravitational force, $\overline{F}_c$ the Coriolis force, and $\overline{V}$ the man's velocity.

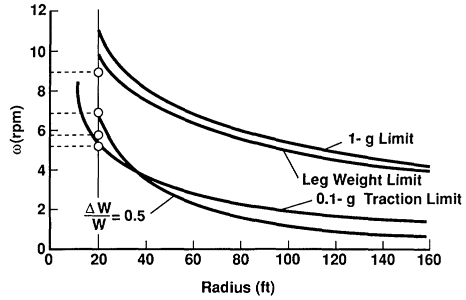

FIG. 22. Rotation rate and radius boundaries for tangential locomotions at a rate of 3.3 ft/s. [Redrawn from McCormack and Nicogossian (1987).]

showed that leg heaviness at this weight could become objectionable (Stone, Piland, and Letko, 1970; Hewes and Spady, 1964). The lower limit of 0.1*g* is set by the necessity for sufficient traction to allow efficient motion. Along the 20-ft radius line, the four points at which simulated studies were made on the Langley simulator are shown. The upper point for walking is 0.5*g*; at this point leg heaviness was noted and found to be undesirable. The lowest point is for $\frac{1}{6}$ *g* at which traction was poor.

At the fourth boundary,where $\Delta W/W=0.5$, the change in weight due to the relative motion in walking at 3.3 ft/s does not exceed half the artificial gravity weight. The best level for the four gravity levels tested (on a limited number of subjects) was 0.3*g*. It is important to note that the curves in Fig. 22 and the data of Stone, Piland, and Letko (1970) were for a curved floor of constant radius.

The boundaries for radial motion of a crew member can be established similarly (Stone, Piland, and Letko, 1970). One boundary is for a Coriolis force at a radial motion at 2 ft/s, 0.3 times the artificial weight. The upper boundary is for 0.3 times the Earth weight. In this case the Coriolis force acts tangentially, and arm loading, rather than leg loading, is involved. The choice of the 0.3 factor is arbitrary at this stage.

3.4.2 Material Handling. Movement in the rotating environment differs from movement in the Earth's gravitational environment. Objects will (a) change weight with radial position according to the equation $\Delta W/W=(r_1-r_2)/r_2$, (b) experience Coriolis acceleration when moved, and (c) experience cross-coupled angular acceleration when rotated.

Table 7. Lower limit of vehicle radius.

ω=rotation rate (rpm)	Radius (ft)
2	150
4	75
6	50

A reasonable boundary for radial motion is that the tangential Coriolis force is never greater than 0.25 times the artificial weight. Another boundary is for tangential motion such that ΔW will be less than 0.25 times the artificial weight. A third boundary is that the weight of an object when raised 6.5 ft (2 m) does not decrease to less than half its original artificial weight. For tangential motion this criterion may be written as

$$\frac{\text{Coriolis force}}{\text{Artificial weight}}=\frac{2\omega_r\omega_v}{\omega_v^2}=\frac{2v_r}{\omega_v r}\leqslant 0.25 \tag{31}$$

where v_r is the relative velocity of movement. For a relative velocity of 4 ft/s this criterion becomes

$r\omega_r > 32.$

If the rotation rate is fixed, the lower limit of the vehicle radius can be determined. Table 7 gives a few calculated lower vehicle radius limits.

3.5 Cross-Coupled Angular Accelerations

When a human subject makes a head movement out of the axis of rotation of the vehicle, cross-coupling of the angular accelerations occurs, stimulating the semicircular canals in the vestibular system. This stimulations results in perceptual misinterpretation of the path of head movement and, if strong enough, evokes symptoms of motion sickness. Adaptation to the cross-coupled angular acceleration generated by movement in rotating rooms has been studied by Stone and Letko (1964), Graybiel and Wood (1969), and Lackner and Graybiel (1986).

Each semicircular canal in the vestibular system is orthogonal to the other two and is essentially a torus filled with endolymph (a fluid having a specific gravity near unity). In a sense, each set of semicircular canals can be viewed as a gyroscopic component when the head is rotated inside a rotating vehicle. The canal lying *in* the plane of vehicle rotation is similar to a gyroscopic rotor spinning about its axis of symmetry. If the canal rotates about an axis normal to the vehicle rotation axis, then an *output* torque is generated about an axis perpendicular to both the vehicle rotation axis and the canal axis of rotation. This output torque (T_o) is given by

$$\mathbf{T}_o = I_v(\omega_v \times \omega_H), \tag{32}$$

where I_v is the moment of inertia of the rotating body about the rotation axis, ω_v is the angular velocity of the rotating body, and ω_H is the angular velocity of the semicircular canal involved (Graybiel and Wood, 1969). Hence, the torque magnitude is

$$T_o = I_v \omega_v \omega_H \tag{33}$$

and the resultant angular acceleration is

$$\dot{\omega}_{\text{res}} = \omega_v \omega_H. \tag{34}$$

Based on experiments performed at Langley in the 15-ft simulator, the torque value on the endolymph that resulted in the onset of malaise in all subjects was 4.40×10^{-10} ft lb (Stone and Letko, 1964). Reducing either ω_v or ω_H by 66% produced a tolerable state with a torque of about 3.0×10^{-10} ft lb. Figure 23 illustrates the rate of head movement versus the vehicle rotation rate for both torque values. Table 8 shows the corresponding values of rotation rates and angular accelerations. Experience with Slow Rotating Rooms (SRRs) has shown that a conservative criteria for tolerance of cross-coupled angular acceleration is 2 rad/s^2 (Graybiel and Wood,1969). Table 8 shows that this value for $\dot{\omega}_{\text{res}}$ limits head movement rates to between 100°/s and 200°/s (fairly rapid movement) for vehicle rotation rates between 11 rpm and 6 rpm.

Substituting a value of 2 rad/s^2 for the tolerable acceleration limit and a torque of 3.03×10^{-10} ft lb, which corresponds to the absence of malaise in Eq. (33), gives a moment of inertia for endolymph about its axis of spin

$$I = 1.51 \times 10^{-10} \text{ ft lb s}^2.$$

Tests in the SRR at Pensacola showed that the semicircular canal tolerance to the above gyro torque can be increased by adapting to incremental increases to an upper rotation rate of about 10 rpm (Graybiel and Wood, 1969). Readaptation to a nonrotating environment, however, is equally demanding. Figure 24 illustrates a set of curves for vehicle radius versus apparent gravity experienced by the crew (in units of g) for a range of vehicle rotation rates from 1 rpm to 10 rpm.

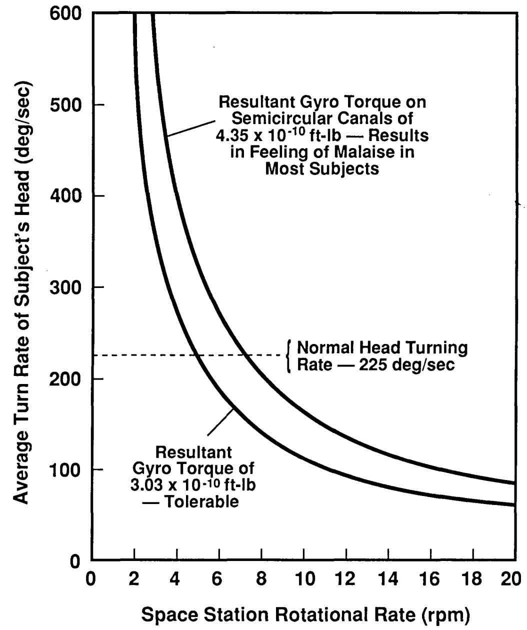

FIG. 23. Gyro torque limits on cross-coupled rotation of semicircular canals in rotating vehicle. [Redrawn from McCormack and Nicogossian (1987).]

The Coriolis acceleration and the centrifugal acceleration obey the relationship

$$A_{\text{Co}} = 2v(A_{\text{ce}}/gr)^{1/2}, \tag{35}$$

where v is the velocity of the body relative to the rotating vehicle (ft/s) and r is the radius (ft). Hence,

$$A_{\text{ce}} = 34 \times 10^{-5} N^2 r, \tag{36}$$

where N is rotation rate in rpm. For a Coriolis force ratio corresponding to 50% of the crewman's apparent weight (force ratio, F_c), an apparent gravity of 0.4 g implies a Coriolis force of 0.2g. Using Eqs. (35) and (36), this leads to an N value of about 10. The broken curves in Fig. 24 correspond to a range of F_c values from 10% to 50%.

Table 8. Tolerable and intolerable head rotation rates.

Rate of head rotation		Vehicle rotation rate (rpm)		Angular acceleration (rad/s^2)	
Rad/s	rpm	Tolerable	Intolerable	Tolerable	Intolerable
1.75	16.7	11.4	15.8	2.08	2.89
3.50	33.4	5.8	8.0	2.13	2.94
5.25	50.1	4.0	5.5	2.20	3.05
7.00	66.8	3.0	4.25	2.34	3.13
8.72	83.5	2.8	3.6	2.52	3.31

If 6 rpm is selected as the maximum tolerable angular rate, then the region bounded by the hatched lines in Fig. 24 corresponds to an artificial gravity range of 0.28*g* to 1*g* and a force ratio between 10% and 20%. This region defines the zone of tolerable and effective human performance for a rotating space vehicle.

Using the various constraints listed above, McCormack and Nicogossian (1987) optimized the basic physical parameters and arrived at the following permissible parameters for a rotating space vehicle: a vehicle radius of 80 ft, a rotation rate of 4.8 rpm, and an artificial *g* value of 0.62*g*. We do not know whether a reduced gravity level of 0.6*g* is sufficient to eliminate the various physiological degradations observed in long-term presence in 0*g*.

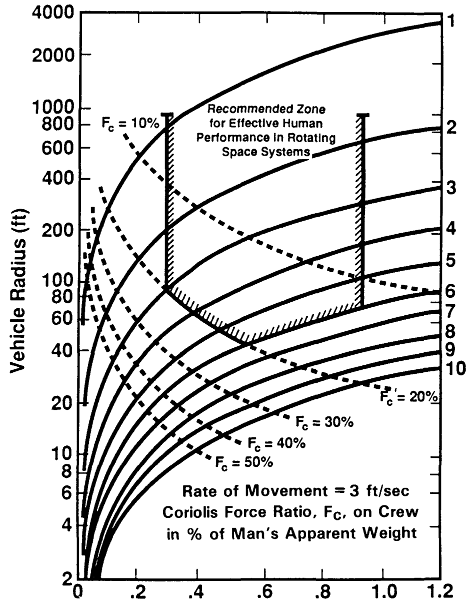

FIG. 24. Design parameters for effective human performance in rotating vehicle. F_C denotes Coriolis force. [Redrawn from McCormack and Nicogossian (1987).]

The boundaries on performance outlined above may be characterized by the criteria listed in Table 6. The various constants $C_1 - C_7$, defined by the inequalities in the table, have been given numerical values and it is useful to reiterate them.

C_1, which is involved in the criterion for tangential motion, is estimated to be 0.5 for man and 0.25 for materials.

C_2, which is involved in the criterion for radial motion, is estimated to be 0.3 for man and 0.25 for materials.

Note that these criteria are expressed as ratios of the force involved to the local artificial gravity level.

C_3, the distance a dropped object falls from its expected position, is assumed to be 1 ft when it is dropped from 3.3 ft.

C_4, change in object weight, is assumed to be 0.5 for objects raised 6.6 ft.

C_5 is related to change in gravity along the human body. This is not specified as it does not affect performance significantly. For the same reason C_6 is not specified.

The constant C_7 is estimated to be 2 rad/s^2. This rate, when associated with a maximum average head rate of rotation (ω_H) of 3 rad/s, gives a vehicle rate of rotation of 0.67 rad/s or about 6 rpm. Adaptation to this rate has been clearly demonstrated in ground-based experiments. Adaptation is still not well understood; however, the guiding criterion generally employed is to set a value as low as practically possible.

4. SPATIAL DISORIENTATION AND MOTION SICKNESS

4.1 Orientation Mechanisms

Humans perceive their orientation in three-dimensional space through the learned interpretation of the input to the cortex of many sensory receptors (Fig. 25). Sets of these receptors form specialized sense organs like the eye or the vestibular apparatus in the inner ear. Others are distributed through the skin, the joint capsules, and supporting tissues. When on the ground or in a nonmaneuvering spacecraft, whether the person is moving or motionless, accurate perception of the spatial orientation of his or her body to the immediate surroundings is readily achieved using visual inputs alone. These visual signals, plus those from nonvisual receptors, allow the person to sense his or her position, attitude, and motion relative to the stable frame of reference—the Earth's surface or the spacecraft—and to the local vertical.

In the case of aircraft in flight, perception is complicated by disorientation to the immediate surroundings in the aircraft (which is changing its orientation to the Earth's surface and to the Earth vertical). Parts of the aircraft are always visible, whereas the Earth's surface may not be visible at times (night, cloud, etc). When in orbit, the shuttle is the immediate reference for the crew. But during reentry the shuttle becomes an aircraft again and its orientation with respect to the Earth's surface becomes important.

Accurate perception of aircraft and deorbiting spacecraft orientation to Earth's surface, which is essential for control of the craft, depends primarily on correct interpretation of visual cues from outside the aircraft or spacecraft or from cockpit instruments. These cues are, of course, supported secondarily by signals from the nonvisual sense organs.

In this text the function of the inner ear and its vitally important vestibular apparatus, a basic ingredient in both spatial disorientation and SMS, will be dealt with exclusively.

4.2 The Inner Ear

Even when there is no visual input, humans can still perceive orientation with respect to gravity and to their state of motion. The most important sense organs that provide this nonvisual capability of orientation and capacity to maintain balance are those of the inner ear.

Figure 26 illustrates the two anatomic and functional parts of the inner ear. The first is the organ of hearing, the cochlea, which plays only a minor role in orientation and SMS. The second organ is the vestibular system, which is specially adapted to sense linear and angular head accelerations. The information it supplies to the cerebellum and cortex allows humans to orient themselves and maintain equilibrium on the Earth's surface or in space. If the motions to which the person is subjected are atypical and fall outside the normal dynamic range of the sensory system,

the vestibular system may supply false information to the brain and lead to disorientation. If it supplies unbalanced information (for example, no linear acceleration information) or information that conflicts with visual cues, motion sickness may result. This is the situation in the space environment.

4.3 The Vestibular System

The labyrinth of the human inner ear consists of three main entities: the cochlea (organ of hearing), the otolith organs (sensors of linear acceleration), and the semicircular canals (sensors of angular acceleration). Collectively, these form the vestibular system. Angular accelerations as low as 0.05 deg/s^2 (0.9 mrad/s^2) and linear accelerations as low as 0.01g (0.32 ft/s^2) may be detected. Figure 26 illustrates the labyrinth of the left ear viewed from the medial aspect. These sensory organs are situated in hollowed-out channels in the petrous part of the temporal bone. The three ducts, or semicircular canals, open into the sac of the utricle. Below the utricle, and connected to it, is the saccule. The four otolith organs are in outpouches of the inner walls of the paired utricle and saccule. This system, or membranous labyrinth, is filled with a watery fluid, the endolymph, and is attached securely to the petrous bone. Rigidly coupled to the skull, its experiences the same angular and linear accelerations as the head.

The space between the membranous ducts and the bony canals is filled with a fluid called perilymph. Table 9 shows that the specific gravities of endolymph and perilymph are quite similar.

Table 9. Specific gravity (at 23 °C) and viscosity (at 20 °C) of canal fluids.

Fluid	Specific gravity	Viscosity (centipoise[a])
Endolymph	1.01	1.91
Perilymph	1.01	1.10

[a] Poise = dyne s cm^{-2}.

4.3.1 Semicircular Canals.

The membranous canal has an average cross-sectional radius of about 0.16 mm in humans, while the bony canal radius is approximately 1.2 mm. The cross sections are more elliptical than circular. The horizontal and posterior canals in humans have radii of curvature between 1.6 and 1.9 mm. The anterior canal has a somewhat larger radius of curvature, about 2.2 mm (Curthoys, Blanks, and Markhan, 1977). At one point in each canal, near its junction with the utricle, the lumen swells to form the ampulla, which contains the sensory epithelium crista ampullaris. A crista is a ridge of epithelium protruding into the lumen of the ampulla carrying many multiciliated sensory cells interspersed with structural cells. The cilia on all the cells project into a common gelatinous structure, or cupula. The cupula reaches to the far side of the ampullae (Fig. 27). When the head's axis of rotation is in the plane of a canal, the endolymph fluid lags relative to the walls of the canal and, thus, flows relative to the walls, counter to the head rotation direction.

FIG. 27. Illustration of ampulla of human semicircular canal.

4.3.2 Mathematical Modeling of the Cupula-Endolymph System. Steinhauesen (1933) was the first to report that the cupula normally functions like a watertight, spring-loaded flaplike structure, whose deflection closely follows the flow of the endolymph fluid in the canal. He hypothesized that the cupula-endolymph canal system could be equated to a heavily damped torsion pendulum, in which the inertial and damping terms correspond to the mass and viscosity of the endolymph fluid, respectively, with a restoring force corresponding to the cupula elasticity. Support for this hypothesis comes from the research of Groen, Lowenstein, Vendirk (1952), Egmond, Groen, and Jongkees (1949), and Jones (1965). These and other workers elucidated the various physiological responses to rotational stimuli.

If I is the moment of inertia of the endolymph-cupula system and α denotes the angular acceleration with which a person rotates his or her head in the plane of a particular semicircular canal, then the torque acting on the cupula is $I\alpha$. This torque displaces the endolymph fluid and cupula through the angle θ relative to the skull. To a first approximation, variations in θ with time are governed by the damped torsion pendulum equation

$$\frac{d^2\theta}{dt^2}+\left(\frac{\Pi}{I}\right)\frac{d\theta}{dt}+\left(\frac{\Delta}{I}\right)\theta=\alpha(t), \tag{37}$$

where Π is the system rotational resistance at unit angular velocity (viscous damping) and Δ is the system rotational stiffness due to the cupula. McCormack (1988) calculated a value of 2.3×10^4 cm^2 g for the moment of inertia of the cupula and endolymph. This value compares quite well with the value 2.4×10^4 cm^2 g computed by Oman and Young (1972). The coefficient of viscous resistance may be calculated from the Poiseuille's law,

$$\Pi=16\pi^2\eta R^3, \tag{38}$$

where η is the viscosity of the endolymph and R is the radius of the canal torus. Steer *et al.* (1967) estimated $\Pi=0.043$ dyne cm^{-1} s^{-1}. Unfortunately, it has not been possible to calculate the elasticity of the cupula because its small displacement, at most 10 μm, is difficult to measure. It is known, however, to be much smaller than the viscous resistance, and, thus, to approximate one can write

$$\alpha I=\Pi\frac{d\theta}{dt}. \tag{39}$$

Taking I and Π as constant gives an angular velocity for the cupula proportional to the head acceleration. It is evident that the angular displacement of the cupula is proportional to the angular velocity of the head. The vestibular canals are, in effect, an integrating accelerometer, or angular speedometers. Making the head angular acceleration, $\alpha(t)$, sinusoidal and observing the phase lag between the $\alpha(t)$ and the eye movement (nystagmus) for any given response (for example, oculogyral illusion) creates an informative experimental technique. Further excitation stimuli can be provided by a variety of rotational devices, such as turntables, torsion swings, and rotating chambers.

The three coefficients I, Π, and Δ of Eq. (37) conveniently summarize the information concerning the mechanical properties of the semicircular canal. Furthermore, the system performance in response to a dynamic stimulus can also be interpreted in terms of an undamped characteristic angular frequency, ω_n, and a damping ratio, ρ. The damping ratio parameter ρ denotes the ratio of the actual damping Π to the critical damping Π_c,

$$\rho=\Pi/\Pi_c=\Pi/2\sqrt{I\Delta}, \tag{40}$$

where ω_n is defined as

$$\omega_n=(\Delta/I)^{1/2}. \tag{41}$$

In terms of these parameters Eq. (36) becomes

$$\frac{d^2\theta}{dt^2}+2\rho\omega_n\frac{d\theta}{dt}+\omega_n^2\theta=\alpha(t). \tag{42}$$

The overall system transfer function, relating the eye velocity to angular acceleration input, can be written (in the Laplace domain) as

$$V(s)/\alpha(s)=K_0G_0(s). \tag{43}$$

It can be shown that in terms of the parameters ρ and w_n

$$V(\omega)=\frac{-u\alpha_m}{\omega_n^2}\times\left(\frac{\angle G_0(j\omega)}{[(1-\omega^2/\omega_n^2)^2+(2\rho\omega/\omega_n)^2]^{1/2}}\right), \tag{44}$$

Table 10. Parameter values for the canal-nystagmus transducer system.[a]

Subject	ρ	ω_n	$2\rho/\omega_n$	k_2	$\angle G_0(j\omega)$
1	6.7	1.9	7.1	0.28	arctan $[7.1\ \omega/(1-0.28\ \omega^2)]$
2	5.0	1.0	10.0	1.00	arctan $[10.0\ \omega/(1-\omega^2)]$

[a] Egmond *et al.*, 1949.

where α_m is the maximum angular acceleration, $\angle G_0$ is the phase angle of $G_0(s)$,

$$\angle G_0(j\omega) = -\arctan\left(\frac{2\rho\omega_n}{1-(\omega^2/\omega_n^2)}\right) \tag{45}$$

and $K_0 = k_1 k_2$, where

$$k_1 = \omega_n^{-2} \text{ and } k_2 = -u. \tag{46}$$

4.4 Nonlinear Characteristics of the Endolymph Cupula-Nystagmus System

Table 10 lists typical parameter values measured in human test subjects (Egmond *et al.*, 1949). Figure 28 shows nystagmus phase shift versus frequency for a typical test subject (Niven and Hixson, 1961). Both the experimental points and the theoretical points inferred using the theory outlined above are given. The agreement is quite good. Figure 29 graphs the phase lag, $\phi_0(j\omega)$, versus peak angular acceleration for the same test subject at a stimulus frequency of 0.02 s^{-1}. The decrease in $2\rho/\omega_n$ with increasing peak implies that the ratio of system damping to system stiffness decreases as the cupula peak displacement (proportional to the peak angular acceleration) increases. This observation constitutes the first nonlinear characteristic identified for the system.

Additional nonlinear characteristics involve the use of the nystagmus transition technique (Hixson and Niven, 1962). Figure 30 illustrates two such transitions. When a subject is accelerated to the left, his or her eyes initially move slowly to the right, return quickly to the left, then start a new slow rightward movement. Conversely, acceleration to the right results in slow eye movement to the left with a fast return to the right. The point at which the eye has zero velocity denotes the transition point. This transition point is easily measured and is not initially dependent on the amplitude of the nystagmic eye motions. Similarly, the phase lag for each nystagmus transition is easily measured relative to the corresponding stimulus acceleration transition [$\phi(t)$ in Fig. 30]. These phase lags and frequency characteristics can be easily established. By experimentally measuring the frequency producing a 90° phase lag, the undamped frequency ω_n can be determined (Niven, Hixson, and Correia, 1965). Figure 29 shows phase lag/peak acceleration results ob-

tained by this technique at a stimulus frequency of 0.02 Hz. These results agree with the results obtained by the previous techniques. Figure 31 shows the dependence of $\angle\phi_0(j\omega)$ on peak acceleration for stimulus frequencies of 0.02, 0.04, 0.06, and 0.2 Hz. For frequencies of 0.08 and 0.2 Hz the phase shift is virtually independent of stimulus magnitude. Thus, in this frequency range the cupula-endolymph system is operating in a linear mode. At stimulus frequencies of 0.04 and 0.02 Hz the phase shift decreases significantly with stimulus magnitude; the slope increases as the frequency decreases. This is a nonlinear characteristic and is likely due to a saturation or overloading effect. It is likely that the mechanical properties of the cupula are nonlinear (Oman, 1981; Oman and Young, 1972).

If the cupula is attached around its periphery, as suggested by Dohlman, then low-frequency stimuli should produce maximum displacement for small volume displacement in the base region. The dynamic range of motion of the midpoint of the cupula has been estimated to range from about 10 mm at the behavioral threshold of 0.1 deg/s^2 to approximately 3 mm for the upper limit of self-induced sinusoidal head motions (30 deg/s^2) (Oman and Young, 1972). As noted already, nonlinearity in the system response starts at a stimulus frequency of about 0.04 Hz. This is consistent with the observed time lag constant of the system response, Π/Δ, of approximately 20 s. At stimulus frequencies below 0.04 Hz, and for quite moderate peak acceleration stimuli (less than 50 deg/s^2), the cupula deflection can easily reach saturation, resulting in the observed nonlinearity.

The cupula is attached to hair cells (Fig. 27). During a rapid turn of the head, for semicircular canals that lie in the plane of the angular movement, the rings of endolymph tend to remain in their original position due to their inertia. This results in a shearing movement near the attachment of the hair cells to the cupula. The hair cells are thus stimulated and send nerve impulses to the vestibular nuclei located in the brain stem. The dynamics of the hydromechanical system are such that the cupula deflection and the associated signal from the sensory cells closely match the angular velocity of the head. The semicircular canal acts as a rapid rate-of-turn transducer.

Difficulties arise, however, when the speed of rotation remains steady for a time as occurs in a prolonged roll in flight. As soon as the rate of roll becomes constant, the cupulae of the stimulated canals begin to return to their neutral position, as there is no longer any angular acceleration. Typically, in a roll at 100 deg/s (≈2 rad/s) the sensation of roll vanishes in 10–15 s. There is also an erroneous signal of rolling in the opposite direction on recovery from a constant rate of roll.

4.5 The Otolith Organs

The four otolith organs appear as thickened portions on the inner walls of the paired utricle and macule. The latter are two endolymph-filled sacs, which lie below the canal and contain platelike congregations of sensory cells. These cells have many hairlike projections that, when deflected, alter the sensory cell activity. The cells in both maculae are grouped in a saucerlike area and are covered with a gelatinous layer. The outer sur-

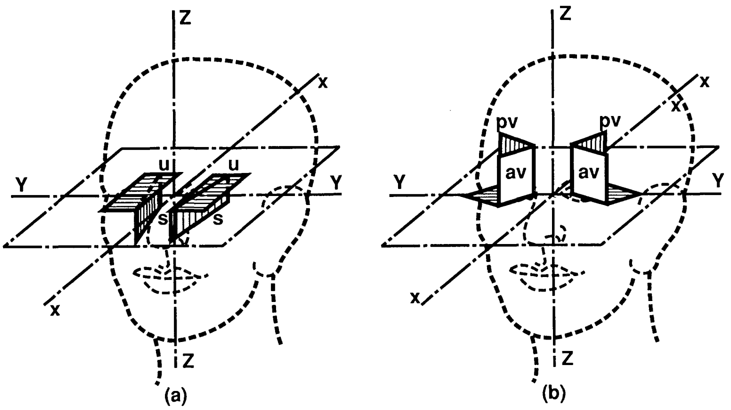

FIG. 32. Approximate planes of (a) otolithic maculae and (b) semicircular canals.

face is covered with small calcium carbonate crystals that look like a white stony plaque, whence the name otolith. The specific gravity of the otoliths is about 2.74. Displacement of the heavy otoliths produces shear forces on the hair cells resulting in output signals that are sent to the brain. Such displacements are induced by changes in the extent or direction of the linear acceleration of the head that are caused by changes in the magnitude or direction of the linear velocity of the head or by a tilt of the head with respect to gravity. Only a nonaccelerated person in the weightless condition of space is free of linear accelerative forces.

4.5.1 Dynamics of the Otolith Organs. Trinker (1962) recorded changes in potential in the macula of the guinea pig and demonstrated that only shearing forces produced by *tangential* displacement of the otolith membrane relative to the macular surface stimulate the afferent nerves. Pressure or tension *perpendicular* to the macular epithelium produces no effect. Shearing forces produce a response proportional to the sine of the angle of tilt of the macular surface from the horizontal.

The excess mass of the otolith membrane, β, is defined as its mass, m, minus the mass of an equivalent volume of endolymph. If the density of endolymph is taken as one ($\rho_a = 1$), then

$$\beta = m[1-(\rho_a/\rho)], \tag{47}$$

where ρ is the density of the otolith membrane.

The shearing force acting on the otolith organ equals the product of β and the linear acceleration acting in the plane of the macula (a). This is opposed by the elastic, or position dependent, resistance k; the viscous, or velocity-dependent, resistance μ; and the mass, or acceleration-dependent, resistance m. Hence, if x denotes the linear displacement of the otoliths,

$$\beta a = kx + \mu\frac{dx}{dr} + m\frac{d^2x}{dt^2}, \tag{48}$$

where m is the effective mass of the otolith membrane. DeVries (1950) measured these constants for fish and found that the otolith membrane of the saccule was displaced by about 33 μm by a 1g tangential force. If similar values are assumed for humans, and given a human threshold for saccular stimulation of 0.005g (Melvill Jones and Young, 1978), then the threshold displacement of the saccule for humans is about 0.15 μm. This displacement is of molecular dimensions and suggests that the critical event is a deformation of organic molecules.

Figure 32 shows the approximate planes of the otolithic maculae and the semicircular canals. There are two otolith organs on each side of the head; those of the utricle lie in an approximately horizontal plane when the head is in a normal upright position and those of the saccule lie in the vertical plane. By observing the displacement of the otolith membrane during oscillatory stimulation, de Vries (1950) deduced that the structure is critically damped and is fully displaced within 5 ms after the application of a constant tangential force. Furthermore, the membrane apparatus rapidly returns to its normal position upon removal of the stimulus.

Table 11. Physiological thresholds for the cupula-canal system.

Threshold	Angular acceleration (deg/s^2)
Oculogyric illusion[a]	0.1
Nystagmus illusion[b]	0.8
Self-induced head motion	30.0
Motion sickness (Coriolis)[c]	115.0

[a] Meiry (1965).
[b] Buys and Rijhaut (1939).
[c] Graybiel and Wood (1969).

There is, however, a basic ambiguity in signals from the otolith organs. Specifically, the effect of a horizontal linear acceleration, *a*, acting in the plane of the utricles is indistinguishable from the effect of tilting the head through an angle whose sine is *a*. Thus, if an aircraft gains speed, the otolith organs are stimulated to the same extent as if there was an upwards pitch of the aircraft. When flying in a cloud, the aircraft pilot may try to correct for this apparent upward pitch and fly the plane into the ground. However, input from the semicircular canals may help to correctly interpret the otolith inputs.

4.5.2 False Perception of Angular Motion: Somatogyral and Oculogyral Illusions. During a coordinated turn, a sustained roll, or a spin, the semicircular canal receptors only give correct information during the first few seconds of the maneuver. As the aircraft comes out of the spin, there is angular acceleration in the opposite direction. The semicircular canals are stimulated again and give a sensation of turning in the opposite direction. This effect is called the somatogyral illusion. The inappropriate signals from the canal affect visual perception and add to this disorientation. These phenomena were called oculogyral illusions by Graybiel (1952); they take the form of apparent motion and errors in the localization of targets. Table 11 lists some physiological thresholds for the cupula-canal system. The threshold for the oculogyric illusion is the lowest.

The threshold for Coriolis (cross-coupled acceleration) induced motion sickness most likely results in saturation of the cupular movement. As shall be seen in the next section, the sensory conflict theory offers the most likely explanation for this form of motion sickness.

4.6 Space Motion Sickness

Approximately 50% of those who enter the microgravity environment of low-Earth orbit experience the symptoms of SMS. Symptoms vary from stomach awareness to vomiting. In all cases studied these symptoms vanish almost completely within 48 h. The occurrence of SMS does not appear to correlate with previous sickness, such as parabolic flight sickness, air sickness in general, or sea sickness. There are some indications that adaptation occurs because the intensity of symptoms appears to lessen with successive flights. Common anti-motion-sickness drugs, especially scopolamine, lessen the intensity of symptoms, and many susceptible crewmembers use these drugs liberally.

Although considerable research has been performed in the last 20 years, no fully successful theory has been developed and we cannot predict who will be affected by SMS and who will not. For these reasons many researchers have attempted to model the relevant neurophysiological systems.

A system model of SMS is needed to categorize and order the observed facts into a rational structure, encode the measured data and dynamic processes efficiently, and clarify several key experiments needed to predict and/or prevent motion sickness on earth and in space.

One theory of the etiology of SMS is the sensory conflict theory, which suggests that the sensory orientation cues from the eyes, the vestibular system, and the proprioceptors are interpreted and modified by a "central comparator" in the brain with respect to a "neural store" of expected correlations in normal experience. A significant unexpected correlation would then result in SMS. The model must include the vestibular system; the visual system; a neurochemical system upon which drugs may act; a "learning center," including habituation and training effects; and a nauseogenic system that induces its symptoms. Figure 33 illustrates the comprehensive model called the "cue conflict" model.

The vestibular and visual systems in Fig. 33 have been replaced with linearized mathematical models. However, the limitation of this model should be apparent in that the cu-

pula-canal system has nonlinear characteristics. Moreover, the vestibulo-ocular reflex (wherein eye movements may be evoked by purely vestibular stimuli) and the eye stabilization system have not yet been incorporated. At finer levels of detail the following key facts must be included.

1. Vestibular signals dominate in the short-term, high-frequency determination of acceleration, while visual signals process long-term, low-frequency velocity information (Clark and Graybiel, 1963).
2. When vestibular cues confirm visual cues, the vestibular cues are weighted slightly; when a conflict occurs, vestibular sensations dominate (Young and Dichgaus, 1973).
3. Cross-coupled or Coriolis accelerations provoke motion sickness due to a canal-otolith conflict (Miller and Graybiel, 1970).
4. Rapid head movements in the weightless environment cause SMS, possibly due to the absence of otolith indication of a 1g environment (Miller and Graybiel, 1970).

These facts suggest a comparator structure composed of elements that compare vestibularly perceived velocity with visually perceived velocity, and compare canal-deduced orientation with otolith-deduced orientation. Conflict can arise from two signals or when one signal is absent. The three levels of comparison possible are direct canal-otolith comparison, actual and expected canal signal comparison, and actual and expected otolith signal comparison.

In recent years the sensory conflict theory has been replaced by the neural mismatch hypothesis (Oman, 1982). An essential feature of the neural mismatch hypothesis is that the presence of the sustained mismatch signal rearranges the internal model and evokes the sequence of neural and hormonal responses that constitute the motion sickness syndrome. Figure 34 shows the components and processes that the hypothesis embraces. The output from the comparator is the mismatch signal that updates the internal model and activates the neural centers and pathways that produce the symptoms of motion sickness.

Unfortunately, the neural mismatch hypothesis fails to explain why motion sickness takes the form that it does, or why it occurs at all. However, the hypothesis provides a unifying concept and explains why motion sickness occurs in some motion environments and not others. It also explains the basic features of adaptation in the context of sensory rearrangement.

Animal research has yielded considerable information on the relevant neural mechanisms involved in SMS. Figure 35 summarizes the principal elements and pathways that have been identified as implicated in the genesis of motion sickness. There is strong evidence that the vestibular apparatus, and hence the vestibular nuclei and their projections to the cerebellum, are essential for motion sickness to occur. Convergence of vestibular, visual, and kinesthetic and cerebellar afferents occurs at the level of the vestibular nuclei, and so the comparison of actual and expected motion cues could occur in these brain stem nuclei. It is most likely that the cerebellum is the site of the comparator and the internal model. How the cerebellum initiates the sequence of sensory and autonomic responses that constitute the motion sickness syndrome, however, remains to be resolved.

5. THE RADIATION ENVIRONMENT AND ASSOCIATED HAZARDS

5.1 Earth's Radiation Environment

In addition to the Earth's two fundamental fields, magnetic (Sugiura and Heppner, 1968) and gravitational, the Earth is surrounded by a particle radiation field. From data acquired by the 1958 Explorer IV and Pioneer III missions, van Allen and Frank (1959a,b) inferred the first complete map of the trapped radiation (Fig. 36). This model led to the concept of inner and outer radiation zones or what are commonly called the "belts of radiation." The inner zone extends up to an altitude $R < 2R_e$, where R_e is the Earth's radius, and is comprised mostly of high-energy protons with energies up to tens of MeV. The outer zone, extending over distances R between $2R_e$ and $10R_e$, consists mainly of electrons with energies varying from a few tens of keV to several MeV. The energies and particle fluxes comprising these zones depend on the altitude distance R. Particles in the outer zone, especially the electrons, show large temporal variations, changing their fluxes by more than an order of magnitude in less than a day. The inner-zone properties, on the other hand, are quite stable in time. The outer zone edge is very sharp. For the special case of electrons having $E > 40$ keV the flux decreases to cosmic ray background levels, a factor of

FIG. 36. Van Allen's initial map of the Earth's radiation belt illustrating the inner and outer zones of high count rate. Contours are labeled by the Geiger counter rate of 1-cm^2 area behind 1g/cm^2 of lead. [Redrawn from Frank *et al.* (1964).]

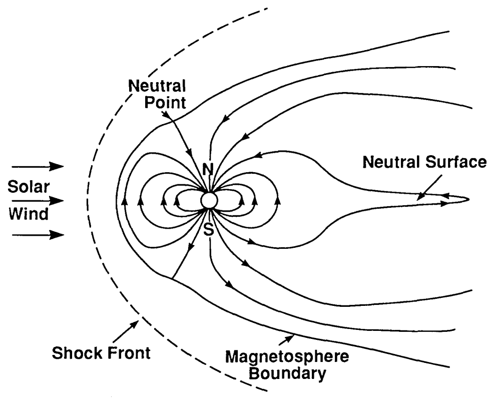

FIG. 37. Schematic of the deformation of the outer magnetosphere as derived from experiment and theory.

over 1000, in a distance as small as 100 km. This sharp spatial variation is a consequence of the solar wind. The solar wind consists of particles streaming continuously outward from the sun at speeds averaging 300–500 km/s; its composition is primarily protons and an approximately equal number of low-energy electrons, although a small percentage of higher element nuclei are also present. Its density at the Earth is about 10 ion/cm^3. The solar wind exerts a pressure, P, on the geomagnetic field, pushing the Earth's field ahead of it until it is balanced by the compression of the Earth's magnetic field. The boundary location, called the magnetopause (Hess and Mead, 1968), between the solar wind and geomagnetic field is determined by the hydromagnetic pressure balance equation

$$P^2+(B^2/8\pi)=0, \qquad (49)$$

where B (in gauss) denotes the magnetic flux density. Figure 37 illustrates the deformation of the outer magnetosphere caused by the solar wind. A general solution of the pressure balance equation for the magnetosphere boundary requires a solution of a nonlinear second-order partial differential equation (Beard, 1964). In the special case for a point on the equatorial plane, Eq. (49) gives the geocentric distance to the boundary of approximately $10R_e$ if typical values of 10 particles/cm^3 at 400 km/s are assumed for the solar wind.

5.1.1 Inner Zone.

Figure 38 shows the energy spectrum for the inner-zone protons as determined by Freden and White (1962). The solid line is the theoretical curve that was derived on the basis of cosmic-ray albedo neutron injection and ionization and nuclear collision losses. Several sources have been suggested for the origin of the trapped radiation belt particles, including primary cosmic rays, solar winds, and neutrons produced by cosmic ray protons colliding with primarily oxygen and nitrogen nuclei in the Earth's upper atmosphere. In the last case several neutrons are generated in high-energy stars (approximately seven per primary). A few of the neutrons (approximately 2.5 per star) escape from the top of the atmosphere and eventually decay according to the reaction

$$n\rightarrow p+e^-+\overline{\nu}, \qquad (50)$$

where $\overline{\nu}$ denotes an anti-neutrino. Calculations based on this process give a proton spectrum source near the Earth at the equator

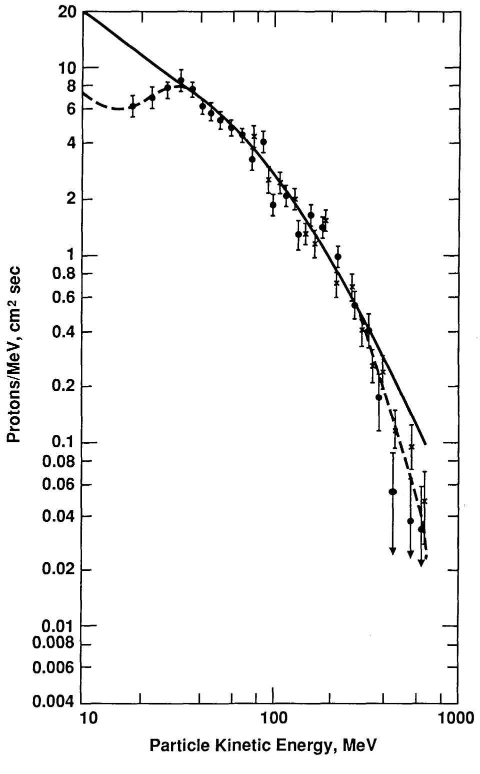

FIG. 38. Energy distribution of high-energy protons in the middle of the inner zone of the radiation belt. The solid circles are data from Freden and White (1962). The crosses are the data from the April 1959 flight normalized to data in region of 100 MeV. The dashed curve is a fit to the data. The solid curve is the theoretical spectrum expected from the cosmic-ray neutron albedo decay theory. [Redrawn from Hess, 1968.]

$$S_p(E)=0.8E^{-2.0}/\gamma v T_n, \tag{51}$$

where v is the neutron velocity; T_n is the neutron mean life; and γ is the time dilation factor, $\gamma = [1 - (v^2/c^2)]^{1/2}$. A quantitative description of the flux-energy spectrum can be obtained by solving the continuity equation

$$\frac{dN(E)}{dt}=S_p(E)-L(E)+\frac{\partial J(E)}{\partial E}, \tag{52}$$

where $N(E)$ is the equilibrium proton density, $S_p(E)$ denotes the proton source, $L(E)$ represents the loss term due to inelastic nuclear collisions, and $J(E)$ is the current

$$J(E)=N(E)\frac{dE}{dt}. \tag{53}$$

At equilibrium and assuming no losses $[L(E)=0]$, Eq. (52) gives a proton flux

$$J(E)=110E^{-0.72} \text{ protons/cm}^2 \text{ s MeV} \tag{54}$$

in the energy range $10<E<80$ MeV, assuming an air density of 2.8×10^{-18} g/cm^3 (corresponding to an atomic density of 10^5 atoms/cm^3); an injection coefficient, $\eta=0.30$, defined as the fraction of protons produced by neutron decay that are actually trapped; and using the source term given by Eq. (51). The low-energy region of the solid curve in Fig. 38 agrees with that given by Eq. (54). The general solution to Eq. (52) when loss terms are explicitly included was given by Freden and White (1960) and is denoted by the full solid line in Fig. 38. The agreement between theory and experiments offers strong support that secondary neutrons are an important source of the inner radiation zone. In addition to galactic cosmic ray (GCR) protons, protons in the solar winds with energies up to a few hundred MeV reach Earth in the polar regions. Neutrons are made when these protons interact with the polar atmosphere. The decay of these solar-proton–produced neutrons constitutes an additional source of energetic protons for the inner radiation zone. Protons produced from solar-cap neutrons initially were suggested to be responsible for the low-energy component at $L>1.6$ reported by Naugle and Kniffer (1961), although recent measurements showed that the large fluxes for $E<50$ MeV are not completely accounted for by either of the above processes. Nevertheless, neutron-decay electrons are a major source of the trapped inner-zone electrons. Here L is McIlwain's magnetic shell parameter (Scraf, 1966; McIlwain, 1961) and is a distance (expressed in Earth radii) defined in terms of integral invariants; in a dipole field L is the distance to the Equator for a particular magnetic field line. L is nearly constant along a field line and, therefore, replaces the commonly used equatorial radius with the real values of the Earth's magnetic field.

5.1.2 Outer Zone. The outer zone consists mainly of electrons and low-energy protons. Outer zone protons having energies 0.1 MeV$<E<$5 MeV were initially investigated on the Explorer XII, XIV, and XV missions. At these altitudes, the energy spectra largely obey the relationship

$$N(E)=k \exp(-E/E_0), \tag{55}$$

where k is a constant and the characteristic energy E_0 is proportional to L^{-3}. That $E_0 \propto L^{-3}$ has been interpreted in terms of the radial drift of the outer zone protons. Time variations in the proton fluxes are seen for $L>6$, but for lower L values the fluxes are quite stable.

In contrast to protons, electrons in the outer zone show large time variations. For $E>1.5$ MeV the electron flux can increase or decrease by a factor of 10 or more in hours. Typical intensities of electrons in the central part of the outer radiation zone ($L=4.0$ near the geomagnetic equator) are $J(E>40$ keV$)=3\times10^7$ (cm^2 s)$^{-1}$; $J(E>230$ keV$)=3\times10^6$ (cm^2 s)$^{-1}$; and $J(E>1.6$ MeV$)=3\times10^5$ (cm^2 s)$^{-1}$ (Frank, Van Allen, and Hills, 1964). For $E>0.5$ MeV the energy spectra are exponential with 0.2 MeV$<E_0<$0.6 MeV; electrons of a particular energy E peak at lower L as E increases.

5.1.3 Cosmic Rays. Cosmic rays are energetic nuclear particles found in interplanetary space; they arrive at the Earth's upper atmosphere from all directions. Cosmic rays can be considered as either solar or galactic, depending on their site of origin. There may be, in addition, a small high-energy (greater than 10^{15} eV) component that originates in extragalactic space. The charged particles are principally protons; heavier nuclei make up about 10% of the total and electron and positions contribute about 3% of the total. A small contribution from antiprotons has also been

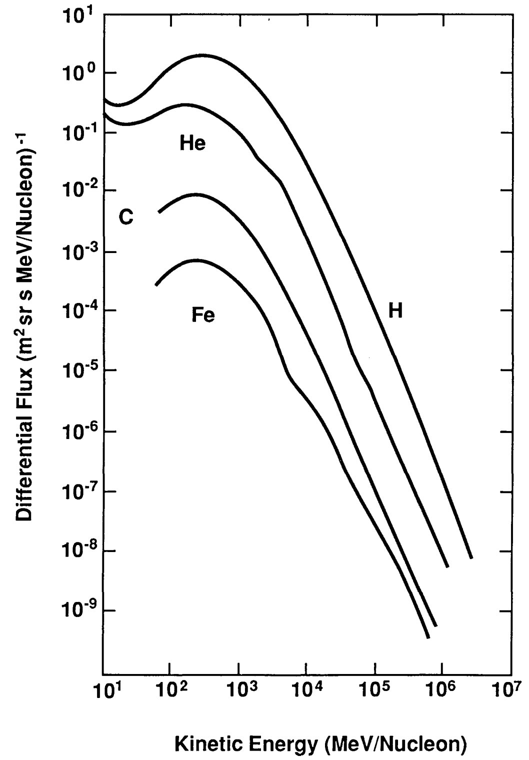

FIG. 39. Differential energy spectra of cosmic rays for the elements hydrogen (H), helium (He), carbon (C), and iron (Fe) measured near earth. [Redrawn from Gow and Taylor (1968).]

detected. The γ radiation accounts for approximately 10^{-6} of the total, and neutrinos predominate by many orders of magnitude, as they originate largely from our Sun. Although cosmic rays were detected by Hess in 1912, their origin and the processes by which they achieve their high energies are still subjects of debate. Energies as high as 3×10^{19} eV have been recorded.

5.1.4 Galactic Cosmic Rays. Galactic cosmic rays (GCRs) are high-energy particles that do not originate from our Sun. Their flux is approximately 2 particles $\text{cm}^{-2}\ \text{s}^{-1}$. Contrary to previously held views, recent measurements demonstrated that GCRs do not impinge on the earth isotropically but show slight anisotropies that increase with energy for $E>3\times10^{11}$ eV. Figure 39 shows the spectrum of the more pronounced components. Simpson (1983) reviews the elemental and isotopic composition of the GCRs extensively.

For total energy E greater than a few BeV, the flux of protons can be represented by the formula

$$N(>E)=CE^{-\gamma} \tag{56}$$

where the exponent γ varies from 1.4 for E between 5×10^{9} eV and 5×10^{11} eV to 1.5 for E between 10^{13} eV and 10^{15} eV, and is approximately 2 for $E>10^{15}$ eV. An important feature of the proton spectrum is its variability within the 11-year solar cycle. When the solar wind fields are minimal, modulation in the GCR spectrum is minimal. Solar modulation is more effective for low-energy nuclei than high-energy particles. Figure 40 shows this correlation between solar activity and GCRs in plots of the differential rigidity proton spectrum during solar minimum and solar maximum activity. The rigidity R of a particle of momentum p and charge Ze is defined as

$$R=pc/Ze, \tag{57}$$

where c is the speed of light. A larger rigidity corresponds to a particle with higher energy. Another important characteristic of GCRs is their constancy in time. An analysis of deep-sea core samples indicates a variation in the GCR flux of less than 20% over the last 30 000 years.

Several proposals have been given for the origin of GCRs (Morrison, 1961). For energies of 10–100 BeV, GCR particles are presumed to be produced in the atmosphere of

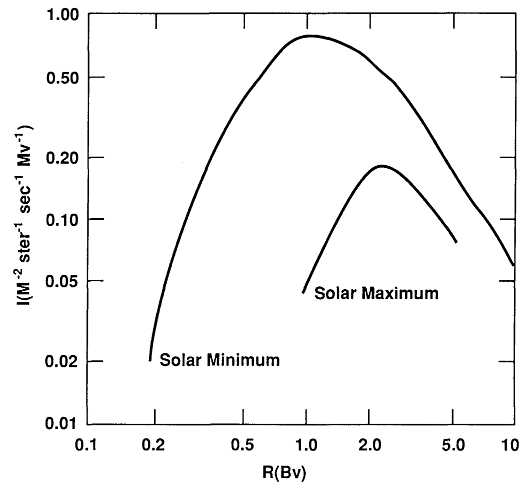

FIG. 40. Differential rigidity spectrum (*I*) for protons during solar minimum and solar maximum. [Redrawn from Heinrich *et al.* (1989).]

Sun-like (or possibly special) stars. For energies in the range of 10^2–10^9 BeV, the particles originating in Sun-like stars acquired these high energies by accelerating through the action of the weak random interstellar magnetic fields. For very energetic particles, several mechanisms, such as remnants of supernova, pulsars, and black holes have been suggested.

5.1.5 Solar Cosmic Rays. Solar cosmic rays (SCRs) are high-energy particles that originate at the Sun and are present near the Earth's upper atmosphere 10%–20% of the time. SCRs are distinct from the continuous stream of particles that comprise the solar wind. SCRs occur only in conjunction with solar flares (Hirman, 1988), which are disturbed regions on the Sun's surface. Solar flares are classified as either ordinary events (OR) or anomalously large events (AL). AL events are quite rare; only three occurred in the 19th solar cycle, one in the 20th solar cycle, and none in the 21st cycle. Flares release enormous amounts of energy in a short period of time (hours to days). For example, in the flare of August 1972, the 10-MeV proton fluxes at geosynchronous orbits exceeded 10^5 p $\mathrm{cm}^{-2}\ \mathrm{s}^{-1}\ \mathrm{sr}^{-1}$ and released over 10^{32} ergs of energy; this is more energy than mankind has used in all of history. As with GCRs, protons are the dominant species in SCRs, although higher element nuclei are also present. Not all solar flare activity on the Sun results in particle emission, and even these events may not emit particles directed toward the Earth. Solar flares that satisfy both criteria are termed solar particle events (SPEs). SPEs occur at a rate of about 100 per 11-yr solar cycle, predominately during solar maximum, although they can appear at any time in the solar cycle. For energies >10 MeV, they have proton fluxes of 10 p $\mathrm{cm}^{-2}\ \mathrm{s}^{-1}\ \mathrm{sr}^{-1}$ or greater as measured at geosynchronous orbits. Because a single AL solar particle event can be the dominant part of radiation dose received during a space mission, considerable research has been concerned with solar proton event forecasting (Hirman, 1988). The National Oceanic and Atmospheric Administration is responsible for space weather forecasting.

In summary, the space radiation environment is a function of location and time. Radiation in low-Earth orbits (LEO) is primarily trapped protons, whereas in geosynchronous earth orbits (GEO) trapped electrons (and bremsstrahlung radiation produced by electrons interacting with the spacecraft) dominate. For journeys beyond the Earth's radiation belts, the effects GCRs and large solar particle flares are the main sources of ionizing radiation. Table 12 lists the sources of radiation, their locations, and the secondary radiation produced by interaction of the primary component with a spacecraft.

5.2 Shielding

5.2.1 Geomagnetic Shielding. Incident particles originating from outside the geomagnetic field are deflected by the Earth's magnetic field. The concept of the rigidity, R, of a particle in a magnetic field can be used to study the influence of the Earth's magnetic field on the energy spectra of cosmic rays. The rigidity was defined by Eq. (57) as

$$R=B_{\perp}C=Pc/Ze, \tag{58}$$

where $B_{\perp}$ is the field component perpendicular to the particle's instantaneous velocity. For inhomogeneous fields, each point on the particle curve trajectory defines a radius of curvature, r. If one approximates the Earth's magnetic field as a dipole field, then it can be shown that particles must have a rigidity greater than R_s to reach the Earth's surface (Störmer, 1930), where

$$R_s=\frac{M\cos^4\lambda}{r^2[1+(1-\sin\theta\cos\phi\cos^3\lambda)^{1/2}]^2}. \tag{59}$$

Here M denotes the Earth's dipole moment and has a value of 8.1×10^{25} G cm^3; r is the radial distance from the center of the dipole; and λ, θ, and ϕ are the geomagnetic latitude, zenith, and azimuth angles, respectively. Hence, each location on the Earth defines a cutoff energy,

$$E=[(m_pc^2)^2+R_s^2\Lambda^2]^{1/2}-m_pc^2 \tag{60}$$

in the cosmic ray particle energy below which particles cannot reach the Earth's surface. Here $\Lambda=ez/A$ is the charge-to-mass number ratio of the particle and m_pc^2 is the rest energy of the proton. R_s is called the Störmer cutoff. In the special case of vertical incidence ($\theta=0$), $R_s = M\cos^4\lambda/4r^2$. At the geomagnetic equator ($\lambda=0$), R_s is maximal; $R_s = 0$ at the poles. More precise values of R_s can

Table 12. Sources of radiation, location, and types of secondary radiation.

Type	Description	Location	Secondary radiation
Trapped electrons	Low LET[a] Large temporal variations Not very penetrating Low dose rate	(3–12) R_e[b] GEO[c]	Bremsstrahlung Penetrating Low LET
Trapped protons	Ranges from low to high LET Penetrating Low dose rate	LEO[d]	Neutrons High LET

---

[a] LET: linear energy transfer—a measure of the amount of energy deposited as radiation interacts with matter; for a given radiation dose, biological effects are strongly dependent on the LET of the radiation.

[b] R_e: Earth radius, approximately 6378 km.

[c] GEO: geosynchronous Earth orbit

[d] LEO: low-Earth orbit.

be calculated by including the effects of higher order magnetic multipoles. Including higher-order multipoles on R has been considered by Shea, Smart, and McCracken (1965) and Shea and Smart (1967), to which the reader is referred.

The radiation exposure received by an astronaut is altered by the effects of geomagnetic shielding and spacecraft attenuation. The effects of geomagnetic shielding on the incident flux $I_0(E)$, where E denotes energy, can be related to the energy-dependent flux at the desired location $I(E)$ by the equation (Heinrich and Spill, 1979)

$$I(E) = I_0(E)\,W(R), \tag{61}$$

where $W(R)$ denotes the probability that particles with rigidity R can penetrate the field. In general, $W(R)$ varies with location, and is, therefore, a function of the longitudinal position of the intersection of the orbit with the equator, the angle between the intersection point of the orbit with the equatorial plane and the perigee of the spacecraft, the space-

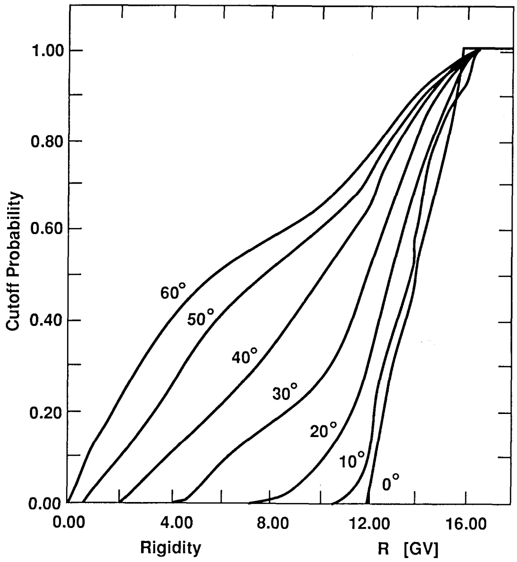

FIG. 41. Cutoff rigidity functions for a circular orbit at an altitude of 223 km for several inclinations (i). [Redrawn from Heinrich and Spill (1979).]

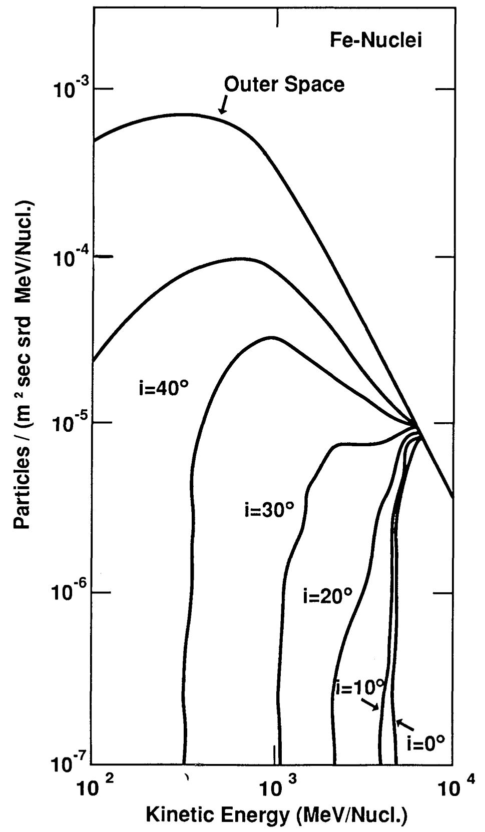

FIG. 42. Iron (Fe) nuclei energy spectra for circular orbits at 223-km altitude for different inclinations (*i*). [Redrawn from Heinrich and Spill (1979).]

craft altitude, its orbit inclination, and the solar cycle. Figure 41 illustrates the variation expected in $W(R)$ for a circular orbit at a fixed altitude (223 km) for several inclinations i (Heinrich and Spill, 1979). Figure 42 illustrates the effects of geomagnetic shielding on the energy spectra for iron nuclei. As expected, the cutoff rigidity by having a steeper slope for lower inclinations introduces a sharper and higher-energy cutoff in the energy spectrum. The uppermost curve in Fig. 42 gives the spectrum for iron nuclei outside the magnetosphere.

5.2.2 Shielding by Materials. Apart from nuclear collisions of an incident particle with material nuclei, a charged ion loses most of its kinetic energy through electromagnetic interaction, transferring more energy to the light electrons than to heavy nuclei comprising the target. The energy lost by this latter mechanism results in either excitation or ionization of target atoms. A quantity helpful in discussing the interaction of ionizing radiation with matter is the linear energy transfer (LET) of a particle, which is defined as the energy loss per unit of path length. LET is a function of energy and charge of the incident ion or nuclei, and it depends only weakly on the material composition (Ablen, 1980). The path length of a particle down to its stopping point is called the particle range.

In nuclear collisions of high-energy heavy ions with target nuclei, fast nuclear fragments are produced. These fragments have approximately the same velocity and direction as the incident particle. The fragmentation process alters the composition of a heavy-ion beam passing through the material and reduces the number of original beam nuclei. This reduction is almost independent of energy, because the interaction mean free paths λ_j (j labels the nuclei type) exhibit no strong energy dependence. In a more quantitative treatment of projectile fragments, one must solve the coupled equations

$$\frac{dN_j(x)}{dx}=\frac{-N_j(x)}{\lambda_j}+\sum_{i\neq j} P_{ij}\left[\frac{N_i(x)}{\lambda_i}\right], \qquad (62)$$

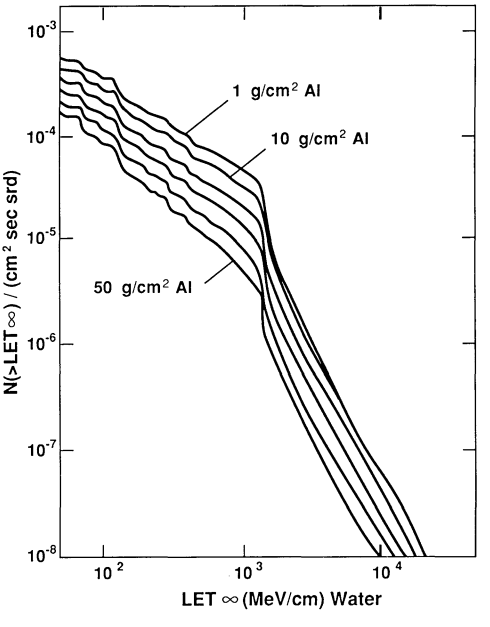

FIG. 43. Calculated integral linear energy transfer (LET) spectra illustrating effects of shield thickness of (1, 10, 20, 30, 40, and 50 g/cm²) aluminum (Al). Altitude 241 km, inclination 57°. [Redrawn from Heinrich *et al.*, 1989.]

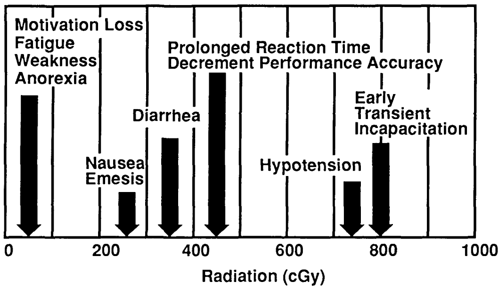

FIG. 44. Performance degradation events occurring at various doses of gamma irradiation in centigrays (cGy). (Redrawn from *Exploring the Living Universe: A Strategy for Space Life Science,* NASA, 1988.)

where $N_j(x)$ is the number of nuclei of type j at depth x, and P_{ij} denotes the probability that a nucleus of type i in a collision with a target nucleus produces a projectile fragment of type j,

$$P_{ij}=\sigma_{ij}/\sigma, \tag{63}$$

where σ is the total interaction cross section and σ_{ij} denotes the partial fragmentation cross sections. Our ignorance of the complete process lies in our limited knowledge of σ_{ij}, as these must be derived from experimental data. In the case of fragmentation in collisions with hydrogen, the empirical cross sections given by Silberberg and Tsao (1973) are useful. Other cross sections can be found by invoking the factorization law suggested by Lindstrom *et al.* (1975). Figure 43 illustrates the effects on the differential LET spectra for the SL-1 (SL-1 denotes the European Spacelab mission of November '83 which had a circular orbit at an altitude of 241 km and an inclination of 57°) behind varying thicknesses of aluminum (Al) shielding (Heinrich *et al.*, 1989); a difference in thickness of 10 g/cm^2 introduces a factor of 1.5 in the LET spectra.

5.3 Biological Effects of Radiation

Radiation is generally measured by its physical dose unit, the *rad*, which denotes the energy deposition by radiation per unit mass of absorber material (1 rad = 100 erg/gm) without reference to its effects. When the effects of radiation on living organisms are evaluated, the absorption of equal amounts of energy per unit mass under different irradiation conditions, for example, heavy ions or neutrons versus gamma irradiation, does not guarantee the same biological effect. To quantify the probable biological effect of a given radiation exposure, the concept of dose equivalent was introduced. The dose equivalent H is the product of the absorbed dose D and the quality factor QF that characterizes the specific radiation:

$$H=D\times \mathrm{QF}. \tag{64}$$

The quantity QF depends on the type of radiation, its energy, and the organ being irradiated. QF can vary from unity for x rays to greater than 20 for alpha particles of typical energies and multicharged particles (ICRU, 1986). If D is expressed in rad, then H is defined in units of rem. If D is expressed in SI units or grays (Gy) then the corresponding unit of dose equivalent is called the sievert (Sv). (See also BIOLOGICAL EFFECTS OF ELECTROMAGNETIC RADIATION.)

The effects of ionizing radiation are generally grouped into two categories: acute effects and long-term effects. Acute effects include radiation sickness and death; long-term effects are carcinogenesis, teratogenesis, and cataract formation. Figure 44 summarizes the types of acute physiological responses and the doses that typically cause their onset, and Figure 45 describes the temporal pattern of radiation effects following ^{60}Co exposure (Conklin and Walker, 1987). For a review of the effects of ionizing radiation on neural function the reader should consult Kimeldorf and Hunt (1965); for a view of the effects of ionizing radiation on behavior one should consult Maier and Landauer (1989) and references quoted.

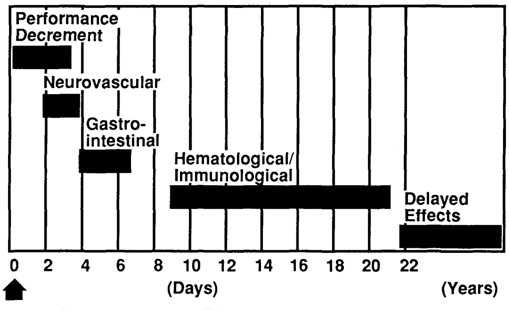

FIG. 45. Temporal relation of postexposure medical effects after gamma irradiation. (Redrawn from *Exploring the Living Universe: A Strategy for Space Life Science,* NASA, 1988.)

5.4 Expected Radiation Exposures in Space Missions

The types of radiation hazards experienced by space crews depend on the mission scenario. Each scenario determines the type and magnitude of the biological effects expected.

5.4.1 LEO Missions. The principal mission for LEO is the Space Station Freedom at orbital parameters of 450 km, 28° inclination. In this case the main source of radiation is trapped protons in the South Atlantic Anomaly (SAA) with GCR contributing a smaller fraction. SAA refers to the region where the van Allen belts are at lower altitudes. This depression of the magnetic field over the coast of Brazil occurs because the dipole term of the geomagnetic field is shifted about 11° from the Earth's axis of rotation and displaced approximately 500 km towards the Western Pacific. In LEO, SAA accounts for nearly all the trapped proton radiation astronauts receive with a small contribution of galactic cosmic radiation. Curtis (1974) estimated for the proposed LEO missions a dose rate of 97 mrem/day to blood-forming organs shielded by 1 g/cm^2 Al. For comparison, a total dose equivalent of 0.1 rem is about equal to that received on Earth from natural sources (other than radon) in 1 yr. For the Apollo missions, during which no major SPEs occurred, astronauts received a skin dose of less than one rad (Atwell, 1979).

5.4.2 Geosynchronous Orbits. During missions in GEO a crew would be exposed to several radiation sources: electrons in the outer radiation belt, bremsstrahlung from electron-shielding interactions, GCRs, and SPEs. The GCR contribution to the total dose is significant but smaller than that of fast electrons. Shielding does not profoundly affect the dose rate, which is estimated to be about 100 mrem/day with no shielding and 50 mrem/day behind 4 g/cm^2 of Al. The dose from SPEs varies with magnitude and duration of the solar flare. For SPEs in solar cycle 19, doses were estimated to be 100–200 rad/day for 2 g/cm^2 shielding and 15–30 rad/day for 5 g cm^{-2} shielding (Silberberg *et al.*, 1985). These are doses sufficient to produce acute effects.

5.4.3 Lunar Mission. In contrast to orbits about the Earth, the Moon offers little or no protection from GCRs or SPEs. At solar minimum the annual dose-equivalent rate from GCRs is estimated to be about 30 rem/year, and doses from SPEs are substantially larger. GCRs are penetrating and their interaction with target material generates a substantial number of neutrons that have a high biological effectiveness. QFs for neutrons between 10 and 20 have been proposed. Figure 46 illustrates this complex dose-depth relationship for the lunar environment. If individuals are to spend years on the Moon, substantial shielding, presumably provided by the surface itself, would be necessary if the lifetime exposure limits given in Table 13 are not to be exceeded. These career limits are based on a lifetime excess risk of cancer of 0.03.

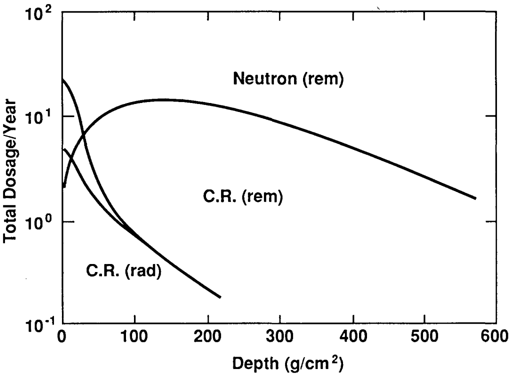

FIG. 46. A comparison of the annual dose equivalent due to secondary neutrons and cosmic-ray nuclei, as a function of shielding depth, and the absorbed dose rate due to cosmic-ray nuclei. (Redrawn from *Exploring the Living Universe: A Strategy for Space Life Science*, NASA, 1988.)

5.4.4 Mars Mission. The radiation space environment for a mission to Mars is essentially the same as for a lunar colony but without the advantage of building sleeping quarters below the surface. A baseline dose for a Mars trip has been calculated to be 43 rem/

Table 13. Career limits (in rem) for lifetime excess risk of fatal cancer at 3×10^{-2}.

	Age of first exposure			
	25	35	45	55
Male	150	250	325	400
Female	100	175	250	300

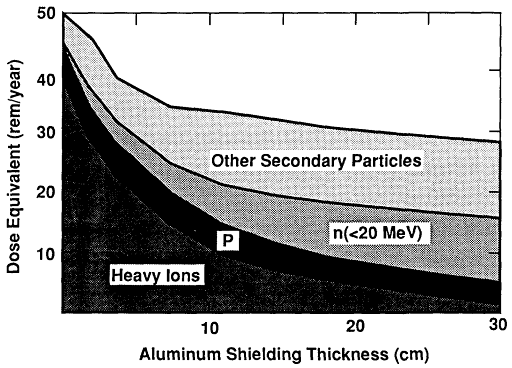

FIG. 47. Dose equivalent at 5-cm tissue depth versus aluminum shielding thickness at solar minimum showing radiation component individuality.

year in free space and 36 rem/year when shielded by 4 g/cm^2 of Al (Letaw, Silberberg, and Tsao, 1986). The capacity of Al for shielding astronauts from galactic cosmic radiation in free space is given by the dose versus depth curves shown in Fig. 47 under solar minimum conditions. It is evident that the heavy ions, the primary source of radiation, are attenuated *e*-fold by approximately 10 cm of shielding, whereas the secondary components, including neutrons, protons, and recoil heavy nuclei, tend to accumulate. For 30 cm of shielding the annual dose equivalent is reduced from 500 mSv to 20 mSv. An identical calculation for solar maximum conditions shows that shielding is even more ineffective (Letaw, Silberberg, and Tsao, 1988).

GLOSSARY

Afferent: Carrying toward a center; centripetal.

Alveoli: Plural of alveolus; small saclike structures that are the terminal elements in the airways (bronchioles) in the lungs.

Anthropomorphic: Having human form.

Atelectasis: Collapse of lung tissue, preventing the respiratory exchange of carbon dioxide and oxygen.

Autonomic Nerve: Part of the nervous system that regulates the activity of cardiac muscle, smooth muscle, and glands.

Baroreceptor: Pressure-sensitive nerve ending found in the walls of the atria of the heart, the vena cava, the aortic arch, and the carotid sinus.

Bradycardia: An abnormally low heart rate (below 60 beats per minute).

Cephalad: Toward the head.

Cerebellum: The inferior part of the brain located in the posterior cranial fossa behind the brain stem; it consists of two lateral lobes and a middle lobe.

Cerebrospinal: Pertaining to the brain and the spinal cord.

DNA: Deoxyribonucleic acid, the genetic material contained in all living cells.

Dorsalis Pedis Artery: Continuation of the anterior tibial artery starting at the ankle joint.

Dose-Equivalent (DE): The product of the dose in rads and a quality factor (QF), that varies with the LET of radiation.

Edema: The abnormal accumulation of fluid in the tissue spaces due to increased transudation of the fluid from the capillaries; dropsy.

Endocrine System: Network of ductless glands and other structures that secrete hormones into the blood.

Enteric: Pertaining to the small intestines.

Epistaxis: Nose bleed.

Genome: The complete set of genes in the chromosomes of each cell of a particular organism.

Gray (Gy): Système International unit of absorbed dose; one gray denotes the absorption of one joule of energy in a mass of one kilogram.

Homeostasis: A tendency to stability in steady states in the organism by coordinated physiologic processes.

Ischemia: Decreased blood supply to a body organ or part, due to inflow of arterial blood or to vasoconstriction; localized tissue anemia.

Jugular bulb: Inferior bulb or superior bulb of the internal jugular vein.

Kinesthetic: The sense of perception of movement, weight, resistance, and position.

Lachrymation: Secretion of tears by the lacrimal glands in the eyelids.

LET: Linear energy transfer; the average loss in energy per unit length of path of the incident radiation.

Lumen: A cavity or channel within any organ or structure of the body.

Meiosis: Division of a sex cell into two, then four, gametes.

Mitosis: Cell division in somatic cell resulting in two genetically identical daughter cells.

Nystagmus: Involuntary, rhythmic movement of the eyeball—horizontal, vertical, rotary, or mixed. It may be congenital, acquired, physiologic, or pathologic, due to neurogenic, myopathic, labyrinthine, or oscular causes.

Oculogyration: Movement of the eyeball about the anteroposterior axis.

Orthostatic Intolerance: Inability to maintain blood pressure in the brain when an individual assumes the standing position.

Os Calcis: Heel bone.

Osmole: The amount of substance that dissociates in solution to form one mole of osmotically active particles; e.g., 1 mole of glucose, which is unionizable, forms 1 osmole of solute, but 1 mole of sodium chloride forms 2 moles of solute. Symbol: osm. Also written osmol. 1000 mosm = 1 osm. Osmolarity refers to osmoles per liter.

Perfusion: Introduction of blood into tissue by their injection into blood vessels.

Petechia: Tiny purple or red spots that appear on the skin as a result of minute hemorrhages within the dermal or submucosal layers.

Proprioceptor: Any sensory nerve ending, in, for example, muscles, tendons, and vestibular apparatus, that responds to stimuli originating in the body regarding movement and spatial position.

Protist: The protoplasm of a cell without its containing membrane.

Quality Factor (QF): An LET-dependent factor by which absorbed dose is multiplied to obtain a quantity that corresponds more closely to the degree of biological effects produced by x or low-energy gamma rays.

Rad: Radiation absorbed dose; a unit of absorbed dose that represents the absorption of 0.01 J of energy per kilogram of absorbing material.

Relative Biological Effectiveness (RBE): Biological potency of one type of radiation as compared to another producing the same biological end-point. It is numerically equal to the inverse of the ratio of absorbed doses of the two radiations required to produce equal biological effects.

Residual Volume: The volume of gas in the lungs at the end of a maximum expiration.

Ribosome: A cytoplasmic organelle composed of ribonucleic acid and proteins.

Scotomata: Dark areas of lost or depressed vision.

Sievert (Sv): Système International unit of radiation dose equivalent; equal to dose in grays times a quality factor.

Smooth Muscle: One of two kinds of muscle, distinguished by being under autonomic (involuntary) control.

SMS: Space motion sickness.

Systole: The period of heart contraction when blood is forced into the aorta and pulmonary artery.

Transmural: Across the wall of an organ.

Urticaria: An itchy skin eruption characterized by transient wheals of varying shapes and sizes.

Venous Compliance: Change in diameter of vessel per unit blood pressure.

Venous Pressure: Pressure exerted by circulating blood on the walls of veins (60–100 mm of water).

Ventilation: Process by which gases are moved in and out of the lungs.

Vital Capacity: Amount of air that can be expelled after a maximum inspiration; normal values range from 4000–5000 mL.

INTRODUCTION

There are literally thousands of pollutants present in the atmosphere. These pollutants are trace contaminants that, either by themselves or upon interaction with other pollutants, adversely impact our environment. Not all contaminants have universally adverse impacts, even though they affect the environment. Consider the environmental havoc precipitated by the buildup of free oxygen as the earth evolved. Many existing organisms had to seek refuge below the surface of the land or water. However, at the same time it allowed other organisms to flourish. To the previous inhabitants oxygen was a pollutant, to those that followed it is a necessity.

Most pollutants, however, have an overall negative impact on the environment as judged by health, environmental, and mate-

rial degradation. In an economic or social sense, indoor radon, urban smog, regional acid deposition, destruction of stratospheric ozone, and rapid global warming are undesirable. For this reason the chemical compounds that lead to these phenomena are termed pollutants. A pollutant can be defined as a substance that is present at some location at an undesirably high concentration. This definition allows for the possibility that a compound may not be a pollutant at one concentration, although its buildup may have adverse consequences. CO_2 is necessary for plant life, but too much leads to global warming. Likewise, a compound may be beneficial in one location and not another; e.g., ozone is beneficial in the stratosphere but is a primary component of urban air pollution in the troposphere. Time is also important in determining how a contaminant will impact the environment. If the buildup of a pollutant is slow enough, the ecological system can adjust, as was the case with the buildup of oxygen over millions of years. However, man's activities have led to increases in pollutants at a rate that does not allow complete adjustment. This is one of the concerns of the greenhouse effect—not only that there is a warming trend, but that it is warming more quickly than the environment can adapt to the new conditions.

The approach taken here is to review the general characteristics of the more common air pollution systems and then to discuss their chemistry, physics, and control in more detail. More extensive information on certain aspects, such as meteorology, the climate, and atmospheric physics are contained in articles devoted to those fields (see ATMOSPHERIC PHYSICS; METEOROLOGY). Following this introduction is a brief history of air pollution. Next, the compounds commonly considered air pollutants are discussed, including their effects and where they are found. Included are brief discussions of the more pressing air pollutant problems we now face. Most air pollution systems are due to the interaction of pollutant transport and chemistry, as is discussed in the sections on meteorology and atmospheric chemistry. The last sections cover pollution control, including control devices, air quality regulations, and the development of effective control strategies.

1. HISTORY

Air pollution is not a new phenomenon, though it is growing in scope and complexity. Use of fire by early man was accompanied by smoke filling their dwellings. As people started to congregate into cities, the problem intensified. Accounts from early Rome testify to the soot and stench of the city (e.g., Stern *et al.*, 1984; Brimblecombe, 1984).

In London, the smoke and fumes from wood and coal burning have plagued the city since medieval times. In spite of a series of royal edicts and laws, the air continued to worsen. In 1661 John Evelyn wrote for Charles II and Parliament the classic "Fumifumigium, or the Inconvenience of the Aer, and Smoake Dissipated," describing the sources, effects, and remedies for the air pollution inundating the city. While the work was far-sighted, it had relatively little impact, and London continued to experience "Great Stinking Fogs," the result of coal smoke and fog.

The industrial revolution was spurred by the ability to use steam to drive machinery, and coal was used to generate the steam. The prosperity afforded by the increased manufacture of products accompanying these plants made smoke a tolerated inconvenience, a view still held today in developed and developing nations. In London, however, the oppressiveness of the smog caused sufficient pressure for Parliament to pass Great Britain's Public Health Act in 1848. Again, neither that legislation, nor later versions, were entirely effective. In 1952, the Great Smog encompassed London for four days, leading to an estimated 4000 excess deaths. London was not alone. The Meuse Valley (Belgium) and Donora, Pennsylvania, were hit by similar conditions in 1930 and 1948, respectively, leading to increased rates of illness and death.

While London, and indeed most large cities, were struggling to clean up coal smoke, Los Angeles was "cooking up" a new form of air pollution (Finlayson-Pitts and Pitts, 1987). Unlike London, Los Angeles smog was not a result of smoke mixing with fog. In this case, the severity increased with sunlight. Photochemical smog, as it has become known, was a result of automobile, power plant, refinery, and other source emissions interacting in the sunlight to form ozone, formaldehyde, and acids. The pollutants formed were more obnoxious than those originally emitted. It is now recognized that most major cities experience photochemical smog. Through aggressive control measures instituted, the magnitude of the problem has been reduced in Los Angeles, despite continued population growth.

While we are still struggling for solutions to urban air pollution, expansion of man's activities, accompanied by our ability to identify more subtle, global changes, has raised other problems. In the 1970s and 80s, increasing attention has been focused on regional and global changes in air quality. On the regional scale, power plant and automotive emissions are reacting to form atmospheric sulfuric and nitric acid. These compounds deposit on the ground, acidifying lakes and streams and stressing tree growth. Acidification has resulted in dramatic ecological changes in lakes in Canada, the northeastern United States, and Scandinavia. In addition to acids, it was found that the urban ozone and its precursors were being carried into rural areas.

Probably the most alarming discoveries involve global changes in the Earth's atmosphere arising from man-made emissions. Increased carbon dioxide emissions and other man-made emissions may be leading to global warming, or the "greenhouse effect." Emissions of chlorofluorocarbons (e.g., Freon from automobile air conditioners) are expected to continue to decrease stratospheric ozone. This layer of ozone protects the Earth's surface from harmful UV radiation. What is most ominous about the global problems is that they are very tough to attack, and even with very aggressive efforts they are expected to worsen. In contrast, controlling urban smog and acid deposition has begun with some success. As man's activities have diversified, the variety of impacts has multiplied as have the strategies necessary for remedial action.

2. COMPONENTS AND SCALES OF POLLUTANT SYSTEMS

Air pollutant systems are comprised of a variety of compounds, and differ markedly depending on spatial scale and location. Historically, air pollution was first an indoor and local phenomenon. Next, the scope grew to urban areas, then regional. Now the global consequences of man's actions are recognized. This provides a convenient framework for classifying pollutant systems. First, however, it is instructive to identify the compounds that are called pollutants, their sources and effects.

2.1 Pollutants, Sources, Effects, and Measurement

Airborne matter is present in all three phases: gas, liquid, and solid. In the condensed phases, the pollutants are found as small particles (called aerosol or particulate matter) less than about 10 μm in diameter. Particles larger than this rapidly settle out. Pollutants may be either primary or secondary. Primary pollutants are emitted directly. Secondary pollutants are formed in the atmosphere by chemical reactions of primary pollutants. A number of both primary and secondary pollutants are listed in Table 1, along with representative concentrations and sources (Brimblecombe, 1986; Seinfeld, 1987; Finlayson-Pitts and Pitts, 1987; Stern *et al.*, 1984; Schwartz, 1989). Many of the pollutants are both anthropogenic (man-made) and natural in origin, and it is evident that a single source is seldom the sole cause of an air pollution problem. Also included in the table is the lifetime of each pollutant, which is the approximate period before the compound is chemically destroyed in the troposphere. Also listed is the spatial scale where the compound acts. Below, various pollutants are discussed in more detail, along with their effects and techniques used to measure the atmospheric concentration. Their role in particular air pollutant systems and atmospheric chemistry are delineated in later sections.

2.1.1 Formaldehyde, Benzene, and Other Organics. Organic gases are emitted by a variety of processes and, except for individual species detailed below, are of concern as a precursor to photochemical smog. Hundreds of organics have been identified in the atmosphere. Their role in forming ozone can be viewed as providing the energy and chemical pathways necessary to oxidize NO to NO_2. Hydrocarbons, which comprise a majority of the organics emitted, can be measured by gas

Table 1. Pollutant lifetimes, concentrations, and sources.

Pollutant	Atmospheric chemical lifetime	Scale of action[a]	Concentrations[b] rural/urban (ppb)	Major sources (as a pollutant)
Methane	7 yr	R, **G**	1600/2000	Swamps, rice paddies, animal digestive systems
Butane	4 d	**U**, R	1/10	Automobiles, solvents

[a] Letters refer to the scale of air pollutant system where species play a significant role: I, indoor; U, urban; R, regional; and G, global. The bold letter indicates scale where the compound is of particular interest.

[b] Approximate concentrations in rural areas and polluted urban areas affected by these pollutants. Many pollutants have strong diurnal and spatial variation.

[c] Long-lived species. Primary removal is not via chemical reaction.

[d] NO and NO_2 are in rapid steady state with ozone. Lifetime of the two combined in an urban atmosphere is about 8 h.

chromatography and flame ionization (Wellburn, 1988).

Formaldehyde is a major indoor pollutant because it is emitted by many building products. Outdoors, formaldehyde is formed by the oxidation of other organics. It photolyzes rapidly, leading to ozone formation. Formaldehyde is an eye irritant at low concentrations [~ 100 parts per 10^9 (ppb)]. Exposure to these levels would occur primarily indoors and very seldom outdoors in a polluted urban area. Formaldehyde also is a suspected carcinogen, though tests are not definitive. Benzene, which is a component of gasoline, is of concern because it is a carcinogen.

2.1.2 Nitrogen Oxides. Oxidized (or odd) nitrogen is a primary ingredient in photochemical smog and in the stratospheric ozone balance. Anthropogenic odd nitrogen is primarily emitted as nitric oxide (NO), which is oxidized in the atmosphere to NO_2, nitric acid (HNO_3), aerosol nitrate, nitrogen trioxide (NO_3), and dinitrogen peroxide (N_2O_5). Of these, NO and NO_2 (referred together as NO_x) are the most plentiful in urban atmospheres, followed by nitric acid and aerosol nitrate. Nitrous oxide, N_2O, is emitted biogenically by denitrification of other nitrogen compounds. It is relatively stable in the troposphere, and is a source of stratospheric odd nitrogen.

NO and NO_2 are measured by chemiluminescence with O_3. Nitric acid and aerosol nitrate are measured by collection on an absorbing medium followed by ion chromatography. NO_3, which is found at very low concentrations (part per trillion range) is measured spectroscopically.

NO is of concern as a pollutant because it is a precursor to NO_2, nitric acid, and ozone formation. NO_2 is an oxidant and can impair lung function, particularly in concert with other pollutants such as ozone. Nitric acid is a primary component of acid deposition, and is an irritant. Health impacts of aerosol nitrate, or individual components of most aerosols, are not well characterized. However, small particles can be respired easily into the lung, and be deposited there. Aerosol nitrate inhibits visibility and is one of the most abundant components causing the haze associated with Los Angeles smog.

2.1.3 Ozone and Other Photochemical Oxidants. Ozone is the highly reactive, triatomic form of oxygen, O_3. It is a strong oxidant, formed in the atmosphere by the combination of atomic oxygen with an oxygen molecule. In the troposphere, it is a primary constituent of photochemical smog, and the severity of photochemical air pollution episodes is often measured by the maximum ozone level reached (National Research Council, 1977). Ozone is a secondary compound, formed by reactions of organic gases and nitrogen oxides. Exposure to ozone impairs lung function and can cause pulmonary stress in humans. Recent studies have indicated that effects on humans are noted above 0.08 ppm. This can be compared to urban levels reaching maximum levels of 0.4 ppm. Ozone also attacks plants, inhibiting growth and increasing susceptibility to attack by pests. Ozone can also attack materials, such as rubber, causing premature aging and oxidation. As an indication of the attack of ozone on materials, a previous measurement technique relied on how rapidly a rubber band cracked from exposure. Currently, tropospheric ozone is measured by use of chemiluminescent reaction with ethylene.

In the stratosphere ozone is desirable. The depletion of stratospheric ozone by manmade pollutants is of concern because ozone shields the earth's surface from harmful UV radiation. Stratospheric ozone is measured by both ground-based and satellite-based spectroscopy systems. In this case, the absorption or emission of light is used to quantify the amount of ozone in a column of air.

Other photochemical oxidants include peroxyacetyl nitrate (PAN) and hydrogen peroxide (H_2O_2). These compounds are formed along with ozone by reactions of nitrogen oxides and organic gases. PAN is a phytotoxin and eye irritant. H_2O_2 is a strong aqueous phase oxidizing agent, converting SO_2 to sulfuric acid.

2.1.4 Acids and Sulfur Dioxide. Sulfuric and nitric acids are recognized as the two most abundant species contributing to acid deposition. Recent attention is also being given to organic acids. In addition to naturally occurring sulfuric acid, excess is formed from the oxidation of anthropogenic sulfur dioxide (SO_2) emissions. Natural sources of sulfur include volcanoes and biological emissions of carbonyl sulfide, carbon disulfide, hydrogen sulfide, and dimethyl sulfide. Nitric acid is a product of NO_x oxidation.

Atmospheric acids are blamed for acidification of lakes and streams in the northeastern United States, Canada, and Scandinavia. These areas are more susceptible to acidification than other areas because they are downwind of major SO_2 sources and they do not have the buffering capacity of other regions. Acidification of lakes and streams has led to dramatic decreases in game fish populations and, in some cases, eradication of the native ecosystem. Acid deposition has also been cited as a reason for forest decline and materials damage. Sulfur dioxide is a lung irritant. Health impacts appear to be exacerbated by the simultaneous exposure to ozone or particulates. Acid is probably a precursor to the compounds responsible for impaired health in London-type smog episodes. Atmospheric sulfuric acid is in a condensed phase, and can be measured by filtration followed by ion chromatography. SO_2 is measured by flame photometric and pulsed fluorescence.

2.1.5 Carbon Monoxide. Carbon monoxide (CO) is emitted by most sources burning fossil fuels. In urban areas, motor vehicles are the largest contributor. The most serious exposure of humans to CO, however, is cigarette smoking. Indoors, CO can result from automobile testing and repair, and from incomplete combustion of fuels in heaters, boilers, or cooking applications. Outdoors, CO builds up during stagnation episodes in large cities, and is particularly severe during the winter months around rush hour.

Carbon monoxide is absorbed into the blood stream, diminishing its ability to absorb oxygen, i.e., carbon monoxide poisoning. This results in fatigue, headache, and, at high levels (>600 ppm), convulsions and possibly death. CO is measured routinely by electrochemical techniques and infrared detection.

2.1.6 Chlorofluorocarbons. Chlorofluorocarbons (CFCs) are man-made compounds consisting of chlorine and fluorine atoms attached to hydrocarbon chains. Of these, Freon 11 and 12 (CCl_3F and CCl_2F_2) are the most well-known and most used. These compounds are very stable in the troposphere, and can migrate into the stratosphere. In the stratosphere, they photodissociate, releasing Cl atoms that lead to the enhanced destruction of ozone. They also absorb light in the infrared range and can lead to global warming.

2.1.7 Carbon Dioxide. A few years ago, carbon dioxide (CO_2) would not have been considered a serious pollutant. However, increased fossil fuel consumption for producing energy is leading to higher CO_2 concentrations, which in turn act to blanket the earth from losing heat, i.e., the "greenhouse effect." The threat of increasing world temperatures, coupled with desertification of major agricultural regions and flooding of coastal cities is of concern. Aside from global warming, ambient CO_2 buildup has no major health impact, and can enhance crop yields.

2.1.8 Aerosols. Atmospheric aerosol, also called particulate matter, is composed of many compounds, including sulfate, nitrate, organics, elemental carbon, metals, sea salt, and soil dust. The abundance of each component changes markedly with geographic location and time. Some aerosols are formed in the atmosphere by the condensation of gas phase species (e.g., sulfate, nitrate, and some organics), while others are emitted directly (e.g., soil dust and sea salt spray).

Health effects of aerosols are not well established, and will undoubtedly be closely linked to their composition. Small aerosol particles, about 0.1 to 3 μm, are easily respirable into the lung, intensifying their health impact. Some of the constituents of aerosols have been shown to be mutagenic and cancerogenic in animals. Atmospheric aerosol composition is usually measured by filtration followed by chromatography or spectroscopy.

2.1.9 Radioactive Contaminants. Radioactive air pollutants can be either anthropogenic or natural. Anthropogenic sources include accidental release from nuclear power plants and detonation of nuclear weapons. The recent Chernobyl, USSR, reactor accident is an example of such a release. Fallout from that accident has been measured across the northern hemisphere.

Radon, a natural, relatively short-lived radioactive gas, migrates through the soil and is emitted into the atmosphere or buildings. Products of radon decomposition, when inhaled, can lead to cancer. Radon is measured by alpha-track detectors, scintillation cells, and radiation detectors.

2.2 Spatial Scales of Air Pollutant Systems

Adverse impacts from the compounds discussed above can be identified on spatial scales from a few meters (e.g., indoors) to those encompassing the globe (1000s of km). In between are local, urban, and regional scale systems. At each scale, particular problems are of interest.

2.2.1 Indoor Air Pollutants. Because of their enclosed nature, indoor environments such as houses, office buildings, and garages can experience extremely elevated levels of many compounds. Examples of man-made indoor pollutants are formaldehyde, NO_x, and carbon monoxide. The most notorious natural indoor air pollutant is radon—a colorless, odorless, radioactive gas. It is ironic that the buildup of both anthropogenic and natural contaminants has been exacerbated by measures taken to reduce energy usage, which was motivated in part by environmental concern.

2.2.1.1 Indoor Anthropogenic Pollutants. Indoor sources of anthropogenic pollutants include the combustion of fossil fuel and the use of certain building materials. Cooking and heating lead to emissions of NO_x and CO. Aging building materials can give off formaldehyde.

Particle board and plywood, both common building materials, are formed using formaldehyde-based resins as adhesives. Also, urea-formaldehyde foam was once used as insulation. As these materials age, they emit formaldehyde. To a lesser extent, combustion of cigarettes and other consumer products may also emit formaldehyde.

Concentrations of formaldehyde (HCHO) in buildings can be greatly elevated above outdoor levels, even in heavily polluted urban areas. Peak levels of up to 4.8 ppm have been measured in mobile homes that used formaldehyde-based resins and insulation (National Research Council, 1981). Average levels are much lower: 0.4 ppm in houses that use formaldehyde foam insulation and 0.01 to 0.1 ppm in houses that do not (National Research Council, 1981). Peak levels in urban areas seldom exceed 0.05 ppm, and average levels are on the order of 0.01 ppm.

HCHO has been shown to cause cancer in rats, but not in similarly exposed mice, and carcinogenicity in humans has not been established. However, at the levels reached indoors, formaldehyde can cause eye irritation, headaches, nausea, fatigue, and thirst. This has led to what is termed the "sick house" syndrome. Reducing HCHO levels can be achieved by replacing the building materials with products that do not emit as much HCHO, by sealing existing walls, or by increasing ventilation either with outside air or with use of a filter that can remove HCHO. Also, new building materials have been developed to alleviate the sick house syndrome.

A second class of indoor anthropogenic pollutants is derived from combustion sources. Combustion in unvented gas appliances, wood burning, and smoking are the major sources of indoor CO and NO_x (Walsh *et al.*, 1984). Under extreme circumstances these sources can lead to indoor levels approaching short term standards. Wood burning can form polycyclic aromatic hydrocarbons (PAHs), such as benzo-(*a*)-pyrene, which are suspected carcinogens.

2.2.1.2 A Natural Indoor Air Pollutant: Radon. Radon is a colorless, odorless, gaseous decay product of radium. After formation, radon migrates through the soil and is emitted into the atmosphere and building basements. In the free atmosphere, it readily disperses and decays, and does not constitute a serious problem. However, in buildings without adequate ventilation, radon can build up to dangerously high levels.

Radon itself is not the direct actor. It further decays into radioactive polonium, which condenses out of the gas phase and attaches to small particles. These particles are easily respirable. Polonium further decays forming radioactive isotopes of lead, then bismuth, polonium again, then finally lead. The half lives of the first four radon progeny, also called "radon daughters," are less than one-half hour. Each decay of polonium is accompanied by the emission of an α particle. In the lung, this promotes cancer.

Radon levels in houses are highly variable, ranging from near zero to 2800 picocuries liter^{-1} (pCi/L) (Lafaviore, 1987). Concentrations above 4 pCi/L are considered hazardous. The reasons for the variability include location, building construction, and age. The large variability in building concentrations and the long times between exposure and the development of cancer lead to difficulty in identifying problem areas. Cracks in subterranean basement walls and floors can greatly increase radon migration into buildings. Control measures include sealing basement walls, increasing ventilation, and ventilation of contaminated air from below the building foundation.

2.2.2 Local Scale Air Pollution. Somewhere between the size of a typical house ($\sim$10 m) and cities (10s of km) lies a class of pollutant systems that are rather localized, impacting street canyons, sections of cities, and small towns. These systems are characterized by relatively concentrated releases of pollutants that have not had a chance to disperse over an area large enough to make their impact negligible. In most cases, the relatively short time involved in dispersion minimizes the role of chemical transformation. Examples of such incidences include inadvertent releases of noxious chemicals, the buildup of exhaust in street canyons, or the buildup of wood smoke in resort areas during the winter. Dynamics of CO and NO_x buildup in street canyons, and of particulates and wood smoke in mountain towns, are very similar to urban systems, though smaller and more concentrated. Concentrated releases of noxious chemicals pose a different type of threat, and are discussed here.

2.2.2.1 Release of Noxious and Toxic Chemicals. Locally high concentrations of noxious and, sometimes, toxic chemicals have resulted from inadvertent releases from storage or production facilities or during transport. Examples include ruptures of storage tanks and accidents involving railroad or truck transport. Contaminants emitted range widely, and include strong acids, bases, fertilizers, and oxidants—virtually any chemical used in processing. The effects are often intensified because the gas emitted is denser than air and tends to stay near the ground. An extreme example of the result of such releases is the Bhopal, India, disaster where methylisocyanate was released into the atmosphere, killing over 2000, and injuring thousands more. Methylisocyanate is an intermediate in the production of a pesticide. In Sarreto, Italy, an inadvertent release of organic gases was found to contain dioxin, an extremely potent toxin, requiring the evacuation of the area. Releases of toxic gases, such as acid, ammonia, and chlorine, also occur during transport.

2.2.3 Urban and Regional Scale Air Pollution. Urban (10s–100s of km) and regional (100s–1000s of km) scale air pollution systems are treated together here because the two are closely linked. The two systems can be characterized as having characteristic residence times on the order of one day to one week. Over this time, atmospheric transport, diffusion, chemical transformation, and deposition are all integral in determining the fate and impact of pollutant emissions. In many cases the pollutants with the greatest impacts are formed in the atmosphere from sources 10s to 100s of km away.

Three relatively distinct types of problems can be identified within this spatial range. "London smog" refers to the type of events that London has experienced for over 500 years, and is a result of particulate and SO_2 emissions. Photochemical air pollution is the type of smog associated with Los Angeles, CA, but also affects urban areas throughout the world. Recently, it has been recognized that the transport of these photochemical pollutants and their precursors impact regional scales. Acid deposition, often referred to as "acid rain," is a result of the deposition of sulfuric and nitric acid, which are products of atmospheric oxidation of emissions from fossil fuel burning.

2.2.3.1 "London Smog." London historically experiences extended periods of meteorological stagnation, inversion, and fog. The inversion, as discussed in Sec. 3, on pollutant transport, traps emissions near the ground. Over a period of a few days pollutants can build up to very high levels. In London, the buildup of the smoke with the fog (the origin of the term smog) and SO_2 led to periods of very dense hazes, a strong odor, and ultimately an increase in deaths. While the 1952 London episode that lasted four days is the most infamous, these events have been noted in London since the 13th century.

The toxic agent(s) directly responsible for the increased mortality rates in London and other areas has not been identified, though one can get a general sense of possible causes. SO_2 emissions are absorbed by the fog and, over the course of a few hours to days, can react. All the products of these reactions, and the mechanism involved, are not known. The presence of fog leads to products that would not be found (at least at such high levels) due to gas phase reactions of SO_2. Bisulfate, which is known to cause allergic reactions in some individuals, can be formed, though this is only one of a myriad of compounds produced by the aqueous phase reactions. Smoke may serve multiple roles in adding to the severity of the smog episodes. First, coal smoke contains metals which promote aqueous reactions of SO_2 products. Smoke and acid particles can also act as a condensation site for water vapor, enhancing fog formation. The fine particulate matter that makes up smoke is readily respirable and can irritate the lung, and the simultaneous presence of particulate matter increases irritation from SO_2 exposure. SO_2 exposure, even at levels below those found during severe smog events, can lead to lung impairment. CO would also be elevated during stagnations. It is possible that the increase in deaths is attributable to more than one agent acting in unison with others. Chronic exposure to London-type smog can also impact health. Prolonged exposure to smoke leading to blackening of the lungs has been cited as possibly accounting for 1 out of 20 deaths in early Britain (Brimblecombe, 1987). John Evelyn noted in 1661 that, of the children born in London, half died before the age of 2, while those living in the country could expect to live to 40. He blamed this on the "foul air."

Reducing the impact of London-type smog has been achieved by a variety of techniques. One of the first strategies was fuel-switching, which is still in practice today to fight not only smoke, but photochemical smog and SO_2. In the 13th century sea coal was recognized as producing excess smoke, and was banned. A second historical measure was to develop cleaner combustors with longer residence times to achieve more complete combustion. A third strategy was to build higher smokestacks in an attempt to disperse the smoke before the plume reached the ground. An obvious shortcoming with the latter maneuver was that it is, in essence, transporting the problem to someone else's backyard. It was found that during severe meteorological stagnation, the smoke did not make it very far. A final alternative was to relocate major sources. Early regulations, however, did not deal with the smoke from home heating.

Modern techniques to deal with London-type smog include refinements to those mentioned above, including building taller stacks and using natural gas or oil instead of coal. More efficient combustors were developed to reduce fuel consumption and emissions. Other measures used today include particle collection using cyclones, filters, and electrostatic precipitators. SO_2 is removed by scrubbing and coal cleaning. The theory behind these devices is discussed in Sec. 5.3.

2.2.3.2 Photochemical Smog: An Urban and Regional Phenomenon.

Urban Smog. In the mid-20th century, scientists noted injury to crops being grown downwind of Los Angeles, CA, and realized the injury was due to the air coming from the city. Haagen-Smit and co-workers went on to establish that this type of smog was different from the type found in London, and that the injury was due to gaseous oxidizing agents. Ozone and other oxidants were being formed by the interaction of reactive organic gases (ROG) and nitrogen oxides (NO_x) in the presence of sunlight. The products of these reactions were attacking the plants. Overall, the reaction can be summarized as

$$\mathrm{ROG} + \mathrm{NO}_x + \text{sunlight} + \text{time} \rightarrow \begin{cases} \mathrm{O_3},\ \mathrm{PAN},\ \mathrm{HCHO}, \\ \mathrm{HNO_3},\ \text{particulate matter} \\ \text{and other products.} \end{cases}$$

In addition to plant injury, the pollutants irritate the eyes and lungs and create the well-known haze. The haze is due to the particulate matter emitted directly by sources like diesel vehicles and to particles formed by the photochemical reactions. Unlike the London case, the haze is not a result of combining smoke and fog, though smog is still the most common term for it.

Photochemical smog is a soup of many gaseous and particulate compounds. The more prevalent pollutants include CO, ozone, SO_2, NO_2, NO, formaldehyde, other organics, peroxyacetyl nitrate (PAN), nitric acid, nitrous acid, soot, and particulate nitrates, sulfates, and ammonium (Watson *et al.*, 1985; Finlayson-Pitts and Pitts, 1987). Some of these pollutants are emitted directly, such as NO, CO, and SO_2, but many of the oxidants, acids, and oxygenated organics are formed primarily by gas phase reaction, which is explained in the section on atmospheric chemistry.

While photochemical air pollution is often associated with Los Angeles, virtually all major cities experience its effects. Reactive organic gases are emitted by a variety of sources including factories, solvent usage, and automobiles as well as by natural sources such as trees. Nitrogen oxides are emitted by virtually all combustion-powered devices, including automobiles, electricity generating facilities, and manufacturing plants. With sunlight, reactions proceed to form smog. Photochemical smog first being identified in Los Angeles is not surprising. The area is known for its sunlight and the large number of cars. In addition, Los Angeles experiences multiday periods of meteorological stagnation with a strong temperature inversion (as discussed in more detail in Sec. 3, stagnation is a period of minimal pollutant dilution). Smog precursors, in essence, react over multiple days to form high levels of ozone. As an

FIG. 1. Evolution of a photochemical smog episode. Photochemical smog intensifies over a number of days. On the first day (a), the inversion is relatively high, confining pollutant emissions to a relatively large mixing volume and allowing dispersion. Sunlight driven reactions form moderate levels of ozone. (Slightly less than 0.2 ppm is shown, but levels vary dramatically depending on location.) During the day the pollutants are relatively uniformly distributed throughout the mixing layer. At night (b), ground cooling forms a ground-based inversion and inhibits pollutant mixing. Pollutants emitted near the ground are trapped, and the ozone aloft is separated from fresh emissions and deposition, allowing the ozone to remain overnight. The next day (c), sunlight again drives chemical reactions, producing more ozone, and the ozone aloft mixes down, intensifying the problem. Also, the inversion depth can be lower, decreasing pollutant dispersion. These events lead to higher ozone levels. This process can repeat over multiple days.

indication of the time delay required for the reactions to occur, the highest ozone levels are seldom found on Sunday or Monday because of reduced emissions over the weekend. The evolution of photochemical episodes is shown schematically in Fig. 1, and the chemistry is discussed in Sec. 4.

Regional Ozone. Though at somewhat lower levels than in cities, elevated ozone concentrations are now found far downwind of cities. This is due to the transport of ozone and reactive nitrogen compounds such as NO_2 and PAN. Organic gas emissions, such as isoprene and monoterpenes from trees, react

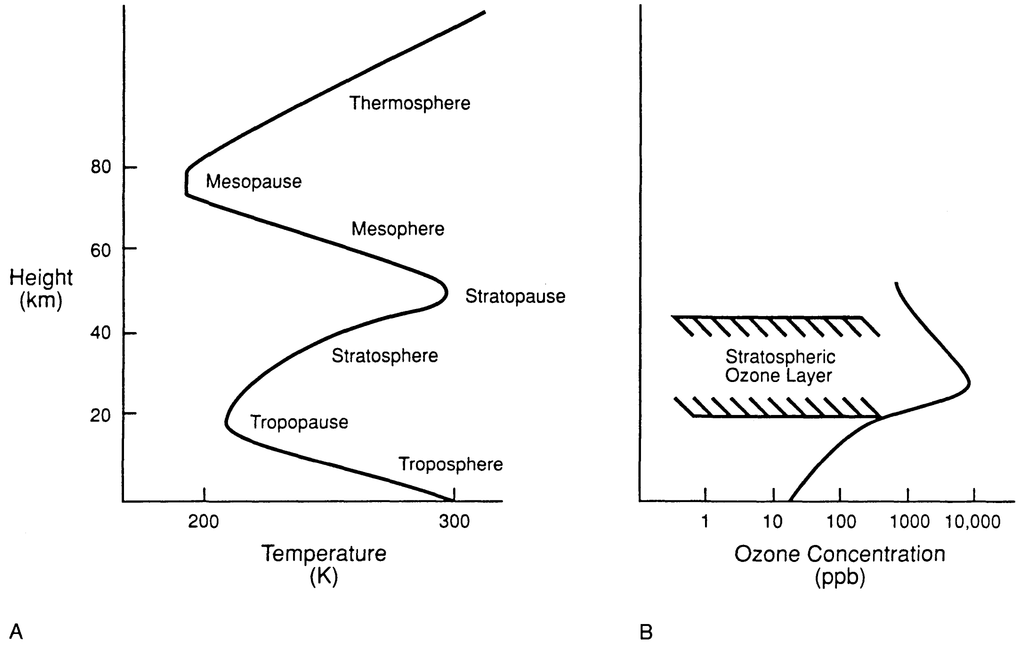

FIG. 2. Vertical (a) temperature and (b) ozone distributions in the atmosphere. Temperatures in the troposphere generally decrease with height, allowing for relatively rapid mixing. In the stratosphere, the temperature increases with height due to solar heating. This leads to a very stable atmosphere and slow transport. Ozone concentration peaks about 10 ppmv at 30–35 km. (Adapted from Anthes *et al.*, 1978; and Whitten and Prasad, 1985.)

in the presence of the nitrogen compounds to form ozone. Even though the pollutant levels are lower than in the cities, the persistence of ozone leads to forest decline as seen in the eastern United States, Canada, and Europe.

2.2.3.3 Acid Deposition. Acid deposition is the name given to the phenomena of the transfer of acidic components in the atmosphere to the earth. While commonly called "acid rain," that term is only half right. Much of the acid is deposited dry as sulfuric acid particles and nitric acid gas. While many areas are subject to acid deposition, eastern North America, China, Scandinavia, and Germany suffer the greatest impact. This is because those areas are downwind of large SO_2 and NO_x sources (e.g., power plants and shelters) and are least resilient to an acidic influx. These soils and water bodies have a smaller buffering capacity than other regions.

The increase in soil and water acidity upsets native ecosystems by the hydrogen ion stressing the biota and by leaching and mobilization of metals. This has resulted in dramatic declines in game fish populations and, in some cases, lakes dying. About 10 000 lakes in eastern Canada and 1000 in the northeastern United States have been acidified to the point that the endogenous fish population has been destroyed. Mobilization of the metals in the soils attacks plant life. Attempts have been made to reverse the trends by adding lime to the affected lakes. Long-term solutions rely on lowering emissions of SO_2 and NO_x in upwind areas.

2.2.4 Global Air Pollution. The 1970s and 80s witnessed a growing awareness of global atmospheric changes in response to man-made pollutants. It was recognized near the turn of the century that increased CO_2 could lead to a warmer earth. Our ability to identify and quantify the magnitude of those changes is an increasing concern. The second global threat is depletion of the stratospheric ozone layer (Fig. 2). The two problems are linked. Both are caused, at least in part, by chlorofluorocarbon emissions. Also, global tropospheric warming may increase stratospheric ozone depletion.

2.2.4.1 Global Warming. Atmospheric temperature is determined by a balance between incoming solar radiation and energy radiated by the earth's surface (Schneider,

FIG. 3. Radiative energy budget of the earth and atmosphere. Incoming solar radiative energy is approximately 175 W/m^2, and is balanced by energy reflected or emitted back into space. Approximately two-thirds of the incoming solar radiation is absorbed by the earth or atmosphere. Greenhouse warming occurs when the atmosphere absorbs radiant energy from the earth before the light can escape into space, and acts as a blanket. Trace cases, such as CO_2, increase the absorption by the atmosphere.

1989). The sun emits nearly blackbody radiation at a temperature of 6000 K, with most of the energy concentrated in the visible and near visible region. Only about 25% of the sunlight penetrates directly to the earth's surface and is absorbed. About 35% is reflected, 15% is absorbed in the atmosphere, and 25% is scattered by gas molecules and particles before being absorbed by the surface. Of the 50% absorbed, most is reradiated at an average temperature of 288 K, corresponding to light with wavelengths in the infrared range between 1 and 30 μm. Much of this energy (90%) is absorbed by water vapor, CO_2, and other trace gases in the atmosphere. This absorbed energy warms the atmosphere, and is reradiated both to space and back to the earth. This is shown, schematically, in Fig. 3. Energy being radiated from the earth's surface with wavelengths between 8 and 11 μm escapes most easily because H_2O and CO_2 do not absorb readily in this region. This region is referred to as the atmospheric window. The absorption of the earth's radiation by the atmosphere acts as a blanket and leads to an increased temperature of about 35 °C.

Increasing tropospheric concentrations of water vapor, CO_2, or gases that absorb infrared light (especially between 8 and 11 μm) would tend to increase the radiation blanket and tropospheric temperatures. Carbon dioxide was the first gas cited that might cause global warming. Industrialization has led to increased emissions of CO_2 because the necessary energy has required fossil fuel burning. A second contributor to CO_2 buildup may be deforestation. Trees metabolize CO_2 to oxygen and fixed carbon. CO_2 is also removed by oceanic absorption. Analysis of polar ice data and recent measurements indicate that atmospheric CO_2 has increased from 290 to 350 ppm since 1900.

Other gases, such as methane, N_2O, and CFCs, add to the greenhouse effect, though

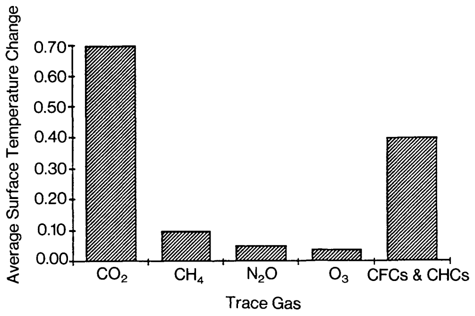

FIG. 4. Impact of trace gases on global warming. The increase in carbon dioxide is expected to be the largest contributor to global warming. Other trace gases combined equal CO_2, though the impact of the CFCs has a large uncertainty and may be much greater than shown here (modified from Ramanathan *et al.*, 1985).

they are found at much lower concentrations than H_2O and CO_2. They absorb light more efficiently at wavelengths other than the regions where CO_2 and H_2O operate, such as between 8 and 11 μm. This intensifies their effect, even though they are found at very low concentrations. Figure 4 shows the relative importance of various gases to the greenhouse effect as compared to CO_2 (Schneider, 1989).

It is at this time impossible to determine the outcome of increasing levels of CO_2 and other absorbing trace gases. The energy balance will certainly be perturbed, and the most advanced models predict an average warming of about 4 K corresponding to a doubling in CO_2. The change in temperature is expected to be greater near the poles, and some areas may see little change. The difficulty in predicting the actual outcome results from not fully understanding a variety of processes, such as how effectively the ocean will take up CO_2 and absorb heat, and how global warming will affect weather such as the formation of clouds and alteration of air currents. Increased cloud cover would reflect solar radiation which would lower the energy flux to the earth. Along with the increases in temperature, models predict changes in rainfall distribution and soil moisture.

Methane concentrations are rising faster than is currently explicable. Sources of the excess methane include termites and cultivation of rice paddies. A third possible cause cited for the rise is that its lifetime may be longer than has been estimated or there has been an increase in its atmospheric lifetime. Methane is removed from the troposphere by reacting with OH. The estimated lifetime, based on OH radical levels, is 7 yr, although it is less than 1 yr in the lower troposphere where OH radical levels are greater. If OH were being depleted by another compound, this could cause methane to build up.

Chlorofluorocarbons are used in spray cans (as a propellant), in refrigeration systems, for cleaning electronics instruments, and in production of polyurethane foams. In the early 1970s, the primary source was spray cans (Gribbin, 1988). Concern over ozone depletion reduced their use in spray cans, and now the major sources include plastic manufacture and automotive air conditioning systems (Fig. 5). While the emissions of CFCs from the most industrialized nations may decrease, emissions from developing nations are expected to offset these improvements.

N_2O is emitted by microbial activity, excess fertilizer use, and combustion. The importance of combustion as a major source of N_2O is being debated because emissions may be much less than assumed.

2.2.4.2 Ozone Depletion. Depletion of the stratospheric ozone layer over the Antarctic was first measured in the mid 1970s. By the early 1980s the loss was so large and so rapid that satellite measurements of the ozone were so low they were taken to be in error. In 1987, October ozone levels over the Antarctic fell to less than half of those found in 1974. This rapid loss of ozone has been found to be a result of catalytic cycles involving halogens that have slowly diffused into the lower stratosphere.

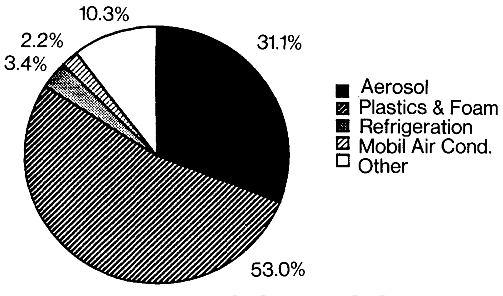

FIG. 5. Estimated use of CFC-11 and CFC-12 by product in 1984. Approximately 3.4×10^9 kg were produced by countries reporting to the Chemical Manufacturers Association.

Most rapid loss of stratospheric ozone is found over the Antarctic during its spring. This is a result of meteorological isolation of the stratosphere, cold temperatures, and the presence of chlorine and bromine atoms. Chlorine and bromine atoms promote the chemical destruction of ozone, as discussed in the section on stratospheric chemistry. The very cold temperatures allow the formation of polar stratospheric ice clouds (PSCs), which in turn provide a surface to enhance the production of reactive chlorine atoms. Meteorological isolation inhibits the transport of new ozone or warmer air to the ozone "hole" over the Antarctic. Similar dynamics can lead to ozone loss over the Arctic, but stratospheric temperatures are higher, decreasing the formation of PSCs.

Ozone loss over the mid latitudes is less pronounced than over the Antarctic because of the lack of PSCs, though a decreasing trend is noted. From 1979 to 1987, there was about a 2%–10% decrease in mid-latitude stratospheric ozone. There are uncertainties in the calculations of the response of the stratosphere to further chlorine input, but it is generally agreed that ozone levels will continue to decrease as more chlorine makes its way into the stratosphere. Increased absorption of light in the troposphere would decrease light transmission to the stratosphere. Thus, tropospheric warming could be accompanied by stratospheric cooling. A colder stratosphere would lead to increased PSC formation and faster ozone destruction. This links the greenhouse effect with ozone depletion.

The destructive chlorine comes from the slow diffusion of chlorofluorocarbons from the troposphere. These compounds are inert until they reach the stratosphere and the strong ultraviolet radiation breaks the molecules apart, releasing chlorine. There are few replacements for the many uses of CFCs, and their emissions will likely keep increasing (Fig. 5).

3. AIR POLLUTION METEOROLOGY AND POLLUTANT TRANSPORT

Air pollutants are transported in the atmosphere by advection, due to the bulk wind, and dispersion, which arises from atmospheric turbulence. Also associated with atmospheric transport is deposition, involving a complex series of interactions between the local turbulence structure of the atmosphere, physical surface characteristics, and the chemical capability of the surface to absorb pollutants. Along with chemical transformation, transport determines the ultimate fate and impact of pollutant emissions.

Pollutants, except for large particles, are effectively carried by local winds. In addition, pollutants are diffused vertically and, to a more limited extent, horizontally by turbulent dispersion. The region where vertical diffusion is rapid is called the mixed layer (or mixing layer) (Anthes *et al.*, 1978). The mixed layer is usually capped by a temperature inversion, described below. Atmospheric turbulence is caused by solar heating of the ground and mechanical generation by surface friction. Heating the ground leads to warm air generation at the surface. The warm air rises and is replaced by cooler air. Thermal mixing on a sunny day is generally greater than mechanically generated turbulence.

Air heated at the ground will continue to rise until it comes into equilibrium with the local atmospheric temperature. As it rises, it cools due to adiabatic expansion. This is shown in Fig. 6 and is called the adiabatic lapse rate. An atmosphere with a temperature structure that drops faster than adiabatically with altitude is unstable because a warm air parcel will continue to rise. Also, a cold air pocket will tend to fall. If the temperature rises with altitude faster than the adiabatic lapse rate, vertical exchange of air parcels is inhibited, and turbulent mixing is suppressed. This is referred to as a stable atmosphere. If the atmosphere cools vertically at the adiabatic lapse rate, it is called a neutral atmosphere.

During the morning and early afternoon of a sunny day, ground-level warming leads to an unstable atmosphere. The thermally generated turbulence rapidly disperses pollutants. If the vertical extent of the turbulent mixing is large, pollutants do not build up to very high levels. A feature commonly associated with urban air pollution is the development of a temperature inversion. In this case, the atmosphere at some height above the ground is stable, reducing vertical mixing and trapping pollutants near the ground. An inversion may develop due to heating of the atmosphere on previous days, or cloud cover

FIG. 6. An illustration of atmospheric stability. In a neutral atmosphere (a), the temperature decreases with height at the same rate that an air parcel cools due to adiabatic expansion. For example, a perfect balloon released from earth would expand as it rose because the pressure decreases with height. The expansion process leads to the gas cooling. Neutral atmospheres neither promote nor inhibit mixing. In a stable atmosphere (b), the temperature decrease with height is less than the adiabatic lapse rate. As an air parcel (or balloon) rises, it becomes colder and denser than the surrounding air and sinks back down. Conversely, if the temperature decreases faster than adiabatically (c), a rising air parcel remains warmer than the surrounding atmosphere and will continue to rise. This is an unstable atmosphere. As shown, the unstable atmosphere is capped by a region whose temperature starts to increase, or is "inverted." This region is called an inversion and is very stable, capping the dispersion of pollutants below.

that absorbs sunlight and insulates the surface from heating. Inversions may start at the ground or up to a few kilometers above. When accompanied by low wind speed, pollutant dilution is minimal, and over a period of days leads to smog episodes such as found in Los Angeles and London. Periods of light winds and strong inversion are called stagnation episodes. Low dilution can be limited to a relatively small area such as mountains, valleys, or urban basins, or may encompass large regions.

Transport of pollutants between the troposphere and stratosphere is slow because of the stability of the air above the troposphere (Fig. 2). Transport within the stratosphere is also reduced for this reason. Pollutants emitted at the surface take several years to reach the stratosphere. Except for the most stable compounds, chemical reaction and deposition (by rain-out or dry deposition) remove the pollutants before they pass through the troposphere. Because the transport to the stratosphere and deposition is so slow, virtually all the CFCs emitted are still present in the troposphere. Ozone depletion is a result of the small fraction that has passed to the lower levels of the stratosphere.

Deposition is the ultimate fate of the material emitted into the air. It is a two-part process. First, the compound is transported to a surface. Then the compound interacts chemically. Pollutants that are highly reactive, such as nitric acid, deposit rapidly. Less reactive pollutants deposit more slowly, allowing those compounds to be transported much further. In the case of ozone, this increases the extent of the exposure from urban to rural regions. Extremely unreactive compounds such as CO_2, methane, and CFCs can have very long lifetimes and build up across the globe. Deposition can be enhanced by rain and cloud droplets scavenging pollutants and then falling to earth.

4. ATMOSPHERIC CHEMISTRY

Smog, acid deposition, and stratospheric ozone depletion are a result of atmospheric chemical reactions. Primary pollutants react to alter the chemical composition of the air. These reactions may occur homogeneously in the gas or liquid phase, or heterogeneously, involving transport of gaseous pollutants to or from droplets and ice particles. This section shows how pollutants chemically evolve in the troposphere and the chemistry leading to ozone depletion.

4.1 Tropospheric Chemistry

4.1.1 Urban Photochemistry. There are two systems involved in the production of ozone and other photochemical oxidants. First is the photolytic cycle forming ozone, and the second is the oxidation of organics, leading to enhanced formation of NO_2. The two are tightly linked by the production and cycling of highly reactive radical species.

The single reaction responsible for virtually all ozone formation in the lower troposphere is the photolysis of NO_2 (see Finlayson-Pitts and Pitts, 1987):

$$NO_2 + h\nu \xrightarrow{k_1} NO + O^\bullet, \qquad \text{(R1)}$$

where $h\nu$ represents energy derived by interaction with photons from the sun. $O^\bullet$, a radical oxygen atom, rapidly reacts with molecular oxygen to form ozone,

$$O^\bullet + O_2 \xrightarrow{k_2} O_3. \qquad \text{(R2)}$$

The two reactions can be combined, giving

$$NO_2 + O_2 + h\nu \rightarrow NO + O_3.$$

The ozone can then react with NO,

$$NO + O_3 \xrightarrow{k_3} NO_2 + O_2. \qquad \text{(R3)}$$

These three reactions are the photolytic cycle, and summing leads to no net production of ozone. The amount of ozone predicted to be present due to these reactions alone is given by

$$[O_3] = \frac{k_1[NO_2]}{k_3[NO]}.$$

Approximately 95% of the NO_x is emitted as NO, and 5% as NO_2. Using this, and values of 0.007 s^{-1} and 0.5 s^{-1} for the reaction rates k_1 and k_3, respectively, leads to a predicted ozone concentration of 7×10^{-4} ppm—three orders of magnitude less than is observed.

Reactions of organic gases provide the necessary components to produce the ozone. For example, formaldehyde (and other aldehydes) readily photolyze in sunlight:

$$HCHO + h\nu \rightarrow CO + 2HO_2, \qquad \text{(R4)}$$

$$CH_3CHO + h\nu \rightarrow CH_3^\bullet + HCO^\bullet, \qquad \text{(R5)}$$

(oxygen molecules are in relative abundance, and their consumption in reactions often is not shown for brevity). The $CH_3^\bullet$ and $HCO^\bullet$ further decompose in the presence of oxygen and NO:

$$CH_3^\bullet + 2O_2 + NO \rightarrow NO_2 + HCHO + HO_2^\bullet, \qquad \text{(R6)}$$

$$HCO^\bullet + O_2 \rightarrow HO_2^\bullet + CO, \qquad \text{(R7)}$$

where reaction (R6) is the condensation of multiple reactions. The HO_2 produced will oxidize NO to NO_2:

$$NO + HO_2^\bullet \rightarrow NO_2 + OH^\bullet. \qquad \text{(R8)}$$

The NO_2 produced is then available to form ozone. Summing up reactions (R4) and (R8), and reactions (R5)–(R8) gives (neglecting oxygen molecules)

$$HCHO + h\nu + 2NO \rightarrow CO + 2NO_2 + 2OH^\bullet,$$

$$CH_3CHO + h\nu + 5NO \rightarrow 2CO + 5NO_2 + 4OH^\bullet,$$

and repeating reaction (R1)+(R2),

$$NO_2 + h\nu \rightarrow O_3 + NO.$$

Thus, the photolysis of one molecule of acetaldehyde, by this scheme, could produce five extra ozone molecules. There are, however, insufficient quantities of aldehyde emissions to form appreciable amounts of ozone, and most urban organic gases, such as alkanes and aromatics, do not photolyze. Additional chemistry is needed to overcome the shortfall.

In the late 1960s it was discovered that similar to combustion systems, hydroxyl radical attack accelerates the oxidation of organic gases such as alkanes and, simultaneously, the production of ozone. The photochemistry of propane ($CH_3CH_2CH_3$) provides a useful example:

$$CH_3CH_2CH_3+OH^\bullet \rightarrow CH_3CHCH_3+H_2O, \quad \text{(R9a)}$$

$$CH_3CHCH_3+O_2 \rightarrow CH_3CH(O_2^\bullet)CH_3 \text{ (peroxyalkyl radical)}, \quad \text{(R9b)}$$

$$CH_3CH(O_2^\bullet)CH_3+NO \rightarrow NO_2+CH_3CH(O^\bullet)CH_3 \text{ (alkyl radical)}, \quad \text{(R9c)}$$

$$CH_3CH(O^\bullet)CH_3+O_2 \rightarrow CH_3C(O)CH_3 \text{ (acetone)}+HO_2^\bullet; \quad \text{(R9d)}$$

the net reaction can be written as

$$CH_3CH_2CH_3+OH^\bullet+NO+2O_2 \rightarrow CH_3C(O)CH_3+NO_2+H_2O+HO_2^\bullet. \quad \text{(R9e)}$$

The OH is regenerated by reaction (R8). A net of two NO to NO_2 oxidations take place. The acetone produced further participates in photochemical reactions, increasing the oxidation rate of NO to NO_2 and, ultimately, ozone formation. The cycle can be summarized, rather simply, as

$$ROG+NO_x+h\nu+\text{time} \rightarrow O_3.$$

The $OH^\bullet$ is not shown because it is cycled to its original form. It is, however, quite necessary for the production of ozone.

The hydroxyl radical needed to initiate the chemistry above is formed in the atmosphere by reaction (R8), the photolysis of ozone, and the dissociation of nitrous acid:

$$O_3+h\nu \rightarrow O_2+O^\bullet(^1D) \text{ ("O singlet D" radical)}, \quad \text{(R10a)}$$

$$O^\bullet(^1D)+H_2O \rightarrow 2OH^\bullet, \quad \text{(R10b)}$$

$$HONO+h\nu \rightarrow OH^\bullet+NO. \quad \text{(R11)}$$

These reactions, along with reaction (R1), show the necessary role that sunlight plays, providing the critical energy to initiate the reaction sequence.

Nitric acid, peroxyacetyl nitrate, hydrogen peroxide (H_2O_2), and formaldehyde are also major products of photochemical reactions. Nitric acid is formed by daytime and nighttime mechanisms. During daylight, hydroxyl radicals oxidize NO_2:

$$NO_2+OH^\bullet \rightarrow HNO_3. \quad \text{(R12)}$$

This is an important sink for both NO_x and hydroxyl radical. Very high levels of NO_x tend to slow the photochemical system by absorbing OH radical. At night, NO_2 and ozone combine to form NO_3, which further reacts with another NO_2 molecule:

$$NO_2+O_3 \rightarrow NO_3+O_2, \quad \text{(R13)}$$

$$NO_3+NO_2 \rightarrow N_2O_5. \quad \text{(R14)}$$

During the daylight hours NO_3 photolyzes and reacts rapidly with NO. The N_2O_5 then hydrolyzes (either by homogeneous, gas phase reaction or on the surface of a particle):

$$N_2O_5+H_2O \rightarrow 2HNO_3. \quad \text{(R15)}$$

PAN and other organic nitrates are produced by peroxyalkyl and alkyl radical reactions with NO and NO_2; for example,

$$RCO_3+NO_2 \rightarrow PAN, \quad \text{(R16)}$$

$$RO_2+NO \rightarrow RNO_3, \quad \text{(R17)}$$

where R is a general alkyl group (e.g., CH_3CH_2–). Hydrogen peroxide is formed by the self-reaction of HO_2 radical:

$$HO_2^\bullet+HO_2^\bullet \rightarrow H_2O_2, \quad \text{(R18)}$$

acting as a radical sink from the system. While photochemical reactions do produce high levels of harmful pollutants, it should be recognized that they also cleanse the atmosphere from the buildup of NO_x, CO, and hydrocarbons.

4.1.2 Regional Gas Phase Photochemistry and Acid Formation. The most notable differences between urban and regional photochemistry are the importance of slower reactions in regional chemistry, the increased concentrations of natural pollutants (e.g., isoprene and other organics), and the relatively lower levels of pollutants, especially NO_x (see Table 1). NO_x and organics provide the fuel to drive the photochemistry and the hydroxyl radical still sustains the reactions. The hydroxyl radical is also responsible for the formation of atmospheric acids (Table 2). It was shown above that NO_x is required to cycle $HO_2^\bullet$ to $OH^\bullet$, and to photolyze to form ozone. In rural atmospheres, NO_x is found at levels two to three orders of magnitude less than in urban areas. This leads to rural environments being NO_x-limited, and to increases in oxi-

Table 2. Reaction pathways forming acids over regional scales.

Net $SO_2+OH \rightarrow H_2SO_4+HO_2$	
Aqueous phase	
$SO_2+H_2O \leftrightharpoons HSO_3^-+H^+$	(R22a)
$HSO_3^-+H_2O_2 \rightarrow SO_4^{2-}+H^++H_2O$	(R22b)
Net $SO_2+H_2O_2 \rightarrow SO_4^{2-}+2H^+$	
Organic acids	
$HCHO+HO_2 \rightarrow OOCH_2OH$	
$OOCH_2OH+NO \rightarrow OCH_2OH+NO_2$	
$OCH_2OH+O_2 \rightarrow HO_2+HCOOH$ (formic acid)	

dized radicals such as $HO_2^\bullet$ and $RO_2^\bullet$ (i.e., general peroxyalkyl radicals formed by the oxidation organics such as propane shown above).

The buildup of HO_2 and RO_2 leads to the increased formation of hydrogen peroxide [reaction (R18)] and organic peroxides:

$$RO_2+HO_2^\bullet \rightarrow ROOH \text{ (general organic peroxide)}, \qquad \text{(R19)}$$

both of which are strong aqueous oxidants and act to convert SO_2 to sulfuric acid in cloud, rain, and fog droplets.

On a regional scale, the ozone present is due to formation from local emissions and the transport of ozone and its precursors from urban and industrial sources. Ozone can be transported hundreds of miles (Finlayson-Pitts and Pitts, 1987). NO_x from mobile sources, power plants, and other combustion processes is also transported, but is rapidly transformed into nitric acid by reactions (R12) and (R14). The nitric acid produced reacts readily with terrestrial surfaces and deposits out of the photochemical system.

The transport of NO_x into rural atmospheres can be facilitated by PAN. PAN is relatively stable in colder atmospheres, and is not depleted by hydroxyl radical attack. PAN acts as a reservoir of NO_x, releasing NO_2 as local concentrations drop:

$$CH_3CO_3NO_2 \overset{\text{(PAN)}}{\rightleftarrows} CH_3CO_3^\bullet+NO_2. \qquad \text{(R20)}$$

Many organics have significantly longer lifetimes than NO_x, and are transported with less loss (Table 1). Combined with local, natural emissions of isoprene and monoterpenes, and the ubiquitous presence of methane, rural atmospheres have a relative abundance of organic gases compared to NO_x (often characterized as having a high ROG/NO_x ratio). The oxidation of methane and isoterpene also is preceded by $OH^\bullet$ radical attack, forming radical intermediates that transform NO to NO_2. They may both be precursors to forming acid.

Sulfur dioxide reacts with the hydroxyl radical, in the gas phase, to form sulfuric acid [reaction (R21), Table 2]. This is a major pathway for the conversion of anthropogenic SO_2 emissions to sulfuric acid (Schwartz, 1989).

4.1.3 Regional Aqueous Phase Chemistry. Unlike urban photochemical episodes which thrive on sunlight, regional scale chemical systems can be enhanced by the presence of cloud droplets and fog providing alternative, faster paths for producing acids. In conjunction with gas phase photochemistry, these droplets act as tiny chemical reactors.

Sulfuric acid is produced by the oxidation of sulfur dioxide with H_2O_2, as follows. First, SO_2 gas is absorbed into the cloud or fog droplet, where it is at equilibrium:

$$SO_2(g) \rightarrow SO_2(aq) \overset{H_2O}{\rightleftarrows} HSO_3^-+H^+. \qquad \text{(R22)}$$

The HSO_3^- is oxidized to sulfuric acid by hydrogen peroxide, H_2O_2 [Table 2, reaction (R22)]. The necessary H_2O_2 is formed by gas phase photochemistry. Implicit in the reactions is the transport of the gas phase species to the droplet surface (Schwartz, 1989).

4.2 Stratospheric Chemistry

Stratospheric chemistry is significantly different from the photochemistry of the troposphere because of the flux of very high energy ultraviolet light ($\lambda < 400$ nm). Molecules in the stratosphere absorb this energy, allowing relatively little to pass to the troposphere. This does two things. First, it protects surface life from damaging sunlight, and second, it drives the photochemistry of the stratosphere.

When exposed to UV light below 190 nm, oxygen molecules photodissociate into oxygen atoms, forming ozone (Gribbin, 1988; McElroy and Salawitch, 1989)

$$O_2 + h\nu\ (\lambda < 190\ \text{nm}) \rightarrow O^\bullet + O^\bullet, \qquad \text{(R23)}$$

$$O^\bullet + O_2 + M \rightarrow O_3 + M, \qquad \text{(R24)}$$

where M is a third molecule that absorbs energy, allowing the newly formed ozone molecule to be energetically more stable. This also has the effect of heating the third-body molecules, and the stratosphere itself. The ozone, in turn, photolyzes by absorbing light between 230 and 350 nm:

$$O_3 + h\nu\ (230 < \lambda < 350\ \text{nm}) \rightarrow O_2 + O^\bullet. \qquad \text{(R10)}$$

This reaction absorbs most of the incoming solar radiation between 230 and 290 nm, and shields the earth's surface. The oxygen atom can then recombine with an oxygen molecule via reaction (R24), or with O_3:

$$O^\bullet + O_3 \rightarrow 2O_2. \qquad \text{(R25)}$$

Stratospheric NO is found in very trace quantities and can act catalytically to destroy ozone:

$$\begin{array}{ll} NO + O_3 & \rightarrow NO_2 + O_2, \qquad \text{(R3)} \\ NO_2 + O^\bullet & \rightarrow NO + O_2 \\ \hline \text{Net } O_3 + O^\bullet & \rightarrow 2O_2. \end{array} \qquad \text{(R26)}$$

These reactions lead to a dynamic equilibrium level of ozone that responds to the influx of radiation and NO_x level in the stratosphere. Solar activity has been shown to perturb ozone concentrations in the stratosphere.

Chlorofluorocarbons (CFCs) perturb the chemistry of the stratosphere and deplete the ozone layer by adding three more routes for the catalytic destruction of ozone. CFCs, which are inert in the troposphere, slowly diffuse into the stratosphere. In the presence of high levels of UV they dissociate, releasing chlorine:

$$CF_2Cl_2 + h\nu \rightarrow CF_2Cl + Cl^\bullet. \qquad \text{(R27)}$$

(Upon further reaction a second chlorine atom is released.) The chlorine then reacts with ozone:

$$\begin{array}{ll} 2(Cl^\bullet + O_3 & \rightarrow ClO^\bullet + O_2) \\ ClO^\bullet + ClO^\bullet & \rightarrow Cl_2O_2 \\ Cl_2O_2 + h\nu & \rightarrow Cl^\bullet + ClOO^\bullet \\ ClOO^\bullet & \rightarrow Cl^\bullet + O_2 \\ \hline \text{Net } 2O_3 & \rightarrow 3O_2. \end{array} \qquad \text{(R28)}$$

The second cycle has a similar outcome:

$$\begin{array}{ll} Cl^\bullet + O_3 & \rightarrow ClO^\bullet + O_2 \\ OH^\bullet + O_3 & \rightarrow HO_2^\bullet + O_2 \\ ClO^\bullet + HO_2^\bullet & \rightarrow HOCl + O_2 \\ HOCl + h\nu & \rightarrow OH^\bullet + Cl^\bullet \\ \hline \text{Net } 2O_3 & \rightarrow 3O_2. \end{array} \qquad \text{(R29)}$$

A third destructive cycle involves bromine and chlorine:

$$\begin{array}{ll} Cl^\bullet + O_3 & \rightarrow ClO^\bullet + O_2 \\ Br^\bullet + O_3 & \rightarrow BrO^\bullet + O_2 \\ BrO^\bullet + ClO^\bullet & \rightarrow Br^\bullet + Cl^\bullet + O_2 \\ \hline \text{Net } 2O_3 & \rightarrow 3O_2. \end{array} \qquad \text{(R30)}$$

Each of these cycles destroys two ozone molecules. The chlorine can be recycled thousands of times before being stabilized as HCl and chlorine nitrate. These reactions, as written, are homogeneous, gas phase reactions that can lead to ozone loss throughout the stratosphere. Heterogeneous reactions assist the more rapid depletion of ozone over the Antarctic by increasing the availability of free chlorine.

Reactions which proceed negligibly slowly in the gas phase can occur rapidly in the presence of an ice surface or in aqueous solution. During the austral winter, extensive ice clouds (polar stratospheric clouds, PSCs) form in the stratosphere over the Antarctic, providing a heterogeneous system. For example, two reactions releasing chlorine are

$$ClONO_2(\text{surface}) + HCl(\text{solid solution}) \rightarrow Cl_2(\text{gas}) + HNO_3(\text{surface}) \qquad \text{(R31)}$$

and

$$ClONO_2(\text{surface})H + H_2O(\text{ice}) \rightarrow HOCl(\text{gas}) + HNO_3(\text{surface}). \quad (R32)$$

Besides releasing chlorine, these reactions also trap nitric acid. Nitric acid scavenges OH, slowing reaction (R12), and the NO_x released by that reaction binds free chlorine as $ClONO_2$. The heterogeneous reactions then drive the depletion of O_3 from the Antarctic stratosphere more rapidly than is found over the rest of the globe.

At the time of this writing (1989), the relative importance of the reaction paths is being debated, and heterogeneous mechanisms are still being explored. There is general agreement that CFCs are primarily responsible for ozone depletion and that polar ice clouds accelerate depletion.

5. AIR POLLUTION CONTROL

Air pollution control is a three-step process. First, the acceptable air quality levels are stipulated via regulatory action. Then, source(s) of the pollutant emissions must be identified, along with how they affect air quality, i.e., developing source-to-air-quality relationships. Next, means for controlling those emissions are identified. Often, more than one type of control device might be suitable and more than one source may be responsible; so, finally, a strategy (or strategies) for implementing controls is constructed. It is desirable to compare the competing strategies and control alternatives in order to derive an optimal control strategy. Optimal may refer to least cost, greatest air quality improvement, highest probability for success, or more likely some combination of the three criteria.

5.1 Air Quality Regulations

Most developed countries have addressed problems of deteriorating air quality within their boundaries by setting air quality standards, emission standards, or both. An air quality standard mandates attaining a prescribed level of atmospheric cleanness, i.e., pollutant concentrations are to be at or below a specified level. An emission standard differs in that the mass (or volume) efflux from a source is limited to be below a specified value, or a certain type of control must be used. Often, the different approaches are not used independently, i.e., only those areas that do not meet air-quality-based standards are subjected to emission-control-based requirements.

Royal proclamations in England during the 13th century were some of the earliest regulatory actions to improve air quality (Brimblecombe, 1984). These edicts limited the use of imported "sea" coal which burned less cleanly than wood or charcoal. Later edicts and commentaries from the residents of London indicate that those actions were not entirely effective. The problem intensified through the years, and further measures were taken with varying results. Finally, the Great Fog of 1952 led to Britain's Clean Air Act of 1956 bringing about emission reductions and averting future events of similar magnitude. A notable aspect of the act was control of emissions from personal residences.

Air pollution control in the United States developed initially through local ordinances limiting smoke emissions (Bibbero and Young, 1974; Stern *et al.*, 1984). However, local control of air pollution in a mobile society did not prove entirely effective, and federal action was taken with the Clean Air Act of 1963, revisions to the act in 1970 and 1977, and the establishment of the Environmental Protection Agency (EPA). The amendments established national air quality standards and emission levels from certain sources, most notably automobiles. Canada similarly passed a Clean Air Act, setting ambient concentration standards for pollutants. Air quality standards for a variety of pollutants in a number of countries are listed in Table 3. Meeting the standards listed, however, has in many cases proved politically infeasible, and economic growth has been chosen over compliance.

In addition to air quality standards, the United States also set emission standards affecting all motor vehicles. Increasingly stringent standards call for decreasing emissions of reactive organic gases (ROG), CO, NO_x, and particulate matter. These regulations have forced the development of more efficient automotive emission controls and the use of catalysts on cars sold in the United States. In Europe, use of the same catalysts would require cooperation by the countries to provide un-

Table 3. Sample air quality standards and recommendations in several countries. Times given in parentheses are averaging periods.

	Pollutant standard (μg m^{-3})			
Country	CO	NO_x	O_3	SO_2
Austria	38 900 (1 h)			500 ($\frac{1}{2}$ h)
Canada	35 000 (1 h)	400 (NO_2) (1 h)	160 (oxidant) (1 h)	900 (1 h)
Japan	23 000 (8 h)	100 (24 h)	110 (1 h)	
USSR	3000 ($\frac{1}{2}$ h)	85 ($\frac{1}{2}$ h)		500 ($\frac{1}{2}$ h)
United States	40 000 (1 h)	100 (1 yr)	235 (1 h)	365 (24 h)

leaded fuel, or the devices would become ineffective. Instead, the European Council of Environmental Ministers has set vehicle emission limits that can be met without NO_x-reduction catalysts.

Pollutant problems that involve transboundary transport of contaminants have been difficult to deal with from a regulatory basis. In a few instances, countries have taken action against or in concert with polluting neighbors. In response to acid deposition, many European countries and Canada banded to form the "30% club," committing themselves to reduce SO_2 emissions 30% from 1980 levels by 1993 (O'Riordan, 1989). A similar agreement, the 1987 Montreal Protocol, calls for a reduction in CFC emissions, and was ratified by over 40 nations. This action was prompted in an attempt to slow down stratospheric ozone depletion. While this treaty does curb the increasing use of CFCs in signatory countries, it is not expected to return the stratospheric ozone to pre-1970 levels; and increased CFC use by developing nations is expected to overwhelm the reductions by those signing the agreement. Further international cooperation is needed to address both stratospheric ozone loss and acid deposition, though the mechanism for such action is uncertain.

5.2 Determining Source–Air-Quality Relationships

Three means are available for determining source-to-air-quality relationships. Field studies are the traditional means and have lately been supported or supplanted by mathematical and physical modeling. Currently, two or three of the techniques usually are used together. Field studies to establish source impacts can use tracers, either tagging a component of the pollutant emissions or emitting the tracer along with pollutants. Perturbing source emissions, chemical fingerprinting, and mass balance techniques have been employed effectively.

One of the most direct ways to establish the impact that a source has on air quality is to remove the source and see what results. However, this is seldom viable. A less drastic approach is to perturb the emissions and follow how the pollutant concentrations respond. Often this can be accomplished passively, as sources such as manufacturing facilities, shelters, and power plants vary emissions due to demand changes. However, changes in meteorological conditions can inhibit detailed source-impact reconciliation.

Many sources typically emit a well characterized assortment of pollutants that can be peculiar to a single type of activity. For example, particulate emissions from an oil-fired boiler contain about 7% vanadium, 6% iron, 5% sodium, 2% nickel, and trace amounts of many other metals. This composition acts as a fingerprint of oil-fired boilers, and if a particulate matter sample is rich in these elements in the same proportions, then the culprit (or one of the culprits) has been identified. When used with regression-type mathematical models, this is a powerful method for quantifying the contribution of sources to air pollutant concentrations. This method is detailed below.

Physical models simulate atmospheric processes with a scaled-down representation of the atmosphere in a laboratory setting. Wind tunnels and scale models of city structures are used to study pollutant transport through street canyons and around buildings. A second physical model is a smog chamber used to study atmospheric chemistry. Reactive gases, such as NO_x and organics, injected into glass chambers and large Teflon bags are exposed to natural sunlight or man-made light. The radiation then drives the chemistry, and the evolution of the pollutants is followed. Because of the use of confined volume, physical models are limited in application.

Currently, mathematical models are the most powerful tool available to establish source-to-air-quality relationships. They can embody our knowledge of the details of atmospheric transport and chemistry and integrate this knowledge into a structured framework. The primary limitations of mathematical models are the knowledge of atmospheric physics and chemistry, and the ability to describe the processes mathematically. Mathematical models are of one of two types: empirical/statistical or deterministic. Empirical models are based on establishing a statistical relationship between previous air quality and the corresponding emissions. Their predictive power is based on the assumption that future air quality will depend on the same set of relationships. This limits their utility to linear processes. One of the more powerful classes of empirical models is receptor-oriented models. By using the chemical fingerprint of source emissions, statistical regression is used to estimate the contribution of a variety of sources. Empirical models have been used very effectively to establish sources of particulate matter using the characteristic fingerprints, as well as nonreactive pollutants such as CO.

Deterministic models describe in a fundamental manner the individual processes that affect the evolution of pollutant concentrations. These models are based on solving the atmospheric diffusion/reaction equation (Seinfeld, 1987):

$$\frac{dc_i}{dt}+\mathbf{U}\cdot\nabla c_i=\nabla\cdot D_i\nabla c_i+R_i(c_1,c_2,c_3,\ldots,c_n)+S_i(\mathbf{x},t),\quad i=1,2,3,\ldots,n, \tag{1}$$

where c_i is the concentration of species i; $\mathbf{U}$ is the instantaneous wind velocity vector; D_i is the scalar molecular diffusivity corresponding to species i; R_i is the net production (depletion if negative) of species i by chemical reaction; S_i is the source rate of species i; and n is the number of species. In essence, this equation states that the time rate of change of pollutant (term 1) depends on convection (term 2), diffusion (3), reaction (4), and emissions (5). Turbulence, which occurs at time and spatial scales smaller than the local scale of the model, is often parametrized by an increased diffusivity rate K, replacing D. Except for the simplest source terms, reaction schemes, and turbulent diffusivity distributions (S, R, and K), there are no analytical solutions to Eq. (1), and the equation is solved computationally.

Within this framework, the ability to characterize accurately the evolution of pollutants is limited by the understanding of the physical processes, especially chemistry and pollutant deposition, and accurate specification of input data. In practice, these models require more data than is commonly available, and gaps must be approximated. For example, the models use wind fields specified at all points within the modeling domain, but the measurements seldom exist in such detail. A second, more fundamental limitation is that the models use volume- and time-averaged quantities, but measurements are point values.

Deterministic models have been used for characterizing and understanding pollutant evolution at all scales. As the scale and complexity of the system increases, computational limitations become a factor and the models are often simplified. This has been utilized in modeling global geochemistry as applied to ozone depletion where either the

Table 4. Commonly used control devices.

Source	Pollutant	Control Devices
Automobile	CO, ROG	Oxidation catalyst, alternative fuel
	ROG	Fuel blending
	NO_x	Exhaust gas recirculation (EGR), reduction catalyst
Diesel truck	Particulate matter	Alternative fuel, particulate trap
Stationary boilers and heaters	SO_2	Scrubber, fuel cleaning, alternate fuel
(e.g., power plants)	Particulate matter	Electrostatic precipitation (ESP), filter, cyclone separations
	NO_x	Ammonia injection with/without catalyst, staged combustion
Stationary internal combustion engines	NO_x	EGR, catalyst
Organic gas venting (e.g., coke production, petrochemical processing, waste disposal)	ROG	Afterburners, catalysts
Metallurgical operations	Particulate matter	Cyclone, ESP, filter
	CO, ROG	Flare/afterburner

ROG=reactive organic gases
NO_x=nitrogen oxides
CO=carbon monoxide
SO_2=sulfur dioxide

chemistry is simplified or a one-dimensional model (vertical column) is used. Exercising these models with varying inputs can establish the impact of source emissions on air quality, deposition of acids and oxidants, global warming, and stratospheric ozone. At present, greatest use has been made for modeling local and urban areas. The ability to model global chemistry and transport accurately is still being improved.

5.3 Control Devices

Emissions can be controlled by three means: removing the source (or at least decreasing its use), lowering the emissions via a device to alter emission characteristics, or moving the point of emission. Common control devices are listed in Table 4.

Many control devices are aimed at reducing pollutant mass flux. For combustion devices, controls include fuel switching, fuel cleaning and conditioning, combustion modification, and exhaust cleanup (Stern *et al.*, 1984; Flagan and Seinfeld, 1988). The most familiar control device is the automobile catalyst used to reduce NO_x, ROG, and CO. In addition, automobiles use exhaust gas recirculation to cool combustion and lower NO_x. Combustion has also been optimized to lower emissions. To control evaporation of gasoline, charcoal filled canisters are used to absorb the vapors. These devices have cut emissions by about 90% per vehicle. A less obvious control has been to reformulate gasoline to reduce the vapor pressure and lower emissions of the most reactive organics. Removal of lead from gasoline served two purposes. It reduced lead in the atmosphere, and it eliminated the poisoning of catalysts by the lead. Use of alternative, "clean" fuels such as methanol, natural gas, hydrogen, or electric powered vehicles is a means for further pollution reduction.

Organic gas emission control from stationary sources has relied on process modification, solvent reformulation, and catalytic oxidation. Process modification may involve application procedures (e.g., electrostatic spraying) or use of collection devices (e.g., fume hoods and afterburners). Solvent reformulation relies on the use of less reactive solvents, such as water. Charcoal filtering can also be used to absorb organic vapors.

Sulfur dioxide can be removed from exhaust gases, for example, in utility boilers, by wet or dry scrubbing. The exhaust stream is passed through a shower of alkaline material, such as a lime slurry. The particles in the shower absorb the pollutant. A drawback to this type of control is the production of solid and/or liquid waste that must be treated or disposed of.

Particulate matter control is much different from controlling gases. Inertial separation is very effective for removing larger particles (e.g., cyclone separators). Smaller particles can be removed by filtration and electrostatic collection. In the latter, a corona discharge is used to charge the particles in an electric field. Electrostatic forces cause the particles to migrate to a collection surface.

Controlling pollutants that cause tropospheric warming and ozone depletion is probably the most difficult task. Carbon dioxide emissions are tightly linked to power generation. Lowering CO_2 emissions requires developing and using suitable alternative sources (e.g., solar or nuclear), or energy conservation. CFC control relies on finding suitable replacements. While its use in some applications, such as spray can propellant, may decrease, its use in foam manufacturing and air conditioning will increase (Fig. 5).

Pollution control can be expensive. Control equipment on automobiles costs hundreds of dollars per vehicle. Emission control equipment on power plants can account for a third of the costs. Proposed control devices are estimated to cost tens of thousands of dollars per ton of pollutant removed. There is a definite need to identify the most cost effective control measure to improve air quality.

5.4 Developing Strategies to Improve Air Quality

Improving air quality can be very costly. In 1985, approximately $30 billion dollars was spent in the U.S. alone to control air pollutants. To achieve the air quality standards in the United States and elsewhere will require many times that amount. There is a critical need to be able to identify cost effective means for improving air quality. This task is complicated by the multitude of sources contributing to pollutant formation, and by the uncertainties in the relationships between source emissions and air quality.

As an example, urban ozone is formed by reactions between organic gases and nitrogen oxides. Both are required to form high levels of ozone. If one of the two precursors is in great excess, ozone levels may not respond to its decrease. The task is then to show if controlling one of the precursors or both is most effective for reducing ozone. A similar question arises in controlling acid deposition: Which sources of sulfur dioxide and nitrogen oxides are most advantageously controlled to reduce acid deposition in the most ecologically sensitive areas? In this case it is necessary to develop spatially accurate source–air-quality relationships. Both of these issues are being addressed using detailed, photochemical air quality simulation models. A large number of competing strategies may be tested using these models to determine an optimal path for improving air quality. As seen in Fig. 7, a vital component of a candidate strategy is that it be economically, technologically, and politically feasible. The control measures determined to be most effective can then be adopted for implementation.

6. SUMMARY

Air pollution problems have grown from very local disturbances to having global consequences. Indoor radon, urban smog, acid deposition, global climate change, and stratospheric ozone depletion pose the most severe threats to human health and the environment. Knowledge of the problems has led to identifying solutions and to significant improvements in air quality in some local and urban areas. The air quality in other areas and the problems of regional and global pollution have not seen significant progress. Control of global pollutants requires international cooperation.

Our ability to address issues in atmospheric pollution has developed rapidly in response to the need to improve air quality. Experiments and mathematical modeling have identified how pollutants are transported and interact in the atmosphere. This in turn has made it possible to develop strategies to reduce air pollution in economically and technically feasible ways. Control devices have also evolved to lower pollutant emissions more effectively. Many major pollutant sources now emit less than a tenth of previous levels. The persistence of urban smog in spite of these efforts testifies to the severity of

Control strategies are designed to meet these goals. Mathematical models are used to test the candidate strategies and to relate emissions to pollutant concentrations and environmental impact. The feedback process continues, as shown, until a set of technically, politically, and economically feasible controls are adopted.

the problem and the measures that will be required to achieve clean air. Regulatory action, our understanding of atmospheric dynamics, and technological advancement are driving continued improvement.

GLOSSARY

NO_x: Nitrogen oxides ($NO+NO_2$).

Ozone Layer: Global layer of high ozone concentrations in the stratosphere that effectively shields the earth from UV radiation.

Photolytic: Reaction driven by interaction with light, usually from the sun.

PSCs: Polar stratospheric clouds.

ROG: Reactive organic gas.

Stagnation: Meteorological condition having light winds and low mixing depth. Leads to buildup of pollutant emissions.

Stratosphere: Atmospheric layer above troposphere, extending from about 15 to 45 km.

Troposphere: Atmospheric layer closest to earth, about 15 km thick.

INTRODUCTION

The use of mathematics by physicists, and in particular of algebra, has increased in a remarkable degree during the last 50 years, both in the amount of space occupied in journal articles and in the type and abstractness of the methods employed.

Following N. Bourbaki, it is now conventional to characterize as algebraic structures those parts of mathematics that employ operations, such as addition, which act on a finite set of objects to produce a unique corresponding object. Such operations are contrasted with ideas like limit in calculus or closure in topology, which associate a number or other mathematical object to an infinite set or sequence. Thus, whereas the passage from (2,3) to $2+3 = 5$ is an algebraic operation, to go from the infinite sequence $n \rightarrow 1/n$ (where n is any positive integer) to the limit 0 is a topological operation. The present section is concerned chiefly with algebra.

In this brief article it is impossible to describe all the many algebraic structures which occur in the literature of applied physics. Therefore we have selected those which are absolutely essential for understanding the contemporary literature under the following rubrics: Groups; Fields; Linear Algebra; Rings; Algebras and Modules. As to style, we have attempted to steer a course between that which physicists would have liked 20 years ago and the austerity of contemporary pure mathematicians with which all physicists will be happy 20 years from now. This should leave all readers equally unhappy! Our definitions are seldom painstakingly detailed but rather highlight the essential ideas leaving the reader to use common sense to fill them out. We shall assume that the reader is familiar with elementary properties of vectors and matrices. Recall that a square matrix A is invertible or nonsingular if there is a matrix B such that $AB=BA=I$, where I is the identity matrix. In this case A and B are inverses of each other and we denote B by A^{-1}. Although, logically, rings should be discussed before fields, teaching experience suggests that the reverse order is pedagogically sounder.

NOTATION: We shall adopt the following widely used symbolism: $\mathbb{N}:=$the natural num-

bers, $\{1,2,3,\ldots\}$; $\mathbb{Z}:=$the positive and negative integers and zero; $\mathbb{R}:=$the real numbers; $\mathbb{C}:=$the complex numbers; $i:=\sqrt{-1}$; $\mathbb{Q}:=$the rational numbers. We shall employ Einstein's summation convention in the restricted form that in any monomial an index which is repeated as a subscript and as a superscript will be interpreted as summed over its range unless the contrary is explicitly stated.

1. GROUPS

A group is a set, G, say, together with a binary operation which we temporarily denote by "$*$", which satisfies certain definite rules. A binary operation is one which combines two elements of G to obtain an element of G. Perhaps our first encounter with a group occurs when as babies we push our blocks around on the floor using the translation group in two dimensions! Later in grade school we learn the properties of the integers. Under addition the integers $\mathbb{Z}$ exemplify the axioms of a group:

(i) A group $(G,*)$ is a set, G, together with an operation, $*$, which to any two elements x and y of G associates an element $z=x*y$ of G. For example, in $(\mathbb{Z},+)$, $2+3=5$, $5+(-3)=2$. This property is described by saying that G is closed under the binary operation $*$.

However, for the structure $(G,*)$ to be dignified with the title "group," it must satisfy the additional properties:

(ii) The operation is associative, that is for any x,y,z in G, $(x*y)*z=x*(y*z)$.

(iii) There is a unique neutral or identity element, n, such that $x*n=n*x=x$ for all x in G.

(iv) For any element x in G there is a unique element y in G such that $x*y=n$. In this case, x and y are said to be inverses of each other.

Thus while $(\mathbb{N},+)$ satisfies (i) and (ii) it is not a group because (iii) and (iv) fail. However, $(\mathbb{Z},+)$ is a group when we take $n:=0$.

If G has a finite number of elements, the group is a finite group and the number of elements is called the order of the group. If $x*y=y*x$ for all $x,y \in G$, the group is Abelian or commutative.

The set of symmetries of any mathematical or physical structure constitutes a group under composition of symmetries. Such groups play a major role in physics for analyzing the properties of space-time, understanding crystal structure, and classifying the energy levels of atoms, molecules, and nuclei. Indeed, the role of groups is so important in physics that an article of the *Encyclopedia* is devoted to them. We therefore shall not explicitly pursue the detailed properties of groups further, even though they will occur as substructures in rings and fields.

2. FIELDS

Whereas a group consists of a set together with a single binary operation, a field consists of a set together with two binary operations linked together by a distributive law. The two operations are usually called addition and multiplication. The familiar fields are the real numbers, $\mathbb{R}$; the complex numbers, $\mathbb{C}$; and the rational numbers, $\mathbb{Q}$. We shall use the symbol $\mathbb{F}$ for an arbitrary field. Strictly speaking, we should employ a notation such as $(\mathbb{F},+,\times)$ to denote a field; however, the relevant operations are generally obvious from context in which case it is sufficient to use $\mathbb{F}$ alone.

$(\mathbb{F},+,\times)$ is a field if:

(i) $(\mathbb{F},+)$ is a commutative or Abelian group. That is, $x+y=y+x$ for any x and y in $\mathbb{F}$.

(ii) The elements of $\mathbb{F}$ other than zero form a group under multiplication.

(iii) Multiplication distributes over addition. That is, if a,b,c, belong to $\mathbb{F}$ then $a\times(b+c)=a\times b+a\times c$, and $(b+c)\times a=b\times a+c\times a$.

These properties are, of course, familiar for the reals, complexes, and rationals, but there are fields, such as the quaternions, for which multiplication is not commutative. There are also fields with only a finite number of elements.

A field always has at least two elements, 0 and 1.

2.1 The Characteristic of $\mathbb{F}$

Since a field is closed under addition, $\mathbb{F}$ contains $1+1$, which cannot equal 1 since this would imply that $1=0$, which we excluded. But $1+1$ might equal 0 in which case $(1+1)+1=1$ and one can easily check that $\mathbb{F}=\{0,1\}$ can serve as the set of a field of two elements. This is the smallest possible field and is both famous and useful since it plays a key role in the design of electric circuits, such as those which occur in computers.

More generally, if p is a prime number, we can obtain a field containing p elements in which the sums of j 1's are numbers which are distinct if $0 \leqslant j < p$ and equal to 0 if $j = p$. When this occurs in any field $\mathbb{F}$ we say that p is the characteristic of $\mathbb{F}$ and that $\mathbb{F}$ has finite characteristic. When there is no such p we say that $\mathbb{F}$ has characteristic zero. A field of characteristic zero has an infinite number of elements. If $\mathbb{F}$ has only a finite number of elements it will contain p^n elements, where p is a prime and n is a positive integer. If $n > 1$, $\mathbb{F}$ will contain a subfield of the above type with p elements. The fields with p^n elements are called Galois fields. They are important in coding and communication theory. A finite field is necessarily commutative.

2.2 Algebraically Closed Fields

We know that the square of a real number is positive, so there is no real number x such that $x^2 = -1$. In other words, in $\mathbb{R}$ there is no element x satisfying the equation $x^2 + 1 = 0$. If $\mathbb{F}$ has the property that for every equation of the form $a_j x^j = 0$, $0 \leqslant j \leqslant n$, where the a_j belong to $\mathbb{F}$, there is an element of $\mathbb{F}$ which satisfies the equation, we say that $\mathbb{F}$ is algebraically closed. Otherwise, it is not algebraically closed. Clearly $\mathbb{R}$ is not algebraically closed. If we assume that there is a "number" i such that $i^2 + 1 = 0$, then, as we know, the field containing $\mathbb{R}$ and i is the complex numbers, $\mathbb{C}$. It was proved by Gauss that $\mathbb{C}$ is algebraically closed.

Notice that if σ is a 1:1 map of $\mathbb{C}$ onto itself, such that $\sigma(x+iy) = x - iy$ for all $x, y \in \mathbb{R}$, then σ preserves all the properties of a field and is therefore an automorphism of $\mathbb{C}$. Recall that an isomorphism of two algebraic structures is a bijective (or one-to-one) correspondence between their sets, which preserves all the relations among their elements, and that an automorphism is an isomorphism of an algebraic structure onto itself. Note that $\sigma(x) = x$ if $x \in \mathbb{R}$ and that $\sigma(i) = -i$, which is the root other than i of the equation $x^2 + 1 = 0$. An automorphism of $\mathbb{C}$ must send 0 into 0 and thus must either leave i fixed (and so everything in $\mathbb{C}$ is fixed) or, like σ, send i to $-i$. The set consisting of σ and the identity map is a group of order two under composition of mappings. It is the Galois group of $\mathbb{C}$ over $\mathbb{R}$. Alternatively, it is also called the Galois group of the equation $x^2 + 1 = 0$ with respect to the reals. For more detail about fields, their algebraic extensions, and their Galois groups, the reader is referred to Jacobson (1964) or any of the multitude of algebra texts at the same level.

Are there fields containing $\mathbb{R}$ other than $\mathbb{C}$ which are at most finite dimensional over $\mathbb{R}$? The answer was given by Frobenius. There is one and only one, the quaternions, but in this field multiplication is not commutative. We shall see below that the quaternions can be realized as linear combinations with real coefficients of the Pauli matrices and the 2×2 identity matrix. The significance of the field of quaternions is dramatized by the observation that if it did not exist there would be no spin in physics, therefore no sigma and pi bonds in chemistry, and therefore no life on planet earth if, indeed, there were any stars or planets!

2.3 Rational Functions

If we adjoin a symbol x to any field $\mathbb{F}$ and form all possible sums, differences, products, and quotients involving x and the elements of $\mathbb{F}$, the result is a set which is closed under any finite sequence of these operations and forms a field, denoted by $\mathbb{F}(x)$, which we might describe as the field of rational functions in x over $\mathbb{F}$. There is a subset, denoted by $\mathbb{F}[x]$, of polynomials of the form $a_j x^j$ where j is summed from 0 to some $n \in \mathbb{N}$, where n is arbitary and the $a_j \in \mathbb{F}$. If a_n is not zero we say that the polynomial has degree n. As we shall remark below, the polynomials constitute a ring. As usual $x^0 := 1$, by definition, so when $n = 0$ the preceding polynomial reduces to a_0. Thus $\mathbb{F}$ is contained in $\mathbb{F}[x]$. The field $\mathbb{F}(x)$ consists of all possible quotients of elements of $\mathbb{F}[x]$.

Suppose that the rational function $R(x) = P(x)/Q(x)$, where P and Q are polynomials. Suppose further that $Q(x) = Q_1(x)Q_2(x)$, where Q_1 and Q_2 are polynomials with no common factor. Since we could have used long division to ensure that R is the sum of a polynomial and a rational function, the numerator of which has degree strictly less than the degree of Q, we may assume that deg(P)—the degree of P—is less than deg(Q). It is relatively easy to show that it is then possible to find polynomials P_1 and P_2 with $\deg(P_i) < \deg(Q_i)$ such that

$$P/Q = P_1/Q_1 + P_2/Q_2.$$

This is the fundamental theorem of the so-called method of partial fractions, by repeated application of which it follows that any rational function can be expressed as a sum of a polynomial and rational functions whose denominators have no nontrivial factors.

In particular, if $\mathbb{F}$ is algebraically closed (e.g., $\mathbb{F}=\mathbb{C}$), then Q is a product of factors such as $(x-a)^m$, where $a \in \mathbb{F}$. A summand in $R(x)$ of the form $g(x)/(x-a)^m$ with $\deg(g) < m$ can, by Taylor's theorem applied to $g(x)$, be expressed as the sum $c_j(x-a)^{-j}$, where $1 \leqslant j < m$ and $c_j = g^{(m-j)}(a)/(m-j)!$. Here $g^{(k)}$ is the kth order derivative of g.

The method of partial fractions is quite useful for finding integrals of rational functions. Books on calculus explain helpful tricks for obtaining the partial fraction decomposition of a given rational function.

3. LINEAR SPACES

The theory of linear space with its related concepts of linear transformation, eigenvector, matrix, determinant, and Jordan canonical form is certainly one of the most important and most useful part of mathematics. The abstract concept of linear space is frequently approached by a long discussion of the problem of solving systems of linear equations. We take a direct approach defining a linear space as consisting of a field $\mathbb{F}$ whose elements are called scalars, a set V, called vectors, and two operations called vector addition and scalar multiplication together with a set of rules governing the relation among these various entities. The vectors under addition form an additive Abelian group $(V,+)$. Under multiplication by scalars the set V is closed. Thus, $v \in V$ and $a \in \mathbb{F}$ imply that $av \in V$. Another important property is that multiplication by scalars distributes over addition of vectors. That is $a(v_1+v_2)=av_1+av_2$ for all $a \in \mathbb{F}$ and $v_i \in V$.

3.1 Independence of Vectors

This seems to be the most difficult idea in teaching elementary courses in linear algebra—possibly, the only difficult idea! Two nonzero vectors v_1 and v_2 are linearly dependent if there are scalars a^1 and a^2, not both zero, such that $a^1v_1+a^2v_2=0$, where, of course, by 0 we mean the zero vector. It is clear that neither a^1 nor a^2 is zero, and thus each vector is a scalar multiple of the other. More generally, if, given n vectors v_i, $1 \leqslant i \leqslant n$, there exist scalars a^i such that $a^iv_i=0$, where all $v_i \neq 0$ and not all $a^i=0$; then we say that the n vectors are linearly dependent. If no such relation holds, the vectors are linearly independent. For example, for $n \in \mathbb{N}$ there are no numbers a_n other than 0 such that $\Sigma_n a_n \times \cos(n\vartheta)=0$ for all ϑ. Thus the functions $\vartheta \rightarrow \cos(n\vartheta)$ are linearly independent.

If n vectors v_i are such that any vector v can be written as $v=a^iv_i$ for some choice of scalars a^i, we say that the set $\{v_i\}$ spans V. If the v_i are also linearly independent then the coefficients a^i are unique. We then say that $B=\{v_i\}$ is a basis of V, that the linear space V has dimension n, and that a^i are the components of v with respect to B. A basic theorem assures us that the dimension depends only on the space V and not on the choice of basis. If a linear space does not have a finite basis it is infinite dimensional.

3.2 Change of Basis

How do the components of a given vector change if the basis is changed? This was a key question which led to the theory of invariants in the mid-19th century and opened up the development of much of contemporary algebra. It also led to the emergence of the tensor calculus which was essential for Einstein's exposition of General Relativity Theory.

Suppose V is a linear space and that $B = \{v_i\}$ and $B' = \{v'_i\}$ are two different bases for V. Then there is a matrix, P^j_i called the transition matrix from B to B' such that $v'_i = P^j_i v_j$. Thus if the vector $x = x^j v_j = x'^{\,i} v'_i = x'^{\,i} P^j_i v_j$, it follows that $x^j = P^j_i x'^{\,i}$. If in the usual matrix notation we regard x^j as the jth component of a column vector $\mathbf{x}$, and P^j_i as the element in the jth row and ith column of the transition matrix, $\mathbf{P}$, from the old base B to the new base B', the preceding equation takes the form

$$\mathbf{x}=\mathbf{P}\mathbf{x}' \quad \text{or} \quad \mathbf{x}'=\mathbf{P}^{-1}\mathbf{x}.$$

There is an even more convenient notation. Define $P(B',B):=\mathbf{P}$; then the preceding equations imply that $\mathbf{P}^{-1}=P(B,B')$. Subsequently we shall need the formulas

$$\mathbf{x}=P(B',B)\mathbf{x}' \quad \text{and} \quad \mathbf{x}'=P(B,B')\mathbf{x}.$$

To understand tensor notation it will prove important to note that, whereas **P** sends the old to the new basis, it sends the new coordinates to the old ones. This observation underlies duality in homological algebra and the distinction between covariant and contravariant tensors, which we define below.

3.3 Linear Maps and Their Associated Matrices

Suppose that V and U are linear spaces of dimension n and m with bases $B_v=\{v_i\}$ and $B_u=\{u_j\}$, respectively. A transformation, function, or map from V to U sends each vector $x\in V$ to a vector, say, y of U, which we denote by $Ax:=y$. If A has the property that for any two vectors x and $x'\in V$ and arbitrary scalars a and $a'\in \mathbb{F}$, $A(ax+a'x')=aAx+a'Ax'$, we say that A is linear. The condition that a map be linear is very restrictive. Nonetheless, linear maps play a big role in the application of mathematics to physics (as well as statistics, economics, biology, etc.) for the same reason that the derivative is important in analysis. For example, if $f(x)$ is a real-valued function of the real variable x, such that $f(0)=0$, then $f'(0)x$ is the linear function of x which is the best possible linear approximation to $f(x)$ near 0.

A linear map or transformation, $A:V\rightarrow U$, can be completely described by an $m\times n$ matrix A^j_i, such that $Av_i=A^j_iu_j$, which we describe as the matrix associated to the linear transformation or map A with respect to the bases B_u and B_v. It has m rows and n columns. If we denote this matrix by $A(u,v)$ then if the bases in V and U are changed to B'_v and B'_u, respectively,

$$A(u',v')=P(B'_u,B_u)A(u,v)P(B_v,B'_v),$$

where we use the notation of Sec. 3.2. In terms of coordinates, if $\mathbf{y}=\mathbf{A}\mathbf{x}$, then $y^j=A^j_i\,x^i$, where, as follows from the context, $1\leqslant j\leqslant m$ and $1\leqslant i\leqslant n$.

In the particular case that $V=U$ of dimension n, with $B_u=B_v$, $A(u,u)$ is an $n\times n$ matrix which we denote by $A(u)$. We deduce that for a change of basis

$$A(u')=P(B'_u,B_u)A(u)P(B_u,B'_u).$$

We thus associate to any linear transformation a matrix which is unique, *once bases are chosen* for the domain and codomain of the transformation. But conversely, if the bases are given, then there is a unique linear transformation associated with a given matrix of the appropriate shape. Thus there is a bijection (i.e., a one-to-one correspondence) between $m\times n$ matrices with entries in $\mathbb{F}$ and linear maps from a linear space of dimension n into one of dimension m. We have found how the bijection changes when the bases are altered. It is this bijection which gives meaning to the familiar addition and multiplication of matrices.

A linear map between two spaces over the same field $\mathbb{F}$ has the property of preserving the linear structure and is said to be a homomorphism (i.e., a structure-preserving map), so it is common to denote by $\mathrm{Hom}(V_1,V_2)$ the set of all linear maps between linear spaces V_1 and V_2 where both have the same field. If $A\in\mathrm{Hom}(V_1, V_2)$ then V_1 is the domain of A and V_2 is the codomain of A. The kernel of A, frequently denoted by $\ker(A)$, is the set of all elements in the domain which are mapped onto 0 by A. The range of A consists of all elements of the codomain of the form Ax for some x in the domain. Of course these last four defintions are valid for any function, not merely linear maps. However, when A is linear it can be easily proved that both the kernel and the range are linear subspaces of their ambient spaces. This is probably the secret of the power and relative simplicity of the theory of linear spaces. When $V_1=V_2=V$, we denote $\mathrm{Hom}(V,V)$ by $\mathrm{Hom}(V)$.

If G is a map from V_1 to V_2 and F one from V_2 to V_3, we denote the composition of these two maps by FG and, having fixed bases in the spaces, we define the matrix corresponding to FG as the product of the matrices corresponding to F and G. This "explains" the usual rule for matrices that $(FG)^j_i=F^j_kG^k_i$, where i, k, and j range from 1 to the dimensions of V_1, V_2, and V_3, respectively.

The composition (or product) of two maps can be well-defined if the range of the first is in the domain of the second. The sum of two maps is only meaningful if the codomain is an additive group in order for the sum of Fx and Gx to be meaningful. In this case it is possible to let $F+G$ denote the map such that $(F+G)x=Fx+Gx$ for all x in the intersection of the domains of F and G. When the domain and codomain are fixed linear spaces over the same field $\mathbb{F}$ we can do even better and give $\mathrm{Hom}(V_1, V_2)$ the structure of a linear space over $\mathbb{F}$. This implies that the set of all $m\times n$ matrices with entries from $\mathbb{F}$ is a linear space of dimension mn over $\mathbb{F}$.

The dimension of the range of a linear operator is called the rank of the operator and also the rank of any matrix associated with the operator by a particular choice of bases. The dimension of the kernel of a linear transformation is called the nullity of the transformation and of its associated matrices. It follows from this definition that the various matrices obtained from one another by a change of basis all have the same rank and nullity. The rank of a product of operators or matrices is not greater than the minimum rank of its factors.

3.4 Determinants

If $\mathbb{F}$ is a commutative field, to any square matrix, it is possible to assign a number in $\mathbb{F}$ which is expressible as a polynomial in the elements of the matrix and which vanishes only if the matrix is not invertible. To two square matrices which are related as in Sec. 3.3 by a change of basis, we assign the same number, and therefore it is meaningful to also assign this number to the associated linear transformation belonging to $\mathrm{Hom}(V)$. The function, det, from $\mathrm{Hom}(V)$ into $\mathbb{F}$, has the following properties: (i) $\det(AB)=\det(A)\det(B)$; (ii) $\det(fI)=f^n$, where n is the dimension of V, I is the identity map, and f is any element of $\mathbb{F}$. The usual definition of the determinant follows from these properties (MacDuffee, 1943). In particular since, for a fixed basis, the equation $Ax=y$ is equivalent to the system of equations $A^j_i x^i=y^j$, Cramèr's rule implies

$$\det(A)x^i=\det(Y^i),$$

where Y^i is the matrix obtained from (A^j_i) by replacing its ith column by the column vector (y^k) where i, j, k run from 1 to n. Thus if $\det(A)\neq 0$ there is a unique x for every y so A is invertible; whereas if $\det(A)=0$, there is an x only for particular y satisfying the n conditions $\det(Y^k)=0$. Thus for a finite dimensional linear space V, $A\in\mathrm{Hom}(V)$ is invertible if and only if $\det(A)\neq 0$.

The theory of $\mathrm{Hom}(V_1,V_2)$ is really equivalent to the theory of systems of linear equations in several variables. This topic occurs in articles of this *Encyclopedia* devoted to NUMERICAL METHODS and to MATHEMATICAL MODELING and in at least one hundred elementary textbooks; so we shall not pursue it here.

3.5 Eigenvectors and Eigenvalues

If $A\in\mathrm{Hom}(V)$ then for any $x\in V$, $Ax\in V$. In general we shall not expect Ax to equal x or indeed, even, that Ax be parallel to x. However, in the latter case Ax would be a multiple of x, say, λx. The equation $Ax=\lambda x$ is equivalent to $(\lambda I-A)x=0$. By the preceding section, if the determinant of $\lambda I-A$ is different from zero, the only possible solution of this equation is $x=0$, which is of no great interest. When there is a nontrivial solution of this equation it will be somewhat unusual and is called an eigenvector of A and can occur only for special values of λ. Such a value of λ is the eigenvalue of A corresponding to the particular eigenvector x. The eigenvalue, λ, will satisfy the nth degree algebraic equation

$$f(z;A):=\det(zI-A)=0.$$

The nth degree polynomial $f(z;A)$ is called the characteristic function of A, and the preceding equation is the characteristic equation of A. Any eigenvalue of A satisfies its characteristic equation. For each zero of the characteristic equation there is at least one nontrivial eigenvector.

There is a one-to-one correspondence between the operators in $\mathrm{Hom}(V)$ and the set of $n\times n$ matrices over $\mathbb{F}$, and this set spans a linear space over $\mathbb{F}$ of dimension n^2. If we interpret A^0 as the identity operator, I, it follows that the operators A^k for $0\leqslant k\leqslant n^2$ are linearly dependent. That is, there are $c_j\in\mathbb{F}$ such that $c_j A^j=0$, where not all c_j are zero. Thus there exists at least one polynomial, $p(z)$, such that $p(\mathrm{A})=0$. From the algorithm for long division it easily follows that there is a unique monic polynomial (i.e., a polynomial with highest coefficient 1) of minimal degree with this property. We shall denote this so-called minimal polynomial of A by $m(z;A)$. A famous theorem of Hamilton asserts that A satisfies its characteristic equation. That is, $f(A;A)=0$.

Since $\deg(f)=n$, $\deg[m(z;A)]\leqslant n$. Since $m(z,;A$ divides any polynomial $p(z)$ such that $p(A)=0$, it follows that $m(z;A)$ divides $f(z;A)$.

The form of $m(z;A)$ provides information about A.

(i) $m(z{:}A)=z^p$ implies that $A^p=0$ but that $A^{p-1}\neq0$. Such an operator is called nilpotent, with nilpotency index p.

(ii) $m(z;A)=(z-1)^p$ implies that $A-I$ is nilpotent with index p. Thus in this case $A=I+N$, where N is nilpotent. An operator of this form is called unipotent.

(iii) Suppose the minimal polynomial of A has no multiple zeros, which is equivalent to saying that m and its derivative have no common factors. Then there is a basis of V consisting of eigenvectors of A. Equivalently, among the matrices associated with A there is one which is diagonal. In this case we say that A and its associated matrices are diagonalizable or semisimple.

(iv) If $m(z;A)=(z-\lambda)^p$, then, of course, $p\leqslant n$. A basis can be chosen so that the matrix corresponding to A has zero entries except along the diagonal where there are so-called Jordan blocks, which in case $n=4$, for example, would be

$$\begin{bmatrix}\lambda & 1 & 0 & 0\\ 0 & \lambda & 1 & 0\\ 0 & 0 & \lambda & 1\\ 0 & 0 & 0 & \lambda\end{bmatrix}.$$

That is $n_i\times n_i$ matrices with λ on the diagonal and 1's on the first superdiagonal, $\Sigma n_i=n$, $1\leqslant n_i\leqslant p$, and for at least one value of i, $n_i=p$.

In the preceding we have assumed that the entries of the matrix A could be arbitrary. However, if they are real and nonnegative the remarkable Perron–Frobenius theorem (Senata, 1973) about the eigenvalues and eigenvectors of A gives information which is useful in many contexts; we thus state it here. A matrix $M=(m_{ij})$ is connected or indecomposable if for any two indices i and j there is a sequence r_k, $1\leqslant k\leqslant s$, such that the continued product $m_{ir_1}m_{r_1r_2}m_{r_2r_3}\dots m_{r_sj}\neq0$. We write $M>0$ if all $m_{ij}>0$, and $M\geqslant0$ if all $m_{ij}\geqslant0$. Then, if $M\geqslant0$ is a real connected matrix, it has a largest simple positive eigenvalue, $r(M)=r$, and an associated column vector $x>0$, such that $Mx=rx$ where $r>0$; any other eigenvalue λ of M has absolute value less than or equal to r. Further, if $N\geqslant0$ is another real matrix of the same dimension, such that $M-N\geqslant0$, then $r(N)\leqslant r(M)$ with equality only if $N=M$. This theorem can be used to quickly give the basic classification of Kac–Moody algebras.

3.6 Canonical Form of Matrices

In Sec. 3.3 we noticed that distinct matrices were associated with the same linear operator, so there is a sense in which such matrices are "equivalent." Recall that by an equivalence relation a set is partitioned into distinct mutually exclusive subsets which exhaust the given set. One method of partitioning a set is into the orbits of a group which acts on the set. Thus if g belongs to a group G which is acting on a set S and we denote by gs the element of S into which g sends s, the orbit of s is the set $M_s=\{gs\,|\,g\in G\}$. It follows that $x\in M_s$ implies that $M_x=M_s$. Given an equivalence relation on a set of matrices, the problem considered in this section is that of choosing a canonical or "simplest" matrix in each equivalence class. There are different canonical forms depending on the types of matrices we consider and the different group actions contemplated.

Possibly the basic and most general situation is that considered by H. J. S. Smith in 1861. It is that of Sec. 3.3 where the equation $A(u',v')=PA(u,v)Q$ occurs in slightly different notation. There P and Q are arbitrary invertible $m\times m$ and $n\times n$ matrices, respectively. By choosing B'_u so that the last elements of the basis span the kernel of A and the first ones span a subspace which is complementary to the kernel, while the first elements of B_u span the range of A, one can arrive at Smith's canonical matrix which has 1's in the (i,i) positions for $1\leqslant i\leqslant r$ where r is the rank of A, and zero everywhere else. It would be difficult to demand anything "simpler." It follows that with this meaning of equivalence there are $p+1$ equivalence classes of $m\times n$ matrices where p is the minimum of $\{m,n\}$.

At first one is surprised that there are so few classes. However, on second thought, one notices that we have been acting on a space of matrices of dimension mn by the group $Gl(n,\mathbb{F})\times Gl(m,\mathbb{F})$ $(=G$, say), which has $n^2+m^2\geqslant2mn$ parameters; there is plenty of redundancy unless one of m and n is 1 and the other is 1 or 2.

If we consider an action on the set of $n\times n$ matrices by a smaller group we shall expect more equivalence classes. For $(P,Q) \in G$, subgroups of G can be defined by imposing restrictions on P and Q.

Recall the following definitions. If A is a square matrix the transpose of A, denoted by A^t, is obtained from A by interchanging rows and columns or by reflecting across the main diagonal. The operation of taking the transpose is an involution, that is $(A^t)^t=A$. If $A^t=A$, then we say A is symmetric. If $A^t=-A$, then A is antisymmetric or skew-symmetric. An important property of transposition is $(AB)^t=B^tA^t$. It is worth noting that once the basis of V has been fixed, the mapping defined by transposition of matrices can be transferred to the associated linear transformations, thus defining an involution on Hom(V).

If σ is an automorphism of $\mathbb{F}$, we can define an operation on the matrix A by replacing each of its elements by its conjugate under the automorphism, and denote the new matrix by A^σ. If the field is commutative $(AB)^\sigma=A^\sigma B^\sigma$. In particular, when $\mathbb{F}=\mathbb{C}$, complex conjugation is an automorphism of period two. We follow a common custom and denote the complex conjugate of A by $\overline{A}$, so $\overline{AB}=\overline{A}\,\overline{B}$.

The Hermitian conjugate of A is denoted by $A^*=\overline{A}^t$ and satisfies $(AB)=B^*A^*$. A matrix A is Hermitian if $A^*=A$ and anti-Hermitian if $A^*=-A$.

The approach of this section is based on that of Turnbull and Aitken (1932), a superb book which goes far beyond our brief summary. They distinguish five subgroups of G.

(i) The Collinearity Group is characterized by $PQ=I$. It arises in Sec. 3.3 when $v=u$ and $v'=u'$. Under the action of this group, a square matrix, A, can be reduced to Jordan canonical form, that is to a sum of diagonal blocks, each of which has the form $\lambda I+N$, where λ is an eigenvalue of A and N is a nilpotent matrix, all of whose entries are zero except for 1's along the first superdiagonal. A particular eigenvalue occurs on the diagonal of the canonical form as many times as its multiplicity in the characteristic equation. For any eigenvalue the dimension of the largest Jordan block is equal to the multiplicity of the eigenvalue in the minimal polynomial $m(z;A)$. Thus if the zeros of $m(z;A)$ are simple, A is diagonalizable.

(ii) The Congruent Subgroup is defined by the condition $P^t=Q$. Under this group, symmetry or antisymmetry of A is invariant. A symmetric matrix can be diagonalized. If $\mathbb{F}$ is closed under taking square-roots, we can choose as the canonical element of an equivalence class a diagonal matrix which has only 0's or 1's on the diagonal. If $\mathbb{F}=\mathbb{R}$, the diagonal could also contain -1. In the real case, Sylvester's Law of Inertia asserts that the number of 1's and the number of -1's are invariants. A nonsingular antisymmetric matrix has even rank r and there is a canonical form under the congruent group which contains zeros everywhere except for $r/2$ blocks of 2×2 antisymmetric matrices down the diagonal; each has 1 and -1 off the diagonal and 0 on the diagonal.

(iii) The Conjunctive Subgroup is defined by the condition $P=Q^*$. It changes Hermitian matrices into Hermitian matrices. For real matrices, the conjunctive and the congruent transformations are the same. For any $\mathbb{F}$, one may choose a diagonal matrix as canonical. If $\mathbb{F}=\mathbb{C}$, the diagonal can consist of 1's and 0's.

(iv) The Orthogonal Group is defined by $PQ=I$ and $P =Q^t$ and is thus a subgroup of the groups (i) and (ii). It will preserve symmetry or antisymmetry of a matrix. A symmetric matrix will be equivalent to a diagonal matrix whose diagonal elements are eigenvalues of the original matrix. An antisymmetric matrix will be equivalent to one with zeros everywhere except for 2×2 blocks on the diagonal, the determinants of these blocks being equal to the negatives of the squares of eigenvalues of the original matrix.

(v) The Unitary Subgroup is defined by $PQ=I$ and $P=Q^*$, and is thus a subgroup of (i) and (iii). It preserves the property of a matrix being Hermitian or anti-Hermitian. If $\mathbb{F}=\mathbb{R}$, groups (v) and (iv) are the same. Under this group, a Hermitian matrix is equivalent to a diagonal matrix whose nonzero elements are eigenvalues of the original matrix. An anti-Hermitian matrix is equivalent to one with 2-dimensional blocks on the diagonal whose determinants are the negatives of the squares of eigenvalues of the original matrix.

3.7 Dual Space

We have already noted that Hom(V,U), where V and U are linear spaces of dimension n and m, respectively, over a common field $\mathbb{F}$, can be given a structure of a linear space of dimension nm over $\mathbb{F}$. We can, of course consider $\mathbb{F}$ as a linear space of dimension 1 over $\mathbb{F}$. Thus, Hom(V,$\mathbb{F}$) is a linear space of dimension n over $\mathbb{F}$ and therefore isomorphic to $\mathbb{F}^n$ and hence also to V. It is called the dual space of V and usually denoted by V^*. This use of the asterisk can be distinguished from its use to indicate Hermitian conjugation by the context. The elements of V^* are linear functions on V with values in $\mathbb{F}$. We shall denote them by lower case Greek letters. Recall that the Kronecker symbol δ^i_j takes the value 1 if $i=j$ and 0 otherwise.

If $\alpha \in V^*$ and $x=x^jv_j$ is an arbitrary vector in V expressed in terms of the basis B_v, then $\alpha(x)=x^j\alpha(v_j)=a_jx^j$, where $a_j=\alpha(v_j)$. It is possible to define various bases for V^*. The basis which is said to be dual to B_v, and may be denoted by B^*_v, is defined as follows. Recall that a linear function on V is completely determined by the values it assumes for the elements of a basis of V.

Let α^i be a linear function such that $\alpha^i(v_j)=\delta^i_j$ for all j, $1\leqslant j\leqslant n$. Then $\alpha^i(x)=x^i$. Thus α^i is the ith coordinate function. It easily follows that α^i are linearly independent and that $\alpha=a_j\alpha^j$, where $a_j=\alpha(v_j)$. Thus any element of V^* is a linear combination of the n elements α^j, $1\leqslant j\leqslant n$, so that $B^*_v=\{\alpha^j\}$is a basis for V. Just as the x^i are coordinates of an arbitrary element of V with respect to B_v, so a_i are coordinates of an arbitrary element of V^*. Since $a_i=\alpha(v_i)$, when the basis of V is changed, a_i changes by the same transformation as, or cogrediently with, the basis. As we noted at the end of Sec. 3.2, the x^i transform contragrediently to the basis. This distinction reflects the fact that the definition of the linear function α: $x\rightarrow\alpha(x)$ is independent of the coordinate system used to describe it. A geometrical or physical entity which is described by a sequence of n numbers which transform like (a_i) is called a covariant vector. Similarly, an entity described by a sequence of n numbers which transform like (x^i) when the basis is changed is called a contravariant vector.

3.8 Tensors

Possibly it was algebraic geometers in the middle of the nineteenth century who first focused attention on the behavior of the coordinates of geometrical objects when the frame of reference is changed. But the first time this issue really impinged on physics was with the advent of Einstein's General Relativity Theory (GRT). The basic metric of GRT, $g_{ij}dx^idx^j$, is clearly independent of the coordinate system but since dx^i is a contravariant vector, g_{ij} will have to vary covariantly in both subscripts i and j. Then the n^2 symbols g_{ij} must be describing something (in fact, according to Einstein, the gravitational field!) which is a doubly covariant tensor.

The curvature of space-time, which allegedly explains black holes and how planets circle around the sun, is described by the Riemann–Christoffel tensor, $R^i{}_{jkl}$, which is contravariant in the index i and covariant in the other three.

The great advantage of the indicial notation, as it evolved in the writings of Eddington, Weyl, Synge, and other mathematical physicists between 1920 and 1940, is that it immediately indicates the behavior of the tensor when the underlying basis, or frame of reference, is changed. Thus if a_{ij} is a double covariant tensor and b^i is a contravariant vector (or first order tensor), then $a_{ij}b^k$ is a third order tensor covariant in two indices and contravariant in one. If we now contract on the indices j and k, we see immediately that $c_i=a_{ij}b^j$ is a covariant vector.

An algebraist would say that a_{ij} are the components of an element of $V^*\otimes V^*$, the tensor product of the dual space of V with itself. Similarly, $a^ib^j_k$ are the components of an element in the tensor product $V\otimes V\otimes V^*$. In general, the tensor product (see Sec. 4) of two linear spaces of dimension n and m is a linear space of dimension nm. In particular, $V^*\otimes U$ is isomorphic to Hom(V,U) and is spanned by a basis consisting of elements noted as $\alpha^i\otimes u_j$, where $1\leqslant i\leqslant n$ and $1\leqslant j\leqslant m$.

4. CREATING ALGEBRAIC STRUCTURES

What experimental apparatus is for the physicist, the Cartesian product and quotient structures are for the algebraist. These are the principal tools with which he makes new mathematical structures.

If A and B are two sets, the Cartesian product of A and B is denoted by $A\times B$ and defined as the set $\{(x,y)\,|\,x\in A,\ y\in B\}$. Thus it is a new set consisting of ordered pairs with the first element of the pair belonging to A and the second to B. If $A\neq B$, $A\times B\neq B\times A$, since by definition two ordered pairs (a,b) and (c,d) are equal only if $a=c$ and $b=d$.

Things become more interesting when A and B have some algebraic structure which can be used to impose structure on the Cartesian product. For example, suppose that $A=B=\mathbb{Z}$. We define the addition of pairs $\in \mathbb{Z}\times\mathbb{Z}$ by $(x,y)+(u,v):=(x+u,\ y+v)$. Notice that the plus signs on the right and left have quite different meanings. One acts on pairs of integers; the others on integers. If we think of $+3$ as a translation by 3 units along the number line, we can call $(\mathbb{Z},+)$ a translation group in one dimension. We could then think of $(\mathbb{Z}\times\mathbb{Z},+)$ as the translation group of a two-dimensional lattice. Another familiar example is the idea due to Gauss of imposing the structure of the complex numbers on $\mathbb{R}\times\mathbb{R}$.

The direct sum of two vector spaces provides us with another important example of this construction. Suppose X and V are two linear spaces over the same field $\mathbb{F}$ with bases $\{e_i\}$, $1\leqslant i\leqslant n$, and $\{f_j\}$, $1\leqslant j\leqslant m$ respectively. For $x,y\in X$, $u,v\in V$, and $\alpha\in\mathbb{F}$, define (i) $(x,u)+(y,v):=(x+y,u+v)$; (ii) $\alpha(x,u):=(\alpha x,\alpha u)$. By these definitions we have imposed on $X\times V$ the structure of a linear space for which the $n+m$ elements $\{(e_i,0),\ (0,f_j)\}$ form a basis. This new linear space is called the direct sum of the linear spaces X and V, and has dimension $n+m$, and is denoted by $X\oplus V$.

An apparently minor variation on the preceding definition leads us to an important but quite different object—the tensor product of X and V which is denoted by $X\otimes V$. This is a linear space which has a basis of elements belonging to the Cartesian product $X\times V$, but addition and scalar multiplication are different. (i) $(x_1+x_2,\ v_1+v_2)=(x_1,v_1)+(x_1,v_2)+(x_2,v_1)+(x_2,v_2)$; (ii) $\alpha(x,v)=(\alpha x,v)=(x,\alpha v)$. These conditions imply that $X\otimes V$ is a vector space over $\mathbb{F}$ of dimension mn, with $\{(e_i,f_j)\}$ as a basis.

Recall that an equivalence relation ρ on a set S partitions S into mutually exhaustive subsets which we call equivalence classes. A binary relation ρ on a set is an equivalence relation if it has the following three properties: (i) reflexive, $x\rho x$ for all $x\in S$, (ii) symmetric, $x\rho y$ implies $y\rho x$, (iii) transitive, $x\rho y$ and $y\rho z$ imply $x\rho z$. A subset of the partition of S contains exactly all the elements of S which are related by ρ to any one member of the subset. For example, the nails in a hardware store can be partitioned by length. Thus $x\rho y$ means length(x) $=$length(y).

Now consider the equivalence relation ρ on $\mathbb{Z}\times\mathbb{Z}$ such that $(a,b)\rho(u,v)$ if and only if $av=bu$. We have used only properties of the integers to partition $\mathbb{Z}\times\mathbb{Z}$ into equivalence classes. But the condition we used is identical with the equality of the rational numbers a/b and u/v. We have thus established a bijection, or one-to-one correspondence, between $\mathbb{Q}$ and the equivalence classes of $\mathbb{Z}\times\mathbb{Z}$ under the relation ρ.

For any set S with equivalence relation ρ, the new set whose elements are equivalence classes of S is denoted by S/ρ and called the quotient set of S by the relation ρ. Starting from $\mathbb{Z}$ we have just created the rationals $\mathbb{Q}$ as $(\mathbb{Z}\times\mathbb{Z})/\rho$. The notion of quotient structure frequently arises in physics when we have a group G acting on some set S.

Suppose that G acts transitively on S, that is if Q is a fixed point, and P is any point, there is at least one transformation in G which sends Q to P. The set of all transformations which leave Q fixed is a subgroup H of G—the so-called stabilizer of Q. For any two elements f and g of G we shall say that they are in the relation ρ, that is $f\rho g$, if $fg^{-1}\in H$. We easily prove that ρ is an equivalence relation and that the points of S are in one-to-one correspondence with the elements of G/ρ. Thus the physics of S can be transferred to G/ρ and the symmetries of the physical situation may become more transparent.

When the relation is defined by a subgroup H as above, G/ρ is usually denoted by G/H. Suppose we denote the equivalence class containing g by $\pi(g)$, if g is any element of G. That is π is a mapping from G to G/H, the so-called canonical map. We could ask whether it is possible to impose on G/H a structure of a group in such a way that for any $f,\ g\in G$, $\pi(fg)=\ \pi(f)\pi(g)$. The answer is yes—if and only if H is a normal subgroup of G. A normal subgroup is not only a group but has the additional property that for all $g\in G$, $gHg^{-1}=H$. Further $H=\{g\in G\,|\,\pi(g)=e\}$ where e is the neutral element of the new group G/H. When the subgroup H is not normal, G/H is not a group but is called a homogeneous space on which G acts transitively.

We shall meet below other examples of the use of quotienting as a method of creating new structures.

5. RINGS

A ring like a field consists of a set, R, together with two binary operations which are usually called addition and multiplication. $(R,+,\times)$ is a ring if

(i) $(R,+)$ is a commutative additive group with zero;

(ii) $(R,\times)$ is closed under multiplication and may or may not have a unit;

(iii) multiplication distributes over addition, i.e., $a(x+y)=ax+ay$ for all a, x, and y in R.

We do not require that nonzero elements of R have reciprocals in R, nor that multiplication be commutative or associative, but we do not exclude these properties. Thus a field is a ring but not all rings are fields.

5.1 Examples of Rings

We now list five rings and one "almost ring" which occur frequently in the physics literature.

(a) *The Integers* $\mathbb{Z}$. Perhaps it was this example which led to the emergence of the concept of ring. The integers form a group under addition and are therefore closed under addition and subtraction. They are also closed under multiplication, which distributes over addition. However, the solution, x, of the equation $mx=n$, where $m,n \in \mathbb{Z}$, is not,in general, an element of $\mathbb{Z}$. In contrast with some other rings there are no divisors of zero in the integers. That is you cannot find two integers, neither of which is zero, whose product is zero.

(b) *Square Matrices*. Suppose $A=(a^i_j)$, $B=(b^i_j)$, and $C=(c^i_j)$ are $n\times n$ matrices with entries in a field $\mathbb{F}$; then we define $A+B$ and AB or $A\times B$ to be $n\times n$ matrices whose entries in the ith row and jth column are, respectively, $a^i_j+b^i_j$ and $a^i_k b^k_j$. (Recall the summation convention in the Introduction.) Here $1\leqslant i,j,k \leqslant n$. Let $M_n(\mathbb{F})=M_n$ denote the set of all $n\times n$ matrices with entries in the commutative field $\mathbb{F}$. Then one can verify that $(M_n,+,\times)$ is an associative ring which is noncommutative if $n\geqslant 2$. The zero element of the ring is the matrix all of whose entries are 0, whereas the unit or identity for multiplication is the matrix (δ^i_j) which has 1 on the diagonal and 0 elsewhere.

Notice that if $n=2$,

$$\begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix}\begin{bmatrix} 3 & 7 \\ 0 & 0 \end{bmatrix}=\begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix};$$

thus the ring of square matrices possesses zero divisors.

(c) *Quaternions* were invented by Sir William Rowan Hamilton in order to give a convenient description of rotations in 3-space.

In this section we shall use j,k,s,t as indices with their ranges restricted as follows: $1\leqslant j,\ k \leqslant 3$, and $0\leqslant s,\ t \leqslant 3$. The quaternions, H, form an associative ring with multiplicative identity, $I=e_0$, and contain three elements e_j satisfying the conditions $e_j e_k + e_k e_j = -2\delta_{jk}e_0$, so $e_j^2=-e_0$. Further, $e_j e_k=e_m$ where (j,k,m) is an even permutation of (1,2,3). As a ring, H will contain $e_0+e_0{:}=2e_0$, etc., so that H contains $\mathbb{Z}e_0$. More generally if R denotes any commutative ring, we could assume that H contains Re_0 and note this explicitly by denoting the quaternions as $H(R)$. Hamilton considered only the possibility that $R=\mathbb{R}$, the real numbers, since his concern was rotations in the 3-dimensional space of Newtonian physics—not some esoteric space of super string theory! Over R we can define H by

$$H=\{x^s e_s \mid x^s \in R\}.$$

Then it follows that H is closed under addition and multiplication. If we demand that the associative and distributive properties hold, we obtain a noncommutative associative ring. That it is consistent to demand the preceding properties follows from the fact that they are satisfied by 2×2 matrices with entries in R if we represent e_0 by the identity matrix and e_j by $-i\sigma_j$, where σ_j are the three Pauli matrices:

$$\sigma_1=\begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix},\quad \sigma_2=\begin{bmatrix} 0 & -i \\ i & 0 \end{bmatrix},\quad \sigma_3=\begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}.$$

Thus, if we set $E_0=I$ and $E_j=-i\sigma_j$, we find that

$$X=x^s E_S=\begin{bmatrix} x^0-ix^3 & -x^2-ix^1 \\ x^2-ix^1 & x^0+ix^3 \end{bmatrix},$$

and that if $x^0=0$, then $\det(X)=\delta_{jk}x^j x^k$, which equals the square of the Euclidean length of the vector with components x^j.

If T is any invertible 2×2 matrix and $Y=TXT^{-1}$, then trace of $Y=\mathrm{tr}(Y)=\mathrm{tr}(X)$ and the determinant $\det(Y)=\det(X)$. Since $\mathrm{tr}(X)=x^0$, it follows that $x^0=0$ implies $y^0=0$. Further, $\delta_{jk}x^j x^k=\delta_{jk}y^j y^k$, that is, Euclidean distance is preserved so the transformation from (x^1,x^2,x^3) to (y^1,y^2,y^3) is orthogonal. In particular if $T = \exp(\vartheta\sigma_3) = \cos\vartheta I + \sin\vartheta\sigma_3$, this transformation is a rotation though an angle 2ϑ about the x^3 axis.

If R is a finite commutative ring with m elements, $H(R)$ would be a noncommutative ring with m^4 elements.

When is $H(R)$ a field? Define X' by $X = x^0 I + X'$ and $\bar{X}$ by $\bar{X} = x^0 I - X'$. It then follows that $X\bar{X} = \delta_{st}x^s x^t I$. If $R = \mathbb{R}$, this vanishes only if $X = 0$. Thus $\bar{X}$ divided by $\delta_{st}x^s x^t$ is the reciprocal of X. It is not difficult to verify that $H(\mathbb{R})$ satisfies the requirements of an anticommutative or skew field. This is the field discovered by Hamilton to which we alluded in Sec. 2.2.

(d) *Boolean "Ring".* In studying what he called "The Laws of Thought," George Boole was led to introduce an algebraic structure on the subsets of any fixed set in which union, $\cup$, and intersection, $\cap$, are analogs of addition and multiplication, respectively. The original set acts as the identity for multiplication, and the empty set serves as the zero for addition. The reader can verify that most of the properties of a commutative ring are satisfied by Boole's structure, but a given subset does not have an additive inverse so that $\mathscr{P}(S)$, the set of subsets of S, is not an additive group under the binary operation $\cup$.

(e) *Lie Rings.* Let $(L,+,\circ)$ be a set L together with two binary operators such that $(L,+)$ is an additive commutative group such that the operation $\circ$ distributes over addition, so that

$$x\circ(y+z) = x\circ y + x\circ z.$$

However, the Lie product is neither commutative nor associative but satisfies the properties:

$$x\circ y + y\circ x = 0,$$

and

$$x\circ(y\circ z) + y\circ(z\circ x) + z\circ(x\circ y) = 0.$$

Because of the first of these conditions, we say that the Lie product is anticommutative. The second, which replaces the associativity property of the familiar rings, is referred to as the Jacobi identity. Lie groups are discussed in other articles of this work so we do not go into details here. We merely remark that the elements of a finite dimensional Lie group can be parametrized by continuous real variables and that Sophus Lie associated to such groups what he called an infinitesimal group which is a particular case of a Lie ring. Associativity of multiplication in the group implies the validity of the Jacobi identity in the corresponding Lie ring.

The Jacobi identity can be rewritten in the form

$$z\circ(x\circ y) = (z\circ x)\circ y + x\circ(z\circ y),$$

which is the same as

$$D(x\circ y) = (Dx)\circ y + x\circ(Dy),$$

if we set $Dw = z\circ w$, for fixed z and all $w \in L$. This last equation reminds us of the product rule in calculus, so we say that the linear map D: $w \to z\circ w$ is a derivation of L. The concept of Lie ring, which apparently (Witt, 1937) was first defined by Wilhelm Magnus in 1936, is a generalization of the concept of Lie algebra introduced under the name "infinitesimal group" by Lie and Killing independently before 1880.

(f) *Grassmann Ring.* As a final example of the concept of ring we briefly describe an algebraic structure invented by Hermann Grassmann about 1840 which is basic to the theory of fermions as well as the geometry of many dimensions.

Given a field, $\mathbb{F}$, and a finite vector space $(V,\mathbb{F},+)$ of dimension n, it is possible to define a new vector space, $V^\wedge$, of dimension 2^n over $\mathbb{F}$ and a binary operation, denoted by $\wedge$, called the wedge or Grassmann product, which distributes over addition. $(V^\wedge,\mathbb{F},+,\wedge)$ will be the Grassmann or exterior algebra. In order to define the product $\wedge$, which is the same as that for fermion creation operators in second quantization, we proceed by induction on the grade of homogeneous elements of the algebra. Recall that in the ring $\mathbb{F}[x,y]$ of all polynomials in x and y there are special subspaces such as $ax+by$, or $ax^2+bxy+cy^2$, or $ax^3+bx^2y+cxy^2+dy^3$, of homogeneous elements of dimension 2,3,4, respectively. Any polynomial can be expressed as a sum of homogeneous polynomials, and the summands are unique. It turns out, analogously, that if $\dim(V)=n$, $V^\wedge$ contains $n+1$ subspaces V^p, $0\leqslant p\leqslant n$, such that any element x of $V^\wedge$ can be expressed in precisely one way as $x = \sum_0^n x^p$, where $x^p \in V^p$. An element of V^p is said to be homogeneous of grade p. If x and y are homogeneous of grades p and q, respectively, then $x\wedge y=(-1)^{pq}y\wedge x$ is of grade $p+q$. In particular, $V^0=\mathbb{F}$ and $V^1=V$ by definition. It follows that if x and y are of grade 1 , that is belong to V, $x\wedge y=-y\wedge x$. So if $\mathbb{F}$ has characteristic other than 2 it follows that $x\in V$ implies that $x\wedge x=0$.

If $\{v_i\}$ is a basis of V, the $n(n-1)/2$ elements $v_i\wedge v_j$ for $i<j$ are linearly independent and span the subspace V^2 of $V^\wedge$. Similarly V^3 is spanned by $v_i\wedge v_j\wedge v_k:=(v_i\wedge v_j)\wedge v_k=v_i\wedge(v_j\wedge v_k)$ with $i<j<k$ between 1 and n. The $\dim(V^3)=n(n-1)(n-2)/6$. Proceeding in this way we define all the $n+1$ homogeneous subspaces. As is known, the sum of the coefficients of the nth power of a binomial is $(1+1)^n = 2^n$, so $V^\wedge$ has dimension 2^n.

The preceding terse abstract definition does not immediately suggest that the Grassmann ring is significant for fermion physics. However, this becomes plausible when one realizes that the above basis elements of grade p correspond to the Slater determinants for a system of p electrons which can be formed from a basis set of n linearly independent spin-orbitals.

5.2 Polynomial Rings

For everyday applications there is little doubt that the integers $\mathbb{Z}$ constitute the most important ring which is not also a field. Perhaps the next most important is the ring of polynomials involving one or more variables. Suppose R is any ring; then we consider all expressions of the form $P(x)=a_sx^s$, where $0\leqslant s\leqslant n$, x^s denotes the sth power of the variable x, and $a_s\in R$. If $a_n\neq 0$ we say that $P(x)$ is a polynomial of degree n in x. The set of all such polynomials of arbitrary finite degree will be denoted by $R[x]$. (Note the square bracket which distinguishes the ring from the field $R(x)$ of rational functions.) Assume that the powers of x commute with the elements of R and define addition and multiplication in the obvious way. Then $(R[x],+,\times)$ is a ring which is commutative if and only if R is commutative. For example, if $R=\mathbb{Z}$, $R[x]$ is the ring of all polynomials with integer coefficients. If R is the ring of 2×2 matrices with complex entries, $R[x]$ consists of all 2×2 matrices whose entries are polynomials in x with complex coefficients. In this case the variable is often called λ. The theory of this particular ring is discussed by Turnbull and Aitken (1932), for example, under the title λ-matrices.

An obvious extension of the preceding is to adjoin two or more variables to R. Thus $R[x,y]$ denotes the set of polynomials in x and y with coefficients in R. A term such as $3x^2y^5$, formed by multiplication without addition, is called a monomial. The sum of the powers of x and y is called the degree of the monomial. Thus the degree of the preceding monomial is $2+5 = 7$. Clearly there are 8 different monomials of degree 7 in two variables. Any sum of these with coefficients in R is a homogeneous polynomial in x and y of degree 7. When R is a field we see that the homogeneous polynomials of degree 7 form a linear space of dimension 8.

More generally, it is of considerable interest to determine how many distinct monomials of degree n can be obtained from r variables. It is not difficult to see that the possible such monomials occur as the coefficients of t^n in the expansion of the r-fold product $\Pi(1-x_it)^{-1}$, where $1\leqslant i\leqslant r$ and x_i are distinct variables. Setting all $x_i=1$, we see that the required number is the binomial coefficient $\binom{r+n-1}{n}$.

This is an opportune point at which to explain the concept of a graded ring which appeared in Sec. 5.1(f) and has recently entered quantum physics in connection with supersymmetry. It is clear that any element of $R[x,y]$ is a unique sum of homogeneous terms and that the product of two homogeneous terms of degree p and q, respectively, is homogeneous of degree $p+q$.

A graded ring (R,Σ) is a ring together with a set of grades, Σ, closed under addition, such that R contains special homogeneous elements to which a grade from Σ is assigned; any element of R can be expressed in a unique manner as a sum of homogeneous elements; the product of two homogeneous elements of grade α and β is homogeneous of grade $\alpha+\beta$. For polynomial rings we usually take Σ to be the non-negative integers. For the so-called Laurent polynomials $\mathbb{C}[t,t^{-1}]$, Σ is the set $\mathbb{Z}$ of all integers. For a Grassmann ring of r generators, Σ is the set of non-negative integers. However in that case there are no terms of grade greater than r, and for $0\leqslant n\leqslant r$ the subspace of homogeneous elements of grade n has dimension $\binom{r}{n}$.

5.2.1 Binomial and Multinomial Theorem. For $r \in \mathbb{Z}$, $r \geqslant 0$, $(x+y)^r = C^{\,r}_{n} x^{r-n} y^n$, where n is summed from 0 to r. The binomial coefficients $C^{\,r}_{n}$ satisfy the recurrence relation $C^{\,r+1}_{n} = C^{\,r}_{n} + C^{\,r}_{n-1}$, with which starting from $C^{\,0}_{0} = 1$ we can generate the famous Pascal triangle.

Define $n! := 1 \times 2 \times 3 \ldots \times n$, which we read as "$n$-factorial" or "factorial n." $C^{\,r}_{n}$ is often denoted by $\binom{r}{n}$ and is given by

$$\binom{r}{n} = \frac{r!}{n!(r-n)!}.$$

In this and most other formulas 0! is interpreted as 1.

The binomial coefficient is also the number of subsets of n elements in a set of r elements, or the so-called number of combinations of r things taken n at a time.

In the preceding, r and n are non-negative integers but, as Newton realized, the binomial coefficient can be defined as follows for any real r:

$$\binom{r}{n} = \frac{r(r-1)(r-2)\cdots(r-n+1)}{1 \times 2 \times 3 \ldots \times n}.$$

Here the numerator is a product of n factors which begin with r and are decremented successively by 1. For example with $r = -1$, $\binom{r}{n} = (-1)^n$. Hence,

$$(1-x)^{-1} = 1 + x + x^2 + x^3 \ldots,$$

which is valid when the infinite sum exists, that is if the absolute value of x is less than 1. This form was used in the preceding section to obtain the number of distinct monomials of degree n in r variables, viz. $\binom{-r}{n}$.

The binomial coefficient is a particular case of the multinomial coefficient which arises in powers of sums of more than two variables. Thus,

$$(x_1 + x_2 + \ldots + x_n)^r = C_{r_1, r_2, \ldots, r_n} x_1^{r_1} x_2^{r_2} \ldots x_n^{r_n},$$

where $0 \leqslant r_i \leqslant r$ and the summation is over all $r_i \in \mathbb{N}$ such that $\Sigma r_i = r$. It is not difficult to see that

$$C_{r_1 r_2, \ldots, r_n} = r!/\Pi_i r_i!,$$

with the product for $1 \leqslant i \leqslant n$.

Like the binomial coefficient, to which it specializes when $n = 2$, this number has a combinatorial interpretation which explains its appearance in certain arguments of statistical mechanics. Suppose a set S of r distinct elements is partitioned into the union of n subsets S_i such that S_i contains exactly r_i elements; then there are $C_{r_1, r_2, \ldots, r_n}$ distinct ways in which such a partitioning can be effected.

5.2.2 Fundamental Theorem of Algebra. Since the square of any real number is positive or zero, there is no $x \in R$ such that $x^2 = -1$. Suppose there is a commutative ring R which contains $\mathbb{R}$ and also an element i such that $i^2 = -1$; then R contains all elements of the form $x + iy$, where x and y are arbitrary real numbers. As a ring, together with i, R will contain $-i$. If we require that R has no divisors of zero, since $x^2 + 1 = (x+i)(x-i)$, there are two and only two possible solutions of $x^2 + 1 = 0$, namely, i and $-i$. Further since $(x+iy)(x-iy) = x^2 + y^2 \neq 0$, any element of R of the form $x + iy$ has a reciprocal of the same form. In particular $i^{-1} = -i$. Thus the ring $\mathbb{R}[i]$, generated by the reals together with i, is in fact a field. It is of course the complex numbers which we are denoting by $\mathbb{C}$. Thus any commutative ring R which contains the reals and one solution of the equation $x^2 + 1 = 0$ contains $\mathbb{C}$.

We found $\mathbb{C}$ by starting with $\mathbb{R}$ and demanding that a simple second degree equation have a solution. If one starts with $\mathbb{Z}$ and asks for solutions of equations such as $5x + 7 = 0$, one soon realizes that one needs more numbers than the integers. This leads us to the rationals $\mathbb{Q}$. If, like the ancient Greeks, we ask for solutions of equations such as $x^2 - 3 = 0$, we are forced beyond the rationals and are led to define the reals, $\mathbb{R}$.

The extraordinary property of the complex numbers, first proved by Carl Friedrich Gauss, is that any equation of finite degree, $a_j x^j = 0$, $0 \leqslant j \leqslant n$, whose coefficients a_j belong to $\mathbb{C}$ has a solution which also belongs to $\mathbb{C}$. This result is so important that it has been called the Fundamental Theorem of Algebra. A field $\mathbb{F}$ which contains the zeros of all finite-degree polynomials which can be formed with coefficients in $\mathbb{F}$ is called algebraically closed, as we noted in Sec. 2.2.

If $P(x)$ is a polynomial of degree n with coefficients in a field $\mathbb{F}$ such that $P(\alpha) = 0$ for some $\alpha \in \mathbb{F}$, then one easily proves that $P(x) = (x - \alpha)Q(x)$, where $Q(x)$ is a polynomial of degree $n - 1$. If, like $\mathbb{C}$, $\mathbb{F}$ is algebrically closed, nothing prevents us from continuing this process so that $P(x)=c\Pi_i(x-\alpha_i)$, $0\leqslant i\leqslant n$, if P has degree n, and c is the coefficient of x^n, where the product is over the zeros of $P(x)$. If $\mathbb{F}=\mathbb{R}$ this process will not carry through in general; however, it can be shown that a polynomial with real coefficients can always be expressed as a product of factors of first or second degree with real coefficients.

The Fundamental Theorem of Algebra assures us of the existence of a zero for any polynomial $P(x) \in \mathbb{C}[x]$, but it does not give us an effective procedure for finding such a zero. Indeed, Evariste Galois showed that it is only for polynomials of degree less than five that an explicit formula, analogous to that for solving a quadratic equation, exists. It is worth looking in detail at equations of degree less than 5.

(i) $\deg[P(x)]=1$. Take $P(x)=ax+b$, where $a,b \in \mathbb{F}$ and $a\neq 0$. Then there is a unique zero, $x=-b/a$, which belongs to $\mathbb{F}$.

(ii) $\deg[P(x)]=2$. Take $P(x)=ax^2+2bx+c$, $a\neq 0$, $a,b,c \in \mathbb{F}$. Clearly $P(\alpha)=0$ is equivalent to $aP(\alpha)=0$, but

$$aP(x)=a^2x^2+2abx+ac=(ax+b)^2+ac-b^2.$$

Thus if α is a zero of P, $(a\alpha+b)^2=b^2-ac=D$. To find α it will be necessary to find the square root of D. Since by various choices of a, b, and c, D will vary over the whole of our ground field $\mathbb{F}$, it follows that quadratic equations with coefficients in $\mathbb{F}$ will always have solutions in $\mathbb{F}$ if and only if $\mathbb{F}$ is closed under the operation of taking square roots.

In elementary school we learn to manipulate with square and cube roots and come to take them quite casually. But note that even the world's largest super-computer is not able to find the square root of 2 exactly since it is a nonrecurring decimal. To find it requires an infinite process. In other words, moving from talking about square roots to actually calculating them takes us out of algebra as defined in the Introduction of this essay!

For equations of degree n, if $P(x)=a_jx^j$, $0\leqslant j\leqslant n$, $a_n\neq 0$, we could divide $P(x)$ by a_n, so there is no loss of generality in assuming that $P(x)$ is monic; that is, it has leading coefficient equal to unity. It then follows that if we replace x by $y-b$, where $nb=a_{n-1}$, the resulting polynomial in y has zero as the coefficient of y^{n-1}.

(iii) $\deg[P(x)]=3$. By the preceding argument we may assume that $P(x)=x^3+px+q$. It is easy to see that if $(x-\alpha)^2$ or a higher power of $(x-\alpha)$ divides a polynomial then $x-\alpha$ also divides its derivative. By seeking for a common factor of $P(x)$ and its first derivative we find that two or more of the zeros of $P(x)$ will be equal if and only if $4p^3+27q^2=0$.

This conclusion is valid for p and q belonging to any field, $\mathbb{F}$. If $\mathbb{F}=\mathbb{R}$ we know from a simple graphical argument that $P(x)$ has at least one real zero. If $p,q \in \mathbb{R}$, it is possible to show that the roots will all be real or that there will be one real and two conjugate imaginary roots according as $4p^3+27q^2$ is, respectively, less than or greater than 0. When it is zero all the roots are real and at least two are equal.

It is interesting to note that if $pq\neq 0$, by setting $x=k\cos\vartheta$, the solution of $x^3+px+q=0$ can be obtained by comparison with the identity $4\cos^3\vartheta-3\cos\vartheta-\cos(3\vartheta)=0$. With k and ϑ such that $3k^2+4p=0$ and $pk\cos(3\vartheta)=3q$, the three roots are $k\cos\vartheta$, $k\cos(\vartheta+2\pi/3)$, and $k\cos(\vartheta+4\pi/3)$. When $pq=0$, the solution is trivial.

(iv) $\deg[P(x)]=4$. In this case the solution of the equation $P(x)=0$ can be made to depend on the solution of a so-called resolvent equation of degree 3. Then four zeros are obtained as expressions involving two square roots of rather complicated combinations of the coefficients of $P(x)$ and one zero of the resolvent cubic equation. These formulas are of little theoretical value so we do not display them. Nowadays anyone wanting explicit values for the zeros would obtain them by a computer-implementable algorithm.

There are elegant and deep arguments connecting the solution of equations of degree 5 and 6 with the theory of elliptic functions.

Of course, even for arbitrarily high degree there are particular equations of simple form which have convenient explicit solutions. For example, $x^n=a$ has n solutions: $r\exp(\vartheta+2\pi ki/n)$, $0\leqslant k<n$, with $r>0$ and $r^n\exp(n\vartheta)=a$.

6. ALGEBRAS

The word "algebra" is used in two distinct senses. On the one hand it refers to the subject which the reader began to study with more or less enthusiasm around the age of 13. Recall that when Einstein asked his uncle

"What is algebra?" the latter replied "In algebra you let x be the unknown and then you find x." Bourbaki would not accept this as a satisfactory definition but it started Einstein on the right path. Who knows? Without that initial encouragement we would never have had General Relativity which contains a good deal of algebra!

But *an* algebra also refers to a rather specific type of mathematical structure: a ring, which is also a linear space over some field. It is therefore a very rich structure. As a linear space, an algebra has a dimension—finite or infinite. In quantum mechanics the observables generate an associative algebra of operators on an appropriate Hilbert space, which is finite or infinite over $\mathbb{C}$ depending on the physical system.

As we noted in Sec. 5.1, rings differ among themselves according to whether the "product" is or is not associative or commutative. Because an algebra has linear-space structure and therefore a basis, it is possible to characterize different types of algebras by their structure constants which are defined as follows. Let $\{e_i\}$ be a basis for the algebra over $\mathbb{F}$ and denote the product merely by juxtaposition. Then e_ie_j is a linear combination of the basis such that $e_ie_j= c_{ij}^ke_k$, where the coefficients belong to $\mathbb{F}$. It then follows by linearity that if $x=x^ie_i$ and $y=y^je_j$ are any elements of the algebra, the product:

$$xy=x^iy^jc_{ij}^ke_k=z^ke_k,$$

where

$$z^k=c_{ij}^kx^iy^j.$$

The nature of the product is determined by the structure constants c_{ij}^k. For example, if for all i and j they are antisymmetric in i-j, then $xy+yx=0$, as in a Lie ring [Sec. 5.1(e)].

In understanding and classifying groups there is a class called simple groups with a key role in the sense that they are the building blocks with which other groups are constructed. For complex Lie groups the classification of all possible simple groups was essentially completed by Wilhelm Killing in 1888. The solution of the analogous problem for finite groups was achieved only in 1980 as a result of gigantic efforts over decades by hundreds of mathematicians—undoubtedly one of the truly outstanding intellectual achievements of all time. A simple group is one that contains no normal subgroups other than the full group and the one-element subgroup consisting of the identity. Another way of defining a simple group G is to say that any homomorphism of G into another group either is an isomorphism or sends every element of G onto a single element. Finally, this is the same as saying that if we denote the homomorphism by π then its kernel, $K=\{g\,|\,\pi(g)=e\}$, is either G or $\{e\}$.

The concept of homomorphism—that is, structure-preserving maps—applies to rings and algebras as well as groups. If R and R' are rings and π: $R\to R'$ is a map of R into R' then π is a homomorphism if $\pi(x+y)=\pi(x)+\pi(y)$ and $\pi(xy)=\pi(x)\pi(y)$ for all x and y in R. These are the conditions for a ring-homomorphism. If R is in fact an algebra, then π will also have to satisfy the condition $\pi(\alpha x+\beta y)=\alpha\pi(x)+\beta\pi(y)$, where α and β are in $\mathbb{F}$, if π is to qualify as an algebra-homomorphism. If we then define $K=\{x\in R\,|\,\pi(x)=0\}$, we easily see that K is a subring (or subalgebra) of R. But more! If $x\in K$ and $z\in R$ then both xz and zx belong to K. A subring of R which satisfies this last condition is called an ideal. If K is the kernel of a homomorphism π, and we define an equivalence relation on R by $x\rho y\Leftrightarrow x-y\in K$, then the image $\pi(R)$ is isomorphic to R/ρ. Conversely, if K is an ideal in R there is a homomorphism of R onto R/ρ with K as kernel. A ring (or algebra) is simple if it has no ideals other than $\{0\}$ and itself.

The famous Wedderburn theorem which emerged between 1895 and 1905 asserts that a simple finite-dimensional associative algebra is isomorphic to a complete matrix algebra for some n—that is, the algebra of all $n\times n$ matrices which we considered in Sec. 5.1(b).

6.1 Examples of Algebras

The algebra of $n\times n$ matrices over some field $\mathbb{F}$ to which we have just alluded is undoubtedly one of the most important and useful types of algebras. We mention three other algebras which are widely applied by physicists.

(a) *Frobenius or Group Algebra.* Suppose G is a finite group of order n. We can decree that the elements g_i of G are a basis for a linear space over some field $\mathbb{F}$. Then the set $A=\{x^ig_i\,|\,x^i\in\mathbb{F}\}$ is closed under addition and also under multiplication by elements of $\mathbb{F}$ and therefore is a linear space of dimension equal to the order of G. If $x=x^ig_i$ and $y=y^ig_i$ are arbitrary elements of A, we can define $xy:=x^iy^jg_ig_j=\Sigma_kz^kg_k$, $1\leqslant i, j, k\leqslant n$, where $z^k=c_{ij}^kx^iy^j$. Here, c_{ij}^k is 1 if $g_ig_j=g_k$ and 0 otherwise. With these definitions of addition and multiplication A is an algebra over $\mathbb{F}$. It is named after the Berlin mathematician G. Frobenius who made basic contributions to the theory of group characters, differential equations, and other branches of mathematics.

There is a better way to display the product xy. Denote x^i by $x(g_i)$ so that $x=\Sigma_gx(g)g$ where the sum is over all $g\in G$. It then follows that $xy=\Sigma_gz(g)g$, where $z(g)=\Sigma_hx(h)y(h^{-1}g)$ for fixed g with summation on $h\in G$. Viewed in this way there is a bijection between the elements of A and functions $x(g)$ on G. The sum $x+y$ is mapped onto the function $x(g)+y(g)$, and the product xy onto the convolution, $\Sigma_hx(h)y(h^{-1}g)$, of the functions $x(g)$ and $y(g)$.

Now suppose that G is a continuous group on which there is a concept of volume or measure which is invariant under translation by elements of the group—a so-called Haar measure. Then it is possible to extend the notion of Frobenius algebra from finite to continuous groups where the elements of the algebra are functions on G, addition is point-wise addition of functions, and the product of $x(g)$ and $y(g)$ is the function $\int x(h)y(h^{-1}g)dh$. This convolution of functions occurs in the theory of Fourier and Laplace transforms. A rigorous treatment involves deep problems of continuity, convergence, and measure theory which analysts love. But the algebraic structure is apparent and explains why the idea of convolution is so useful.

(b) *Clifford Algebras* are generalizations of quaternions. They are the E-numbers of Sir A. S. Eddington's Fundamental Theory. They play a key role in relativistic quantum mechanics as the Dirac matrices. They are very useful in the discussion of the orthogonal group in n-dimensions.

Suppose that E_i, $1\leqslant i\leqslant n$, are elements of an associative algebra over the field $\mathbb{F}$ and satisfy the conditions

$$E_iE_j+E_jE_i=2\delta_{ij}I,$$

where the Kronecker delta is 1 if $i=j$ and 0 otherwise and I is the identity of the algebra. Since $E_i^2=I$ and distinct E's anticommute, it follows that the algebra generated by the E's has a basis consisting of I, E_i, E_iE_j, $E_iE_jE_k$,... $1\leqslant i<j<k<...\leqslant n$, and therefore like the Grassmann algebra has dimension 2^n. However, if $X=x^iE_i$ we see that $X^2=\delta_{ij}x^ix^jI$, displaying the Euclidean metric! It follows that if T is any fixed invertible element of the Clifford algebra, the transformation $X\rightarrow TXT^{-1}$ gives rise to a linear transformation of the coordinates x^i under which the metric is invariant. It is therefore an orthogonal transformation.

In the case $n=4$, $2^n=16$ which is the number of entries in a 4×4 matrix. Indeed, there is then a faithful representation of the Clifford algebra by 4×4 matrices among which the Dirac matrices appear in a natural manner.

(c) *Lie Algebras.* A Lie algebra $(L, \mathbb{F}, +, \circ)$, abbreviated as LA, is a Lie ring as defined in Sec. 5.1, which is also a linear space over some field $\mathbb{F}$. As such it could have finite or infinite dimension. The smallest subalgebra of L which contains all the elements of the form $x\circ y$, for $x,y\in L$, is an ideal in L, which we denote by $L\circ L:=L'$. Defining an equivalence relation ρ by $x\rho y\Leftrightarrow x-y\in L'$ leads to a quotient algebra L/ρ which is Abelian; that is the product of any two elements of L/ρ is 0. A Lie algebra is said to be solvable if the descending sequence of subalgebras $L^{p+1}\subset L^p$ where $L^0=L$, $L^1=L'$ and $L^{p+1}=(L^p)'$, terminates in $\{0\}$ in a finite number of steps. Every finite dimensional Lie algebra has a maximal solvable ideal, R, called the radical of L, which is such that the quotient algebra L/R is semisimple—that is, a direct sum of simple LA's. Recall that a simple ring is one with only trivial subideals. Thus simple and solvable Lie algebras are the basic building blocks needed for the analysis of any LA.

The complete classification of simple finite dimensional LA's over $\mathbb{C}$ was obtained by W. Killing (1888) and expounded clearly by Elie Cartan in his thesis (1894). The classification of simple finite dimensional LA's over $\mathbb{R}$ was achieved by Cartan (1913).

The concept of a simple LA was given a far-reaching extension by the Canadian R. V. Moody (1967) and the Russian Victor Kac (1967) quite independently of one another. These infinite dimensional algebras, which are now called Kac–Moody (K-M) algebras, quickly proved to play a key role in fundamental particle theory as does the closely related Virasoro algebra which can be thought of as a set of derivations of a K-M algebra

(Goddard and Olive, 1988). The most accessible K-M algebras are the so-called affine or Euclidean algebras which, together with the finite-dimensional simple algebras, can be classified rather conveniently by means of the Coxeter–Dynkin diagrams, which are exhibited in Table 1. In this table the left-hand column names the finite-dimensional simple algebras and the right-hand column, the affine algebras. These diagrams encode so much useful information that it is worthwhile explaining them in some detail.

Up to isomorphism, a K-M algebra is characterized by a square matrix (a_{ij}), called a Cartan matrix even though it was first defined by Killing, which has the following properties: (i) $a_{ij} \in \mathbb{Z}$, $1 \leqslant i,j \leqslant n$. (ii) $a_{ii}=2$. (iii) For $i \neq j$, $a_{ij} \leqslant 0$ and if $a_{ij}=0$ then $a_{ji}=0$. Then L is a LA generated by $2n$ elements $\{e_i, f_i\}$ satisfying the following conditions: (a) $e_i \circ f_j = h_i \delta_{ij}$; (b) $h_i \circ e_j = a_{ij} e_j$; (c) $h_i \circ f_j = -a_{ij} f_j$; (d) $h_i \circ h_j = 0$; (e) the h_i, $1 \leqslant i \leqslant n$, are linearly independent; (f) $\hat{e}_i^{1-a_{ij}} e_j = \hat{f}_i^{1-a_{ij}} f_j = 0$.

In (f) we use the notation $\hat{x} = ad(x)$ to denote a linear map of L into L defined by $\hat{x}\, y = x \circ y$. The h_i span an Abelian subalgebra, H, called the Cartan subalgebra of L of dimension n, which is also the rank of L. For $h = t^i h_i$, define $\alpha_j(h) = a_{ij} t^i$, so α_j is a linear function on H. Then (b) and (c) imply that $h \circ e_j = \alpha_j(h) e_j$ and $h \circ f_j = -\alpha_j(h) f_j$.

The algebra L is spanned by monomials which are products of the e's and f's but (a)–(d) imply that nonzero products involve only the e's or only the f's or belong to H. The algebra is graded by ascribing a grade α_i to e_i, 0 to $h \in H$, and $-\alpha_i$ to f_i. Hence the possible grades for nonzero elements of L are 0 or $\alpha = k^i \alpha_i$, where the k^i are all non-negative integers, in which case α is said to be positive and noted $\alpha > 0$, or where the k^i are all nonpositive integers, in which case α is negative or $\alpha < 0$. Thus L is a direct sum of homogeneous terms which have positive, negative, or zero grade. That is, $L = L^- \oplus H \oplus L^+$ where L^- is spanned by products of f's and L^+ by products of e's.

The grades form a lattice $k^i \alpha_i$ with $k^i \in \mathbb{Z}$. This lattice is an additive Abelian group, generated by α_i for $1 \leqslant i \leqslant n$, whose elements can be pictured as the points of a crystallographic lattice. The grades for which there is a nonzero homogeneous element of L are called roots and span a sublattice of the lattice of grades. The set of roots other than 0 is generally denoted by Δ which has the obvious partition into the positive and negative roots $\Delta = \Delta^- \cup \Delta^+$, with $\Delta^- = -\Delta^+$. A nonzero element x_α of L with grade α is called an α-root vector.

As mentioned above, the K-M algebras and the simple finite LA's are classified by means of the Coxeter–Dynkin diagrams (CDD) of Table 1. These were first employed by Coxeter (1931) in his study of finite groups generated by reflections and applied by him to LA's in 1934. They were also introduced independently by Dynkin (1946). Bourbaki named them after Dynkin, having first learned about them from Dynkin's important work concerning LA's. It was only in 1949 that Claude Chevalley, a founding member of Bourbaki, learned of Coxeter's papers from the author of the present article.

In 1888 or earlier, Killing noticed that the operation S_i: $\alpha \to \alpha - \alpha(h_i)\alpha_i$ effects a permutation of Δ such that $S_i^2 = I$. The n operations S_i, $1 \leqslant i \leqslant n$, generate a group which is now usually called the Weyl group because in 1923 Hermann Weyl popularized a particular representation of this group. I prefer to call it the Killing–Weyl group. A particular element of this group, $R = S_1 S_2 S_3 \ldots S_n$, which is usually called the Coxeter transformation, was used by Killing to effect the classification of the finite simple LA's over $\mathbb{C}$. He exhibited the orders of all the "Coxeter" transformations some years before Coxeter was born. It is perhaps only fair to follow B. Kostant's usage (1959) and call this operator the Killing–Coxeter transformation. The order of the R associated with a simple LA on the LHS of Table 1 is the sum of the digits appearing on the diagram immediately to the right. For example, the order of $R(G_2)$ is $1+2+3=6$. The Killing–Coxeter transformation is discussed in Coleman (1989), where additional references may be found.

The CDD gives the Cartan matrix (a_{ij}) and also the relations among the generators of the Killing–Weyl group for the corresponding LA. The nodes of the diagram are numbered by the indices 1 to n for the finite algebras and 0 to n for the affine algebras. A branch between i and j indicates that a_{ij} and a_{ji} are different from zero and, therefore, both are negative integers. A simple branch indicates that the product $a_{ij} a_{ji}$ is 1 and, therefore, each factor is -1; a double branch indicates that the

product is 2, so the factors are -1 and -2; a triple branch indicates that the factors are -1 and -3. An arrow pointing from i to j indicates that a_{ij} is numerically larger than a_{ji}. Thus in the graph G_2, $a_{12}=-3$ and $a_{21}=-1$. The symbols A_n, B_n, C_n, D_n were introduced by Killing and Cartan to denote the four infinite classes of Lie algebras corresponding, respectively, to $SL(n+1)$, the general linear group on $n+1$ variables with determinant 1; the orthogonal group on $2n+1$ variables; the symplectic group on $2n$ variables; and the orthogonal group on $2n$ variables. E, F, G denote the exceptional LA's and the subscripts 2,4,6,7,8,n denote the rank of the algebra. For the finite algebras their dimension is noted in Table 1 under the name of the algebra. The left-hand column thus encodes the Cartan matrix for all the finite simple LA's.

But these diagrams also enable us to infer the relations among n or $n+1$ generators, S_i, of the Killing–Weyl group of the finite simple LA's or the affine algebras. $S_i^2 = I$, and for $i \neq j$, $(S_iS_j)p=\mathrm{I}$, where p equals 2, 3, 4, or 6 according as the i-node and the j-node are joined by a 0-, 1-, 2-, or 3-fold branch. For the simple LA's in the first column the determinants of the Cartan matrix and of all its principal subminors are strictly positive, whereas for the matrices in the second column the determinant of the matrix itself is zero but those of all principal subminors, positive. This corresponds to the fact that can be observed from the diagrams that if one node is removed from a diagram in the second column we obtain one or two diagrams of the first column. From this we infer immediately a class of finite semisimple LA's which are subalgebras of the affine algebras.

An open node is numbered 0 and the others retain their numbers from the diagram immediately to the left. The numbers attached to the nodes of the affine diagrams are the coefficients of the canonical null-root of the affine algebra. The affine algebras have infinite dimension, Killing–Weyl groups of infinite order, and an infinite number of roots. The dimension of a root space is finite and called the root multiplicity. Roots are distinguished according as they are in the orbit under the K-W group of a simple root α_i or not. The former are called real, the latter, imaginary. The real roots all have multiplicity 1, whereas imaginary roots can have arbitrarily high finite multiplicity.

By the height, ht(α), of the positive root $\alpha = k^i\alpha_i$ we mean Σk^i. A finite dimensional simple LA has a unique root of greatest height which can be read from Table 1. The numbers attached to nodes 1 to n in the diagram X_n^1 give the coefficients of α_i for the root of greatest height in the corresponding finite algebra X_n. Thus $\alpha = 2\alpha_1+3\alpha_2+4\alpha_3+2\alpha_4$ is the highest root of $\Delta(F_4)$.

We should note that some authors use the symbols $A_2^{(2)}$, $D_4^{(3)}$, $E_6^{(2)}$, $D_{n+1}^{(2)}$, $A_{2n}^{(2)}$, and A_{2n-1}^2 for our algebras A_1^2, G_2^3, F_4^2, B_n^2, BC_n^2, and C_n^2, respectively.

7. MODULES

So far we have not discussed exact sequences, commutative diagrams, or the game called diagram chasing which have played an increasingly important role in algebra in recent decades. The theory of modules provides a convenient context in which to introduce these ideas and is also significant in its own right.

Recall that a linear space is an additive group $(V,+)$, which is closed under multiplication by elements of a field $\mathbb{F}$ (usually commutative). We frequently denote the space $(V,\mathbb{F},+,\times)$ by V. A module is an additive group $(M,+)$ which is closed under multiplication by elements of a ring, R (often noncommutative). Frequently, when the context is clear, a module $(M,R,+,\times)$ is denoted by M. Essential conditions in the definition of an R-module M are that for $r \in R$, and $m_1,m_2 \in M$, (i) $rm_1 \in M$, (ii) $r(m_1+m_2) = rm_1+rm_2$.

7.1 Examples of Modules

(a) Suppose $R=\mathbb{Z}$ and $M=\{3n \mid n \in \mathbb{Z}\}=3\mathbb{Z}$. Clearly M is an additive group. Define the action of R on M as multiplication of integers. Obviously, if $n,m \in \mathbb{Z}$, $3n \in M$ and $m(3n) = 3mn \in M$.

(b) Let $M=\mathbb{Z}/3\mathbb{Z}:=\mathbb{Z}_3$. M has three elements which we could denote [0], [1], and [2]. For example $[1]=\{..-5,-2,1,4,7,...\}$. Take $R=\mathbb{Z}$. For $n \in R$ and $m \in \{0,1,2\}$, define $n[m]=[nm]$. For example, $7[2]=[14]=[2+3\times 4]=[2]$. We easily check that M is an R-module.

(c) For the physicist perhaps the most important example of a module occurs when R is the Frobenius algebra of a group G and M is a linear space over $\mathbb{R}$ or $\mathbb{C}$. In this case the action of R on M is called a linear representation of G. This example will be treated in other articles in this *Encyclopedia.* Of course it was via the representations of groups that Hermann Weyl and Eugene Wigner introduced the "group pest" into physics around 1930. The algebraization of physics then took a dramatic leap forward, and we were able to understand the periodic table, relativistic wave equations, and the classification of fundamental particles.

7.2 Morphisms of Modules

A mapping f: $M_1 \to M_2$ of one R-module into another could merely map one set into the other set. As such it could be (i) injective, such that $x \neq y \Leftrightarrow f(x) \neq f(y)$, (ii) surjective such that for each $y \in M_2$ there is an $x \in M_1$ for which $f(x)=y$, or (iii) bijective, that is both injective and surjective—or, one-to-one and onto. However, f might also have the property that for all $x,y \in M_1$, $f(x+y) = f(x)+f(y)$. We would then say that f is a homomorphism, or, now more frequently, simply, a morphism of additive groups. Even better, f might not only be a morphism of additive groups but also have the property $f(rm)=rf(m)$ for all $r \in R$ and $m \in M_1$. It would then have the distinction of being called an R-module morphism.

The kernel $K=\{x \in M_1 \mid f(x)=0\}$ of an R-module morphism f is an R-submodule of M_1. The image or range of f, $f(M_1) \subset M_2$, is an R-submodule of M_2 and is isomorphic to the quotient module M_1/K. When f is surjective, this situation is now frequently described by saying that the following diagram portrays an exact sequence of mappings:

$$0 \to K \to M_1 \xrightarrow{f} M_2 \to 0.$$

The preceding statement presupposes that the reader realizes that given our context (i) an arrow denotes a morphism of R-modules, (ii) the sequence is exact at K, M_1, and M_2. By exact is meant that the image of an incoming morphism is the kernel of the outgoing morphism. Hence, (i) the mapping from K to M_1 is injective since its kernel is 0, (ii) the mapping f is surjective since its image must be the whole of M_2 because this is the kernel of the final map. Since f is an R-module morphism the diagram implies that $M_2=f(M_1)=M_1/K$.

Though we chose to introduce the concept of an exact sequence for modules, it has wider application. Consider the diagram:

$$1 \to K \to G \to H \to 1,$$

where now the arrows represent homorphism of groups. Then if the sequence is exact, K is injected into G and can be identified with the normal subgroup of G which is the kernel of the map from G to H. We conclude that H is isomorphic to G/K. So this particular exact sequence encapsulates the familiar and basic First Isomorphism Theorem of group theory.

Returning to modules or additive groups for which the neutral element is denoted by 0, we see that for any exact sequence:

$$\dots \xrightarrow{\partial_{n-3}} M_{n-2} \xrightarrow{\partial_{n-2}} M_{n-1} \xrightarrow{\partial_{n-1}} M_n \xrightarrow{\partial_n}$$

$$M_{n+1} \xrightarrow{\partial_{n+1}} M_{n+2} \xrightarrow{\partial_{n+2}} \dots,$$

$\partial_{n+1}\partial_n M_n=0$, since $\partial_n M_n$ is the kernel of ∂_{n+1} and is mapped onto 0.

A topologist will inevitably recall that the boundary of a boundary is empty; a physicist will recall that the curl of a gradient is zero and that the divergence of a curl is zero. Indeed, these observations are the key to the algebraization of topology and of differential forms which led to homology and cohomology theory. The algebraic core of these topics has proliferated as Homological Algebra in which exact sequences and commutative diagrams are rampant.

Diagrams of maps can become quite complex and frequently admit two or more paths from object A to object B. If for all pairs A and B the compositions of maps along all different paths from A to B are identical, the diagram is said to be commutative. The game, art, or science of diagram chasing is the process of verifying that a given diagram is or is not commutative. Here, finally, is a simple but important example of a commutative diagram. It illustrates a method now widely used by algebraists to define universal objects.

Suppose G and $\hat{G}$ are given topological groups and $\pi: \hat{G} \to G$ a given homomorphism of $\hat{G}$ onto G. Suppose further that for any group H and any homomorphism τ such that $\tau(H)=G$ there exists a homomorphism σ which makes the accompanying diagram commutative.

$$\begin{tikzcd}
H & \hat{G} \arrow[l, "\sigma"'] \arrow[d, "\pi"] \\
 & G \arrow[from=1-1, "\tau"']
\end{tikzcd}\,.$$

Then $\hat{G}$ is the universal covering group of G, the kernel K of π is the Poincaré group of G, and the cardinality of K is the connectivity index of G. An example of this, which "explains" the occurrence of spin in physics, is that if G were SO(3) then $\hat{G}$ would be isomorphic to SU(2).

GLOSSARY

This article contains so many words which may be unfamiliar to the reader that if we gave their definition here the glossary would be almost as long as the article. Therefore, we list the most important concepts followed by the section number in which the concept can be found.

INTRODUCTION

The worldwide production of aluminum and its alloys exceeds that of any other metal except iron and its alloys. This economic significance and the widespread application of aluminum in transportation, defense, containers, utensils, construction, and electrical and electronic devices make aluminum one of the most important materials. Yet compared to steel, copper, zinc, and other common metals, aluminum is a relative newcomer. Worldwide production of aluminum at the beginning of this century was only six thousand tons per year, which is almost four orders of magnitude less than current production. The start of the commercial production of aluminum, a little over a century ago, was brought about by simultaneous discovery, by Hall in the USA and Héroult in France, of a suitable molten salt solvent for aluminum oxide, permitting the electrolytic generation of aluminum in what have become known as Hall–Héroult cells. This, coupled with a rapidly growing availability of electricity in the late nineteenth century, led to the establishment of the aluminum industry.

That industry has profited from the suitability of aluminum for a number of uses, ranging from cooking utensils through electrical wiring to aircraft alloys. This suitability arises from aluminum's low density, high electrical conductivity, and good corrosion resistance (see Table 1). The metal is usually regarded as having inferior mechanical properties to steel (at least in applications where density is a secondary consideration) but is superior to most other metals in this respect, particularly when alloyed with magnesium, silicon or lithium. The real cost of aluminum has declined by a factor of approximately one quarter in this century, but it is still significantly more expensive than other structural

Viscosity	0.0012 kg m^{-1} s^{-1} at 933.5 K

materials (such as steel or reinforced concrete) in large part due to the amount of electrical energy used in its production. That energy has declined (on a unit mass basis) by a factor of more than one half over this century and further improvements can be anticipated. Nevertheless, expansion in the production of aluminum is occurring in countries with abundant supplies of inexpensive electrical energy.

The present article emphasizes the physical metallurgy and production of aluminum. Its scope includes the uses of this metal and its alloys; its physical and mechanical properties (crystal structure, density, electrical conductivity, elasticity, strength, ductility, fracture, fatigue, and corrosion); its occurrence in nature as bauxite, the production of aluminum oxide from bauxite by the Bayer process and the subsequent electrochemical reduction of the oxide in Hall–Héroult cells; alloying, casting, rolling and extrusion of the metal; and environmental, occupational, legal, and economic issues concerning aluminum.

1. PROPERTIES AND CHARACTERIZATION

Aluminum, in the broad sense of the metal and its alloys, is among the most widely used of engineering materials. The industry that is concerned with its manufacture and fabrication is among the largest of the basic metals industries. There are literally hundreds of aluminum alloys and product forms in daily commercial use. Their designations and properties are tabulated in a number of reference works [for example, Hatch (1985)]. This section is intended to provide a brief summary of the principal engineering uses of aluminum and its alloys, the properties that govern those uses, the microstructures that determine those properties, and the metallurgical characteristics of aluminum and its alloys that make it possible to achieve those microstructures.

1.1 The Engineering Uses of Aluminum and its Alloys

Most of the commercial applications of aluminum and its alloys exploit one or more of four important properties of aluminum: low density, ductility, corrosion resistance, and electrical and thermal conductivity. With some license the commercial applications can be gathered under the following four headings.

1.1.1 Containers and Utensils. This group of products includes such items as beverage cans, aluminum foil, cooking utensils, and small appliances. The first two, beverage cans and aluminum foil, constitute very large markets for aluminum; the current (1988) domestic consumption of beverage cans alone is approximately 80 billion units per year, of which 98% are presently made of aluminum. The property that permits aluminum alloys to dominate these markets is its ductility (formability), which allows it to be rolled into thin sheets or foil and deep-drawn into thin-walled containers. Density and corrosion resistance are also relevant; aluminum cans are lightweight, which minimizes transportation costs, and can be made relatively inert to most common foods and beverages so that the product does not acquire the taste of the container. Aluminum is attractive for cooking utensils because of its good thermal conductivity, low density, and corrosion resistance, and is attractive for both utensils and small appliances because of its formability. However, aluminum is chemically attacked by some cooking media, and may slightly contaminate the food. The most common problem is a slight metallic taste.

1.1.2 Construction. Aluminum alloys are widely used on the exteriors of buildings because of their resistance to corrosion. Their low density is also an advantage. For purely structural uses, however, their relatively high cost and low strength are competitive disadvantages with respect to structural steel and concrete.

1.1.3 Aerospace and Transportation. Aluminum alloys have been the dominant structural materials in both commercial and military aircraft for more than 50 years. They are advantageous with respect to other metals because of their low density, their formability, and their damage tolerance. In recent years aluminum alloys have been replaced in some important parts of aircraft structures by fiber-reinforced epoxy composite materials. These materials offer lower density, higher elastic moduli, and higher strength (at least in the fiber direction) but are relatively expensive and have low damage tolerance. The aluminum industry has countered the challenge of composites by developing new ingot alloys, such as the modern aluminum-lithium alloys, that offer lower density and higher moduli, and aluminum-matrix composite materials, such as Al-SiC whisker composites and aluminum-polymer fiber laminates, that provide a combination of the properties of aluminum alloys and fiber composites. Aluminum is less widely used in terrestrial vehicles, primarily because of its high cost relative to steel, but is used in an increasing variety of specific applications where its low density and corrosion resistance offer compensating advantages. There is a growing demand for structural materials for cryogenic aerospace systems, such as tankage for liquid hydrogen and oxygen fuel. Aluminum alloys are the dominant candidates for these structures because of their low density, their relatively low permeability and sensitivity to hydrogen, and their excellent toughness at cryogenic temperatures. There is also a growing demand for lightweight materials that can be used at moderate to elevated temperatures in automotive and aircraft engines and in the structures and external skins of hypersonic vehicles, which reach high temperature in flight. New aluminum alloys have been created for use at moderate temperature. There is active research on aluminum intermetallic compounds to achieve good structural properties at elevated temperatures.

1.1.4 Electronics. While the conductivity of pure aluminum is less than that of copper or gold, its good conductivity and relatively low cost have led to its wide use in electrical wiring. In addition, aluminum is the most common conductor for electrical lines on semiconductor chips. In this case it is deposited as a thin film either in pure form or lightly alloyed with copper or, sometimes, with copper and silicon. Aluminum is also widely used in electronic packaging, and in specific applications in microelectronics such as substrates for memory disks.

Pure aluminum is a superconductor with a maximum superconducting transition temperature (T_c) of 1.2 K, which is too low for practical applications. However, aluminum forms intermetallics with the A15 crystal structure, Nb_3Al and $Nb_3(Al,Ge)$ that have superconducting critical temperatures near 20 K and critical fields near 40 T, at 4.2 K, which are among the best properties obtainable with A15 superconductors. These compounds also offer exceptional critical current at 4.2 K in fields above 20 T. Their drawback is a manufacturing difficulty. The "bronze process" that is commonly used to manufacture multifilamentary wire of Nb_3Sn and V_3Ga is inapplicable to Nb_3Al and $Nb_3(Al,Ge)$. Rapid solidification and powder processes have been used with some success in the manufacture of Nb_3Al superconducting wire for use in the windings of high-field superconducting magnets.

While pure aluminum is not currently useful as a superconductor, its low residual resistivity at cryogenic temperatures makes it useful as a cryoconductor in conventional circuits at temperatures of 77 K or below. The combination of low density and high conductivity at low temperature make it particularly useful as a cryoconductor in electronic circuits in space vehicles.

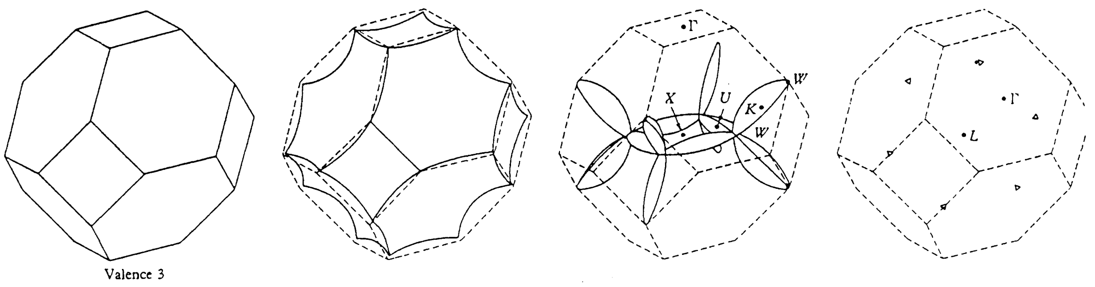

FIG. 1. Free-electron sphere for an fcc metal with valence 3, after Harrison (1960). The surfaces in the third and fourth zones are displaced by half a reciprocal lattice vector in the directions ΓX and ΓL, respectively, to better illustrate their forms.

As indicated by the applications listed above, the properties of aluminum and its alloys that have the greatest technological significance are its density, electrical conductivity, mechanical properties, and corrosion resistance. These are discussed in turn.

1.2 Crystal Structure, Density, and Electron States

Aluminum is the second element in group IIIB of the periodic table. Its crystal structure is face-centered cubic (fcc), both in the pure state and in all alloys in which it is the primary constituent. The lattice parameter of the fcc cell is 0.41 nm at 298 K, which corresponds to an atomic diameter of 0.29 nm. The density of pure aluminum is approximately 2700 kg m^{-3}, which is the lowest value of any cubic material that is useful as a structural metal. The density increases with the addition of most common alloying elements, but is decreased by alloying with the light elements Li, Be, and Mg, which makes these particularly desirable alloy additions in aerospace materials. The most effective of these alloy additions is Li; commercial Al-Li-Cu and Al-Li-Mg aerospace alloys have densities significantly below that of pure aluminum.

Aluminum behaves as a classic free-electron metal, and, as a consequence, is discussed in some detail as the prototype example of a trivalent metal in many treatments of the physical properties of metals (for example, Ashcroft and Mermin, 1976; Heine, 1969; Shoenberg, 1969; Alonso and March, 1989). In keeping with its nearly free-electron character the electron density of states is almost perfectly parabolic up to the Fermi energy. The electron states and many of the physical properties of the pure metal can be calculated with considerable accuracy using pseudopotential and other theoretical techniques (Harrison, 1966; Heine, 1969; Shoenberg, 1969; Hafner, 1989).

The Fermi surface of pure aluminum is almost, but not quite, a free-electron sphere, and is drawn and discussed by Ashcroft and Mermin (1976) and by Shoenberg (1969), among others. In an fcc crystal with valence 3 a free-electron sphere fills the first Brillouin zone, and partly fills the second, third, and fourth, as shown in Fig. 1. The portion of the Fermi surface in the third Brillouin zone forms an interconnected figure of thin, cigar-shaped elements, that is commonly called the "monster." The fourth Brillouin zone contains small, isolated elements of the Fermi surface. In fact, small deviations from ideal free-electron behavior in aluminum eliminate the segments of Fermi surface in the fourth Brillouin zone and break the "monster" in the third Brillouin zone into disconnected "rings of four," as shown in Fig. 2.

The complicated shape of the Fermi surface in the third Brillouin zone is reflected in a complex orientation dependence of the very low de Haas–van Alphen frequencies of aluminum (Shoenberg, 1969). The unfilled state of the second Brillouin zone dominates the high-field Hall effect in aluminum, which behaves as if it had one hole per atom rather than three electrons (Ashcroft and Mermin, 1976).

1.3 Electrical Conductivity

The electrical properties of aluminum are dominated by its crystal structure and metallic bonding, and resemble those of the fcc

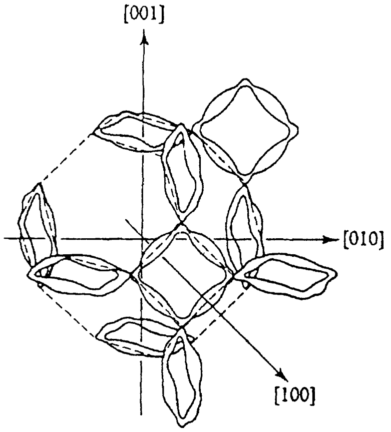

FIG. 2. The "ring of four" shape of the Fermi surface of Al in the third Brillouin zone (after Shoenberg, 1969).

metals Cu, Ag, and Au more than those of the nearby group IIIB elements B, Ga, and In. The electrical resistivity of ultrahigh-purity aluminum is 2.65 $\mu\Omega$ cm at 293 K, and varies approximately linearly with T with a slope $d\rho/dT \sim 0.011$ $\mu\Omega$ cm K^{-1} near room temperature. Its conductivity (reciprocal of the resistivity) is about 60% that of copper and 80% that of gold. As in all metals, the resistivity of aluminum increases with alloy content and is very sensitive to purity at low temperature. The resistivity is isotropic and remains nearly so in deformed samples; it is only slightly affected by grain size and dislocation density. The conductivity of aluminum is high enough to justify its use in electrical wiring, in which it is employed in nearly pure form to maximize its conductivity, and in thin film interconnects in microelectronic devices, in which it is often alloyed with copper or silicon.

The advantage of aluminum for thin film interconnects is the ease with which it can be deposited as a thin film and the relative ease with which it can be processed and etched into controlled complex geometries (Fraser, 1983). However, Al does form a eutectic with silicon. As a consequence it is often lightly alloyed with silicon to decrease reactivity at the interface or is deposited as a composite film that includes a thin diffusion barrier layer, such as W or TiN, that separates it from the silicon substrate. Aluminum interconnects are also liable to electromigration failures in service (d'Heurle and Ho, 1978). While the mechanism of electromigration failure is incompletely understood, it involves the rupture of the aluminum line through the growth of cracks or voids. The electric current contributes to void growth by increasing the effective self-diffusion constant. Electromigration failure is inhibited by the addition of copper, although the mechanism is not yet clear. Electromigration can also be inhibited by depositing a composite film in which thin layers of aluminum are separated by a diffusion barrier layer that prevents the line from rupturing by void growth. However, the increased thickness of the composite film limits miniaturization of the device.

1.4 Mechanical Properties

The important mechanical properties of aluminum alloys include their elasticity, strength, and ductility, and resistance to failure by fatigue and fracture. The mechanical properties of aluminum alloys govern both their formability into practical shapes and their mechanical performance in service and have, therefore, been the subject of extensive research and development.

1.4.1 Elasticity. Pure aluminum is nearly isotropic in its elastic properties. Its tensile (Young's) modulus at ambient temperature (E) is 69 GPa, which is about one-third the modulus of iron, and the value of Poisson's ratio is $\nu = 0.34$. The modulus is increased by most alloy additions to aluminum. However, the increase per unit of alloying element is relatively small except in the case of lithium; commercial Al-Li alloys have tensile moduli more than 10% above that of pure Al. The modulus can be increased further by introducing whiskers or fibers of high-modulus materials such as SiC.

1.4.2 Strength. Many of the structural uses of aluminum alloys are limited by a relatively low yield strength. It is difficult to increase the strength to values that resemble those of the steels and titanium alloys with which aluminum often competes, for two inherent reasons. First, the yield strength of a metal or alloy, with a given microstructure, scales very nearly with its elastic modulus. Since the elastic moduli of aluminum alloys are much lower than those of structural steels and Ti alloys, aluminum alloys are weaker even when they are tailored metallurgically to have similar microstructures. Second, the microstructures of high-strength steels and Ti alloys are generated, in part, through the creative use of the structural phase transformations that both materials undergo on cooling. There is no parallel transformation in the aluminum system.

The principal strengthening mechanisms that are available for use in aluminum alloys include solution hardening, work hardening, grain refinement, and precipitation hardening. In many alloys several mechanisms are used simultaneously.

The most important solution strengthening element in Al alloys is Mg. Mg is believed to strengthen the Al matrix in two ways: fixed Mg atoms act as obstacles to dislocation motion, and Mg also tends to segregate to dislocations, impeding their motion. All aluminum alloys can be strengthened by work hardening; however, the increased strength is often achieved at the price of a significant loss in ductility. Solution-strengthened Al-Mg alloys respond particularly to work hardening; the Mg addition inhibits the agglomeration of dislocations into cells or tangles during deformation so that it is possible to attain much higher dislocation densities. Al-Mn alloys, such as those used in the deep-drawing of beverage cans, also respond well to work hardening; their properties are due in part to a dense dispersion of Mn-based phases that form at high temperature and are retained.

Grain refinement is also used to strengthen Al alloys. Since there is no structural phase transition in the system the grain size is controlled by recrystallization treatments. However, since grain boundaries in Al alloys tend to be weak because of the accumulation of impurities or large precipitate particles, it is often preferable to adjust the alloy so that recrystallization and grain growth are impeded and a fine subgrain structure is created by recovery of the dislocations introduced at high temperature. The subgrains contribute to alloy strength very much as grain boundaries do. Alloy additions that form small, stable particles in the microstructure, such as Mn, Cr, Zr, and Sc, are particularly useful for inhibiting grain growth and controlling the grain and subgrain size after thermomechanical treatment.

Precipitation hardening is the most important of the strengthening mechanisms that are used in Al alloys. The alloys that can be hardened in this way are called "heat-treatable," and include most of the important structural and aerospace alloys. The common alloy additions that lead to controllable precipitates include Cu, Mg, Zn, and Li. While these alloying elements form equilibrium intermetallic phases with Al, the maximum strengthening is ordinarily not associated with the equilibrium phases, but with small, coherent metastable precipitates that appear at a relatively early stage in the precipitation process.

The most thoroughly studied of the precipitation sequences is that in Al-Cu. In the Al-Cu case the initial precipitate (and the one responsible for age hardening at room temperature) is a Guinier–Preston zone designated GP(1), which consists of disk-shaped copper-rich layers on {100} planes. On aging at higher temperature these particles are replaced by a different, multilayer zone, called GP(2) (whose structure is still not entirely clear), which is the predominant precipitate at peak hardness. Further aging creates the transient precipitate θ', which is a coherent modification of the incoherent, equilibrium precipitate phase $\theta(\mathrm{CuAl_2})$. A qualitatively similar behavior is observed in the other alloy systems. Al-Li is a special case that is hardened by the coherent, metastable precipitate $\delta'(\mathrm{Al_3Li})$, which is a well-defined phase in the strengthening precipitates at peak hardness. However, the high-strength aerospace alloys also contain significant concentrations of Cu, Mg, and Zr, and gain most of their strength from fine, coherent precipitates based on their combinations with Al and Li.

1.4.3 Ductility. To ensure ductility an alloy should have a high work hardening rate compared to its strength, because plastic instability occurs when the work hardening rate becomes comparable to the flow stress, and it should be free of large inclusions, precipitate particles, or zones of weakness that may initiate voids that cause early rupture. Solution-hardened alloys generally have good ductility, partly because of their relatively low strength. Precipitation-hardened alloys must be carefully engineered to achieve good ductility. The best properties are obtained when the alloy is aged below or to peak strength since over-aging leads to the formation of large, equilibrium precipitates, particularly in grain boundaries, that lead to premature rupture. The precipitates should be such that dislocations loop around them rather than shearing through them, since the planar slip that is associated with precipitate shearing leads to stress concentrations and relatively low work-hardening rates. It is also important to avoid precipitate-free zones near grain boundaries due to preferential precipitation on the boundary itself, since these constitute layers of weakness that lead to premature rupture. Given these considerations, precipitation-hardened alloys with good ductility are usually aged to near peak strength, adjusted in chemistry so that the dominant precipitate is mechanically hard and nonspherical in its morphology, and carefully heat treated or deformed prior to aging to eliminate precipitate-free zones.

One of the most important reasons to seek good ductility is in forming. Formability generally requires isotropy in plastic deformation; anisotropy causes wrinkling or "earing" (uneven elongation along the edges) in formed parts. The isotropy of plastic deformation is controlled by the crystallographic texture, or tendency for the grains of the metal to align their crystallographic axes. There are two important sources of texture in Al alloys: deformation, which invariably forces some crystallographic correlation between the grains of a polygranular microstructure, and recrystallization, in which new grains grow with a preferential crystallographic alignment to one another. The recrystallization and deformation textures are generally different, and can both be modified by altering the chemical composition. Moreover, the final texture can be adjusted by careful processing that mixes recrystallization and deformation steps so that their textures balance; this is a major objective of the rather elaborate processing that is used in the manufacture of Al sheet for beverage cans.

Several important aerospace aluminum alloys can be processed so that they become superplastic at elevated temperature and can be formed directly into complex shapes. The superplastic state is achieved by modifying the microstructure to obtain a very fine grain size that is preserved during deformation. In Al alloys this is most easily accomplished by adding alloying elements such as Cr, Ca, Zr, or Sc that create small, stable particles that inhibit grain boundary migration and, hence, stabilize a very fine grain size in recrystallized material.

1.4.4 Fracture and Fatigue. The fracture toughness of a material is controlled to first order by its fracture mode. Typical aluminum alloys fracture in one of three basic modes: ductile rupture by the formation and coalescence of voids in the microstructure, ductile rupture through plastic instability in shear, or intergranular fracture through separation on weakened grain boundaries. In the latter case the toughness is very low. Alloys that exhibit this fracture mode must be metallurgically modified to eliminate it in order to obtain high toughness. Intergranular fracture can be minimized by eliminating contaminants, such as the alkali metals, that embrittle the grain boundaries, by controlled processing to prevent the formation of precipitate-free zones or large precipitate particles along the grain boundaries, or by elongating the grains so that no continuous intergranular paths exist perpendicular to the applied load.

When the fracture mode is basically ductile the toughness of the alloy is controlled, first, by the distribution of inclusions that may nucleate voids. The predominant inclusions are large second-phase particles that are particularly likely to reside at grain boundaries. Since the most prominent and deleterious of these often include Fe and Si, the contents of these elements are carefully controlled in alloys that are designed for high fracture toughness. A second major source of inclusion particles that decrease toughness is the equilibrium precipitation that occurs on grain boundaries, especially in overaged alloys. To inhibit intergranular precipitation, alloys that are meant to have high toughness are often used in a slightly underaged condition. Precipitate-free zones near grain boundaries can also lead to early failure, and are minimized by mechanical deformation prior to precipitation to create a dense distribution of preferential nucleation sites near the boundary. When sources of premature fracture are eliminated the toughness is controlled by the inherent ductility of the alloy, which can be influenced by modifying the composition and the type and distribution of the hardening precipitates to control the strength and the work hardening rate.

The fatigue properties of aluminum alloys differ from those of steel in that Al alloys do not exhibit a fatigue limit in cyclic fatigue tests on smooth-bar specimens. Hence fatigue-resistant structures of Al alloys must be designed against crack growth to failure. The fatigue crack growth behavior of Al alloys is somewhat sensitive to composition; for example, Al-Cu-Mg alloys exhibit somewhat lower fatigue crack growth rates than Al-Zn-Mg alloys and are preferred for certain applications in aerospace systems for this reason. However, the most significant improvements in fatigue crack growth resistance occur in alloys, such as several of the Al-Li grades, whose microstructures are anisotropic and tailored so that propagating fatigue cracks blunt or branch at microstructural barriers such as perpendicular grain boundaries. The fatigue crack growth rate at very high stress intensity values is controlled by the fracture toughness.

Aluminum-based structural composites can have very good crack growth resistance when the second phase in the composite blunts or deflects growing cracks. New composites in which aluminum and polymer layers alternate have particularly good fatigue resistance.

1.5 Corrosion

Many of the important uses of Al alloys in structures and containers are motivated by its outstanding corrosion resistance in most common environments. It is important to recognize, however, that the corrosion resistance of aluminum is not due to any inherent inertness of the metal itself (it is among the most reactive of all metals) but to the fact that it forms a very stable and impermeable coherent oxide coating on exposure to the environment which shields it from further attack. In effect, aluminum paints itself. While this behavior makes aluminum alloys very suitable for use in many applications, it has the consequence that the corrosion resistance of aluminum may be poor or even very bad in situations in which the protective layer cannot form or cannot protect. Al alloys can be severely corroded by highly acidic or basic solutions, by chemicals such as Hg and its salts that can prevent the formation of the protective oxide film, and by strong galvanic couples with dissimilar metals.

Even relatively mild corrosion can produce cosmetic defects in appliances and structural parts, and can lead to failure by perforation or by stress corrosion cracking of parts that are subjected to high loads in corrosive environments. These problems can be addressed by the usual methods of painting, coating, cathodic protection (with Mg), or electrical insulation to break galvanic couples. However, there are also metallurgical solutions which are rather specific to aluminum alloys.

The most serious corrosion problem in Al alloys is the intergranular corrosion of high strength alloys that can lead to mechanical failure by stress corrosion cracking. Intergranular corrosion is most severe when a galvanic couple is established between the grain boundary and the grain interior. The problem is usually associated with the formation of precipitate phases in the boundary. Solution-strengthened Al-Mg alloys are relatively immune to intergranular corrosion since they have few intergranular precipitates. Al-Mn alloys are also relatively immune since the intergranular precipitates do not cause a significant galvanic couple. Precipitation-hardened Al-Mg alloys are treated to minimize intergranular attack by decreasing precipitate size and dispersing precipitates through the matrix. This approach is not as successful in Al-Cu alloy; copper in solution makes Al cathodic to Al-Cu precipitates in the grain boundary. Intergranular corrosion in Al-Cu alloys can be minimized by overaging the alloy to deplete copper from the grain interior, as is done in some alloys, but this procedure causes a loss of strength, ductility and toughness. High-strength Al-Cu alloys are hence often protected by a method known as "Alcladding," in which a thin layer of a relatively anodic Al alloy is plated onto the surface to provide cathodic protection.

For other applications Al alloys are protected by coating. A common method is called anodizing, and involves a surface treatment in an electrolytic cell to thicken the natural oxide coating. Since the visible color of the oxide coating can be adjusted by controlling its thickness, the anodizing process has cosmetic value as well.

1.6 Research Directions

Important directions for current research in the physical metallurgy of aluminum and its alloys derive primarily from the need for light structural alloys for use in aerospace vehicles and improved conductors for microelectronic devices. New, low-density structural materials that can perform structurally at the extremes of high and low temperature, and new conductors that can withstand exceptionally high current densities are particularly required. Much of the required research is applied and very specific to particular material requirements. However, there are important needs for supporting fundamental research. Many important research directions can be identified. Among them are three that specifically require development of the corresponding physics.

Intermetallic compounds based on aluminum are the critical hardening phases in precipitation-hardened aluminum alloys. They are also increasingly important as monolithic materials for use as low-density structure materials at high temperature. The structure and stability of the intermetallic phases are important for both applications, and new theoretical understanding is needed to guide development. In the case of hardening phases, these often have metastable structures or shapes that appear because of the elastic constraint of the matrix or preferential kinetics of formation, and hence are difficult to predict or interpret from equilibrium data. In the case of the monolithic intermetallics, many of the most attractive from the perspective of density and stability have noncubic structures that makes them relatively brittle. Theoretical developments are needed to guide the search for more attractive intermetallic phases.

The deformation of aluminum alloys governs strength, formability, and fracture under most conditions. The critical mechanism that governs deformation at moderate to large strains is work hardening. The hardening of a polygranular material during deformation is known to be influenced by both the evolution of the dislocation distribution within it and the development of texture in its polygranular structure. Work hardening is a complex, statistical, nonequilibrium process, and very little progress has been made in its quantitative theory. Probative research is needed.

The reliability of aluminum lines in microelectronic devices is strongly affected by the phenomenon of electromigration, which leads to failure by creating a break in the line. Since electromigration life tends to decrease as a line is made smaller or the current density is increased, the engineering problem of electromigration failure increases in severity with device miniaturization. A sound mechanistic theory of electromigration failure is needed both to guide design for reliability and to suggest material modifications that might improve reliability. The fundamental mechanisms of electromigration are poorly understood, and there is no established theory of electromigration failure. Research is badly needed in this area.

Table 2. World bauxite resources (only countries with largest resources, millions of metric tons).

Current economic reserves	
Jamaica	2 000
Brazil	2 250
Guyana	700
Surinam	575
Greece	600
Cameroon	680
Guinea	5 600
India	1 000
Indonesia	750
Australia	4 440
World total	21 000

2. RESOURCES AND RAW MATERIALS

The principal ore of aluminum is bauxite, which is used as a term for deposits containing gibbsite ($Al_2O_3 \cdot 3H_2O$), boehmite, or diaspore (both $Al_2O_3 \cdot H_2O$). Although this ore gets its name from Les Baux in Provence, large deposits are typically found in tropical regions. Aluminum (in the form of oxides and silicates) is present in the Earth's crust at a mean level of 8.3% and is the most abundant metal. However, leaching of other crustal constituents (principally silicon compounds) by humic acid, produced in tropical conditions by abundant rainfall and vegetation, leads to much higher levels of aluminum in bauxite ores (typically in excess of 30% Al_2O_3).

Table 2 provides data on the world's resources of bauxite, estimated by the U.S. Bureau of Mines for 1985 (U.S. Bureau of Mines, 1985). Major mining activities for bauxite take place in Australia, Guinea, Brazil, and Jamaica.

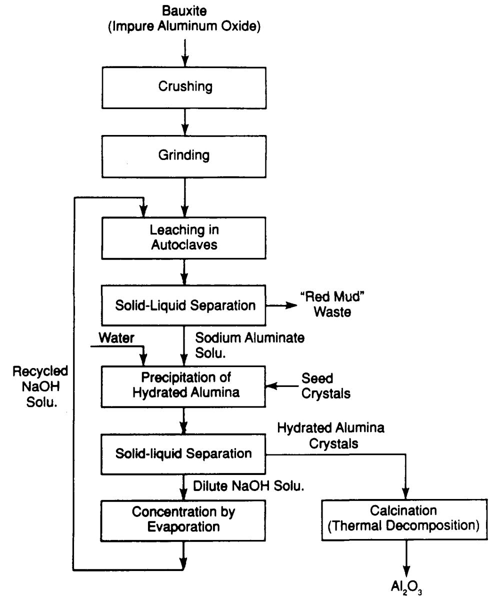

FIG. 3. Schematic diagram of the Bayer process for the production of aluminum oxide from bauxite.

3. PRODUCTION OF ALUMINUM

3.1 The Bayer Process for the Production of Aluminum Oxide

The starting point for the production of nearly all of the world's supply of new (as opposed to recycled) aluminum is the ore bauxite, the occurrence of which was described in the previous section. Bauxite is hydrated aluminum oxide containing oxides of silicon, iron, titanium, and other elements as impurities. The refining of this ore to aluminum oxide of greater than 99% purity is carried out in the Bayer process which relies on the selective dissolution of the aluminum oxide into a concentrated sodium hydroxide solution. Having been separated from insoluble impurities, this solution is then diluted with water to precipitate hydrated aluminum oxide.

Figure 3 is a schematic diagram of the Bayer process. The ore is first crushed and ground to a particle size (typically below 1 mm) to promote rapid dissolution of the aluminum oxide, following which it is contacted in autoclaves with a recycled concentrated solution of sodium hydroxide. At typical autoclave temperatures (200–240 °C) the reaction

$$Al_2O_3{\cdot}xH_2O+2NaOH$$
$$=2NaAlO_2+(x+1)H_2O \qquad (1)$$

proceeds to completion in approximately 100 min. The sodium aluminate solution is then separated from the undissolved impurities by decantation and filtering. The solid residue, known as "red mud," poses a disposal problem that is discussed in Sec. 5.1. The dissolution of aluminum oxide in sodium hydroxide solution can be reversed by cooling and diluting the solution and the precipitation of the solid hydrated aluminum oxide is nucleated by the addition of particles of the oxide. The precipitate is separated by filtration and dried in rotary kilns or fluidized beds while the remaining solution (largely sodium hydroxide) is concentrated by evaporation and recycled to the autoclaves. The product of this Bayer process is aluminum oxide powder (alumina) with a particle size usually in the range 10–200 μm. The principal impurity is sodium oxide (or aluminate) at the level of approximately half of 1%. The crystalline form is gamma alumina with some alpha alumina depending on the temperature reached in the kilns.

3.2 The Hall–Héroult Cell for the Reduction of Oxide to Metal

The most important step in the production of aluminum, in terms of economics, is the electrolytic reduction of the oxide produced by the Bayer process to metal. This reduction is carried out in cells invented simultaneously in the 1880s by Hall in the USA and Héroult in France. While Hall–Héroult cells have evolved over the intervening decades, particularly with regard to size and energy efficiency, the technology would still be recognizable by these inventors. Figure 4 (adapted from Jarrett, 1983) charts the progress of this technology and it is seen that much less energy is now required to produce unit mass of aluminum than early in the century. Nevertheless, in recent years Hall–Héroult cells have accounted for approximately 4% of the electricity generated in the U.S.A. with even higher percentages in some other countries. This electrical energy cost is reflected in the price of newly produced aluminum and has stimulated much research and development aimed at reducing this energy consumption.

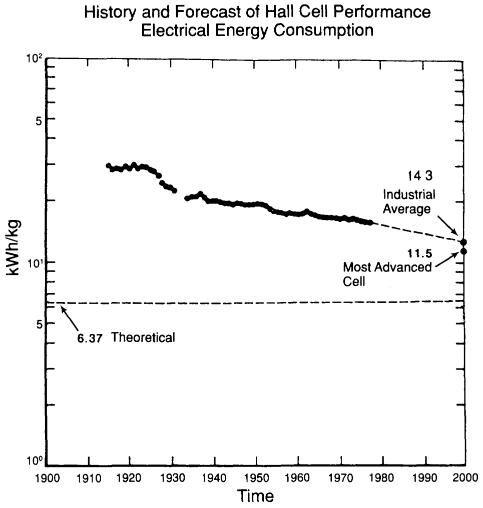

FIG. 4. History and prediction of the consumption of electrical energy in the production of aluminum (adapted from Jarrett, 1983).

The scope for improvement is revealed by the fact that the thermodynamic requirement for the reduction is only 40%–50% of the energy actually expended.

Figure 5 depicts a typical Hall–Héroult cell in cross section. The width of the cell might be three meters, the length (in the direction perpendicular to the paper) ten meters and the cell current 200 kA (dc). The voltage across the cell would be somewhat over 4 V and the cells, connected in series, are arranged in long double rows (usually with their long sides adjacent) known as "potlines." A typical potline would contain over a hundred cells with a representative aluminum plant having a few such potlines and generating 100 000–200 000 metric tons per year of metal.

Current flows from an adjacent cell via aluminum conductors and steel rods to carbon anodes dipping into the molten salt electrolyte. This electrolyte is a mixture of sodium and aluminum fluorides containing dissolved aluminum oxide and additives such as magnesium and lithium fluorides which, as will be described below, are intended to increase the current efficiency of the cell. The sodium and aluminum fluorides are in a ratio approximating the naturally occurring mineral cryolite (Na_3AlF_6) but additional aluminum fluoride is introduced to lower the freezing point to approximately 950 °C (and yet further with more additives) (see the phase diagram, Fig. 6). A typical operating temperature for a cell would be 960 °C and the electrolyte would contain a few percent of dissolved aluminum oxide.

As the current passes through the surface of the carbon anode into the electrolyte the oxidation of carbon to carbon dioxide occurs. The oxidation product expected on thermodynamic grounds (carbon monoxide) is produced in only small amounts because, at the current densities in question (0.5–1 A cm^{-2}), the conditions are far from electrochemical

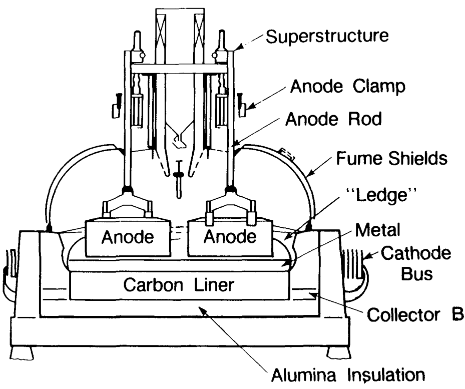

FIG. 5. Cross-sectional drawing of the Hall–Héroult cell for the production of aluminum.

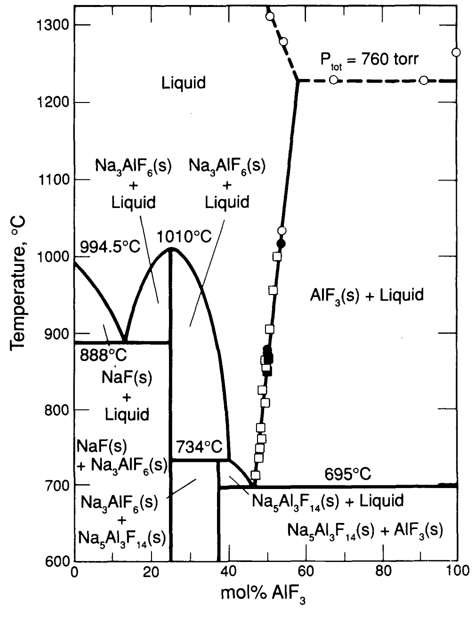

FIG. 6. Phase diagram for the system NaF-AlF_3 (from Grjotheim and Welch, 1980).

equilibrium. The conduction through the electrolyte is ionic and terminates with the current flowing into a pool of molten aluminum beneath the electrolyte. At the electrolyte-metal interface the cathodic reduction of aluminum ions (or, more correctly, fluorinated complexes of aluminum ions) occurs, producing the metal. The current then flows through a carbon lining into steel "collector bars" positioned in the lining and thence via bus bars to the next cell in line.

The overall reaction within the cell is

$$2Al_2O_3+3C=3CO_2+4Al. \qquad (2)$$

Consequently, the anodes are consumed and the aluminum pool grows in depth. Part of the pool is siphoned from the cell at intervals of one or two days. The cell of Fig. 5 has "prebaked" anodes manufactured in a separate operation by baking mixtures of carbon and carbonaceous binding agents. A cell would have 10–20 such anodes and it would be usual to replace the oldest one each day. In an alternative technology ("Soderberg" or "self-baking" anodes) one massive carbon anode is used and is formed continuously in the cell by the baking of carbonaceous materials added to the top of the anode. In both types of cells it is necessary to adjust the anode-cathode distance frequently to compensate for anode consumption, metal removal etc. and this is achieved by raising or lowering the superstructure from which the anodes are suspended.

Alumina is fed onto a frozen crust on top of the electrolyte and provides thermal insulation as well as trapping some of the fluoride vapors emanating from the electrolyte. Periodically the crust is broken, allowing alumina to fall into the electrolyte. Alumina is denser than aluminum and can sink beneath the metal if an excess is fed to the cell, with undesirable interference with the current path. Consequently, the oversupply of alumina to the cell is to be avoided. Neither on-line measurement nor routine laboratory analysis of samples for alumina have proved practical and until recently the alumina content of the electrolyte was controlled by periodically allowing it to approach zero. At low alumina contents, the wetting of the anode by the electrolyte diminishes to the point where carbon dioxide bubbles generated at the anode cover large parts of the anode, greatly increasing the cell resistance. The cell voltage then rises rapidly to several tens of volts, a phenomenon known as an "anode effect." The operator is then aware that the alumina concentration in the electrolyte is near zero and can extinguish the anode effect by (usually) feeding alumina. More recently computer-based data acquisition systems have been used to monitor cell voltages and currents and the alumina fed, so that anode effects can be avoided. Apart from this and intermittent measurement of cell temperature, the cells are not instrumented.

The inefficiency of Hall–Héroult cells has already been mentioned; it is convenient to discuss it in terms of two topics: current inefficiency and excess cell voltage. The current efficiency (the ratio of actual aluminum production to that expected from Faraday's electrochemical law) of a modern cell would typically lie in the range 90–95%. A small part of the current inefficiency can be accounted for by electronic conduction paths paralleling the ionic one through the electrolyte. However, the major cause of inefficiency is due to the "dissolution" of part of the aluminum product into the molten salt electrolyte and its subsequent reoxidation at, or near, the anode. The nature of this "dissolution" is still unclear and is likely to involve chemical reaction of the metal with the electrolyte to produce sodium and subvalent aluminum species (Grjotheim and Welch, 1980). However, laboratory measurements show solubilities in the range 0.05–0.15 wt. %, increasing with increasing temperature and with ratio of sodium fluoride to aluminum fluoride in the electrolyte. Improvements in current efficiency have been sought by using electrolyte compositions (and temperatures) that reduce aluminum solubility and by cell designs which minimize convective mass transport in the interelectrode region. The latter is driven partly by gas bubbles evolved from the anode but also by electromagnetic forces (Moreau and Evans, 1984). The electromagnetic forces arise from the interaction of the cell current with the magnetic field, of the order of 10^{-2} T, generated within the cell by the cell current and that in nearby bus bars and cells (Lympany and Evans, 1983). In designing modern cells great attention is paid to minimizing these magnetohydrodynamic effects (Potocnik and Evans, 1986). Current efficiencies today are superior to those of, say, the 1950s when they were usually in the range 82%– 86%.

The voltage of a Hall–Héroult cell cannot be reduced below a minimum determined by the enthalpy of the electrochemical reaction(s) and the overpotentials needed to "drive" the reactions at acceptable rates. Thermodynamically, the minimum electrical energy input to the cell is the greater of the enthalpy of reaction and the Gibbs free energy of reaction, multiplied by the production rate. Because the overall reaction entails production of gas (carbon dioxide plus monoxide in small amounts) the entropy of reaction is positive and the enthalpy of reaction therefore exceeds the Gibbs free energy of reaction and is the relevant quantity. To this minimum must be added a quantity of heat necessary to bring the reactants (aluminum oxide and carbon) from the temperature at which they enter the cell to the operating temperature (950–1000 °C), less any of that heat supplied by hot gases leaving the cell. Grjotheim and Welch (1980) report a result of 6.34 kWh kg^{-1} of aluminum product for a cell at 977 °C fed aluminum oxide and carbon at 25 °C with no heat transfer from the gas and a current efficiency of 100%. This minimum is increased somewhat if the current efficiency is less than 100% because the reoxidation of the aluminum proceeds with the production of carbon monoxide, rather than carbon such as would occur by reversal of the overall reaction. Adding overvoltages necessary to drive the anodic and cathodic reactions (particularly the former) at acceptable rates, a minimum cell voltage is reached of approximately 1.7 V, far below the actual cell voltages of 4–4.3 V. The difference represents ohmic potential drops in various parts of the cell, and the energy efficiency of the cell could be improved by their elimination. (In reality their complete elimination may be impossible because they lead to generation of heat that balances the heat losses from the boundaries of the cell. Some heat losses from the sides of the cell are mandated by the fact that materials presently in use for the sidewalls must be protected from exposure to molten electrolyte by the frozen "ledge" of electrolyte appearing in Fig. 5.) Means for reduction of some of these voltage drops are obvious (e.g., the use of bus bars of larger cross section) but one voltage drop is particularly troublesome, namely, the voltage drop through the electrolyte. The electrolyte is a poor conductor (2.4–3.2 Ω^{-1} cm^{-1}) and passage of the high current density through the 4–5-cm gap between anode and cathode results in potential drops of 1.4–1.7 V. Clearly significant energy savings would result from a reduction in the size of this gap. Unfortunately, the reduction of this gap is difficult in an industrial situation. Loss of current efficiency results if the anode is brought too close to the cathode; the loss is either by short-circuiting or by promotion of the mechanism discussed in the previous paragraph. Consumption of carbon from the face of the anodes is uneven and therefore the precise location of the faces is not known to the operators. Furthermore, the densities of the electrolyte (2100 kg m^{-3}) and metal (2300 kg m^{-3}) are close and electromagnetic forces perturb the metal-electrolyte interface, sometimes deforming it by a few centimeters. The normal 4–5-cm separation between the carbon and metal therefore represents a margin of safety, determined by experience, at which cell performance is optimized.

This description of the Hall–Héroult cell has necessarily been brief and there has been no opportunity to describe the research that is being pursued on this topic by aluminum companies and a limited number of universities. Nevertheless, the reader will recognize that the cell is governed by a complex mixture of electrical and magnetic phenomena, electrochemistry, turbulent multiphase flow, heat, and mass transport and is therefore a rich field for applied research.

3.3 Alternative Technologies for Producing Aluminum

Considerable effort is currently being expended on modifying Hall–Héroult cells in ways that depart significantly from present practice. Foremost among these are ones aimed at inert anodes and the use of materials for cell linings that are wetted by aluminum. From the discussion of the last section the cell voltage can be reduced by reducing the anode-cathode distance and this may be achieved if the geometry is better known to the operator (or a control computer). An anode that is not consumed by reaction is one step in this direction and cermet anodes, with a copper alloy metallic phase and a nickel ferrite/nickel oxide nonmetallic phase, have shown reasonable lifetime in laboratory tests

(Weyand *et al.*, 1986). With such anodes the anodic reaction is the generation of oxygen, rather than of carbon dioxide. A second step in the direction of a reduced anode-cathode distance is the use of titanium diboride, and composites of TiB_2, to line the bottom of the cell. These materials are wetted by aluminum (in contrast to the conventional carbon lining) and it becomes possible to operate with the aluminum present only as a film (draining to a sump) that is not perturbed by electromagnetic forces (Dorward and Payne, 1985).

The production of aluminum by electrolysis of the chloride, rather than the oxide, was developed to an industrial scale (Russel, 1981) but it is first necessary to produce the chloride from the oxide and unfavorable economics are suggested by the closure of the plant.

Manufacture of aluminum by chemical, rather than electrochemical, routes has been examined many times in the past. A favorite topic has been the "carbothermic" reduction of alumina, i.e., reduction by carbon at elevated temperatures. The standard free energy of reaction becomes negative at approximately 2100 °C but, at these temperatures, aluminum exerts a significant vapor pressure and a volatile suboxide (Al_2O) is stable. Consequently aluminum vapor and the suboxide migrate out of the reaction zone and back-react as they cool. The problem is aggravated if the necessary heat of reaction is supplied by fuel combustion (as in a blast furnace type of reactor) but is alleviated if the activity of aluminum in the reaction zone is reduced by a suitable alloying element. Aluminum-silicon alloys have been produced in the USSR by carbothermic reduction in electric arc furnaces. Use of tin to lower the aluminum activity, followed by separation of the tin, has recently been examined on a laboratory scale (Frank, Finn, and Elliott, 1989).

4. PROCESSING OF ALUMINUM

Following its production the molten aluminum is alloyed with other elements, cast, and processed (frequently by extrusion or rolling) into the many forms familiar to the end user.

4.1 Alloying

The aluminum from the Hall–Héroult cell typically is better than 99.5% aluminum; much higher purities can be produced by an electrolytic refining step. Such aluminums are soft and find their largest application in the production of aluminum foil where the primary consideration is the simplicity with which thin gauges can be rolled. These applications require aluminum free of nonmetallic inclusions and dissolved gases which lead to imperfections in the foil. The molten aluminum is commonly filtered and gases of low solubility (such as argon) blown through it to remove soluble gases before casting.

The bulk of aluminum is used to produce aluminum alloys. Common alloying elements are silicon, copper, magnesium, zinc, and lithium; their effects on the properties of aluminum have been described in Sec. 1. In most cases alloying consists of merely adding the requisite alloying elements to a furnace containing molten aluminum delivered from the Hall–Héroult cells. Sometimes aluminum is melted in these furnaces (either recycled scrap or new aluminum that has been cast for intermediate storage). The furnaces are usually gas-fired, although electric induction furnaces are used when absorption of impurities from furnace atmospheres is to be minimized. The exception to the above simplicity is alloying with lithium. This element is highly volatile at the temperatures (circa 700 °C) at which molten aluminum is processed and also highly reactive. Technologies for producing aluminum-lithium alloys are proprietary.

4.2 Casting

A distinction must be drawn between the casting of parts (lawn mower housings, cylinder heads, domestic utensils, etc.) and the casting of bulk aluminum for subsequent processing by extrusion, rolling and drawing (to window frames, beverage containers, aluminum foil, etc.). The former is conducted in foundries by die casting and sand mold casting and is largely self-evident, except at the level of detail; it will not be treated further here. The latter is carried out by every aluminum plant because little aluminum is supplied to the customer in liquid form. We may subdivide this latter casting into "continuous"

FIG. 7. Three methods for the casting of aluminum into shapes suitable for subsequent rolling or extrusion.

and noncontinuous casting. The latter consists of merely pouring the metal into a mold, usually of cast iron, and allowing solidification to proceed. It is in common use only for producing metal for intermediate storage, i.e., for applications where the metal must be remelted.

The three principal continuous casting technologies for aluminum are "direct chill" (DC) casting, electromagnetic (EM) casting, and roll or belt casting. All three are illustrated in Fig. 7. They are continuous in the sense that they produce solidified metal from a continuous inflow of liquid metal for periods of the order of one to several hours. In DC casting, ingots of sections perhaps 1 m by 2 m and several meters high or slabs of smaller thickness are produced by direct contact between the liquid aluminum and a water-cooled copper mold. The solidified aluminum is supported by a "bottom block" that is moved downwards at a few meters per hour as solidification proceeds. The casting is started with the bottom block placed within the mold. Because solidification relies on contact with the mold, the solidified metal periodically breaks free from the mold surface resulting in surface imperfections and these imperfections must be removed by machining before further processing. It is to avoid this wasteful and expensive "scalping" that electromagnetic casting was devised, originally in the USSR. In EM casting the molten aluminum is confined by electromagnetic forces, rather than an actual mold, and the cooling water is sprayed directly onto the metal surface just below the point of solidification. The forces arise from the currents induced in the metal by current in an inductor surrounding it. The inductor current, of several kiloamperes at several kilohertz, generates a magnetic field and the net effect is a pinch force that supports the molten aluminum against gravity. The electromagnetic forces also cause a stirring of the melt and this is therefore a second example of magnetohydrodynamics in the production/processing of aluminum. Figure 8 provides a comparison between measurements of aluminum velocity made by Vives and Ricou (1985) and those computed by Sakane, Li, and Evans (1988). EM cast aluminum usually need not be scalped and over a million tons of aluminum is cast in this way per year in the West alone. EM cast ingots would be similar in size to DC cast ingots.

Figure 7 shows a Hazlett twin belt caster although related machines operating on similar principles exist. The cross sections cast in such machines (rectangular or near square) would typically be smaller (a few cm) than those of DC and EM casting. The molten

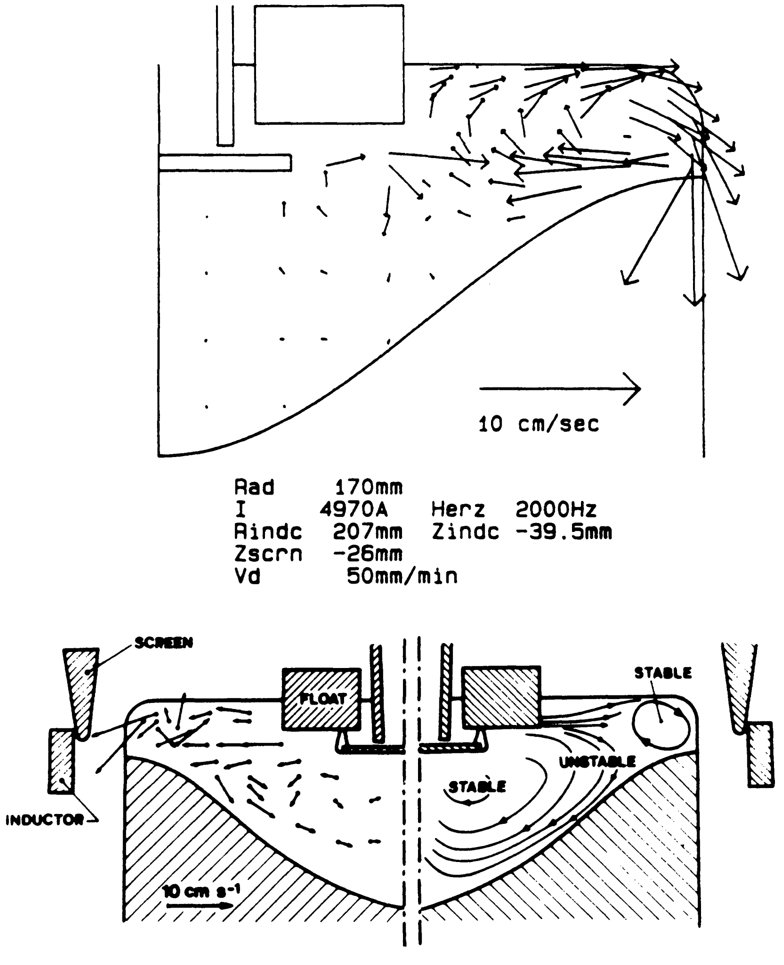

FIG. 8. Electromagnetically driven flows calculated by Sakane, Li, and Evans (1988) and measured by Vives and Ricou (1985) in electromagnetic casting of aluminum.

metal runs between belts driven by wheels at either end of the machine and is confined on the side by vertical dams moving along with the belts. The belts and dams are cooled by water sprays.

4.3 Rolling and Extrusion

The solid aluminum ingots generated by the continuous casting units of the last section are reduced in cross section by rolling or extrusion. The former consists of passing slabs repeatedly between parallel steel cylinders perhaps as much as one meter in diameter ("rolls") that are held at a preset distance apart in a steel frame. Slabs are fed to these machines hot. With each passage the aluminum becomes wider, longer, and thinner. Simple cross sections (rounds, channels, I beams, etc.) can be produced by machines that bend flat sheet subsequent to rolling (e.g., for aluminum guttering). Thin sheet produced in this way is made into beverage containers by "deep drawing" in which a piston-like device forces the sheet into a cylindrical die. Aluminum wire is produced by drawing rounds through dies with cylindrical holes of narrowing diameter.

Extrusion is used to produce cross sections of more complex shape (i.e., finned tube). A length of aluminum rod (heated to a temperature where it has become soft) is forced through a die of required cross section.

5. ENVIRONMENTAL, OCCUPATIONAL AND ECONOMIC ISSUES

5.1 Environmental Issues Related to Aluminum

The poor degradability of the aluminum can is well known; environmentalists and the aluminum industry have promoted the recycling of aluminum cans and other aluminum scrap vigorously. The effort has met with some success; aluminum recycled from users or within aluminum plants represented 25% of total US production in 1988, up from 13% in 1980. The recycling has the additional advantage of reducing energy use since the energy cost of recycled metal is only a fraction of that to produce new metal.

The other major environmental concerns with aluminum are fluoride emissions from Hall–Héroult cells, the red mud from Bayer plants, and the disposal of spent linings from cells. Fluoride emissions can be reduced by the use of "dry scrubbers." These are beds of alumina, en route to the cells, through which the cell exhaust gases are passed before discharge. In this way cell emissions can be reduced to below 0.95 kg per ton of aluminum produced.

Red mud consists of finely divided particles, largely of hydrated iron oxides with some silicon and titanium oxides. The aqueous phase admixed with these particles is highly alkaline and difficult to separate from the particles because of their small size. Consequently, contamination of ground water by the aqueous solution is a concern. Disposal at sea or into rivers has been practiced in the past but environmental concerns now limit such action. Impoundment in dams is now widely employed with abandonment being the eventual fate of the impoundment. In many cases the dams are designed so that, following drainage and evaporation of the liquid, they can be converted to agriculture or recreational use, following coverage by topsoil. Alternatives to disposal (such as use for neutralizing acid soil or manufacturing ceramics and refractories) have been suggested but none appear to have been adopted.

Carbon linings of Hall–Héroult cells have a lifetime of several years but must ultimately be disposed of. Several hundred thousand tons of spent lining are disposed of throughout the world each year. The disposal problem is aggravated by traces of cyanide formed by the reaction of the carbon lining with atmospheric nitrogen.

Table 3. Major uses of aluminum in the U.S. (From Mineral Commodity Summaries, 1987, U.S. Bureau of Mines.)

Packaging	29%
Building	22%
Transportation	21%
Electrical	10%
Consumer durables	9%
Other	11%

5.2 Occupational and Legal Concerns

Apart from exposure to fluorides and the usual hazards of working with hot metals and large pieces of equipment, there is a danger that appears peculiar to the aluminum industry. Contacting molten aluminum with water may lead to more serious accidents than contacting water with other molten metals; it has been suggested (e.g., Epstein and Miller, 1987) that, in addition to explosions due merely to the expansion of the steam, more violent explosions involving chemical reaction of the aluminum with water or steam frequently occur. A number of accidents of this nature take place each year, some involving fatalities. Melting and casting operations where ingots have been stored outside, or scrap is being processed, appear to be particularly susceptible to this hazard.

Allegations that there is a relationship between aluminum and Alzheimer's disease and that aluminum electrical wiring is less safe than copper have been made. Trade organizations such as the Aluminum Association in the U.S. have responded to these allegations.

5.3 Economics of Aluminum

Table 3 summarizes the major uses of aluminum. These have been described in detail in Sec. 1.1. Aluminum use has grown considerably since the start of its wide scale production a century ago, although naturally that growth has suffered occasional reverses. Future growth in worldwide aluminum production appears likely; as indicated by Fig. 9; anticipated future increase in the per capita GNP in developing countries leads to this conclusion. However, a large part of the cost of

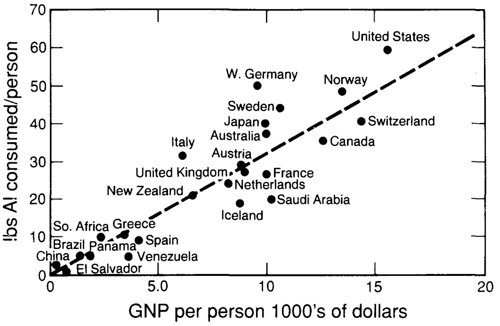

FIG. 9. Aluminum consumption versus gross national product in 1984.

production of aluminum is represented by the electrical energy cost. For example, in the USA this cost fraction is one quarter. Consequently growth in aluminum production is likely to occur in those countries where the cost of generating electricity is low, or the cost to aluminum smelters is limited by political action, self-generation of power, etc. With moderately high power costs the USA, Japan and many European countries do not fall into this category. Recent smelter construction has been in such countries as Venezuela, Brazil, and Australia. Despite this, economic events, particularly the low U.S. dollar, have resulted in U.S. smelters operating at close to capacity. At the end of 1987 aluminum producers in the U.S. were operating at 90% of capacity, compared to 72% at the beginning of that year. In 1988 production reached 96% of capacity.

GLOSSARY

Alumina: Aluminum oxide.

Anode Effect: Sudden increase in voltage across a Hall–Héroult cell brought about by near-zero alumina content in the electrolyte.

Anodes: Positive electrodes (presently of carbon) in Hall–Héroult cells.

Anodizing: In the processing of aluminum alloys, a process in which the alloy is treated in an electrolytic cell to thicken the natural oxide coating.

Bauxite: The ore (impure hydrated aluminum oxide) from which aluminum is produced.

Bayer Process: Process for producing pure aluminum oxide from bauxite.

Carbothermic Reduction: The reduction of aluminum oxide to metal by chemical (rather than electrochemical) reaction.

Collector Bars: Steel bars inset in the carbon lining of Hall–Héroult cells to conduct current out of the cell.

Cryolite: Sodium aluminum fluoride (no longer occurring naturally in significant quantities); the principal ingredient in the molten salt electrolyte of the Hall–Héroult cell.

Crystallographic Texture: Preferential alignment of the crystal axes of the grains of a polycrystalline material.

Current Efficiency: Ratio of aluminum production rate in Hall–Héroult cell to that expected from Faraday's law.

Damage Tolerance: The ability of a material to sustain small flaws, such as small internal cracks, without structural failure.

Deep Drawing: Production of thin-walled aluminum shapes (e.g., beer cans) by forcing sheet aluminum into a cup-shaped die using a piston.

Direct Chill Casting: A common method of continuous casting, whereby the aluminum solidifies as it passes through a copper mold with which it is in contact.

Dry Scrubbers: Devices for trapping fluoride emissions from Hall–Héroult cells.

Ductility: Ability to be deformed; in original usage, ability to be drawn into a thin wire.

Electromagnetic Casting: A common method of continuous casting whereby aluminum is solidified by water jets as it passes through an inductor which serves to support the molten metal.

Electromigration: A coupling between electrical current and chemical diffusion that leads to an enhanced rate of diffusion when a significant current is present.

Extrusion: Production of shapes of uniform cross section (e.g., I beams) by forcing heated solid aluminum through an aperture (die) of the requisite shape.

Fiber Composite: A composite material in which the reinforcing phase has the form of long, thin fibers.

Fiber Laminates: A composite material in which layers of organic fibers or cloth are alternated with layers of metal foil.

Guinier–Preston Zone: Microscopic precipitate within a solid, usually a small cluster of like atoms.

Hall–Héroult Cell: Electrolytic cell used for the reduction of aluminum oxide to metal.

Inert Anodes: Positive electrodes for the Hall–Héroult cell (still under development) that are not consumed by the anodic reaction.

Intermetallic Compound: A material of two or more metals with an ordered crystal structure.

Malleability: Deformability by plastic deformation; in original usage, ability to be hammered or beaten into a thin sheet.

Potlines: Rows of Hall–Héroult cells.

Prebaked Anodes: Anodes produced by baking carbonaceous material in a separate operation from the Hall–Héroult cell.

Precipitate-Free Zone: A layer of material parallel to a grain boundary in a precipitation-hardened material that is free of precipitates due to precipitation on the boundary itself.

Precipitation Hardening: Increasing the strength of a material by precipitating small particles of a second phase in its interior.

Recovery: A process in which dislocations are reconfigured or eliminated by diffusional climb at moderate temperature, softening the material.

Recrystallization: A structural transformation in which crystal defects are largely eliminated from a deformed polygranular material by the nucleation and growth of new grains.

Red Mud: Waste product of the Bayer process.

Roll (or Belt) Casting: A common method of continuous casting, whereby aluminum is solidified as it flows between, and comes in contact with, two moving belts or rolls.

Rolling: Reduction of the thickness of hot aluminum slabs by squeezing them between large-diameter steel rolls.

Soderberg (Self-Baking) Anodes: Anodes produced within the Hall–Héroult cell itself.

Solution Hardening: Increasing the strength of a pure material by adding solute species.

Subgrains: Subvolumes of the crystal grains of a polycrystalline material that are separated from one another by walls of dislocations which form low-angle tilt or twist boundaries.

Superplasticity: Very large plastic elongation prior to failure.

Thermomechanical Treatment: The combination of thermal and mechanical treatments to control the microstructure of a material.

Whisker Composite: Composite material in which the matrix phase is usually a ductile metal and the reinforcing phase is a high-modulus compound in the form of thin, whisker-shaped crystals.

Work Hardening: Increasing the strength of a material by deforming it, which increases the density of dislocations and other defects.

INTRODUCTION

The determination of the atomic structure of amorphous materials is a nontrivial undertaking for a number of reasons. First, the fact that the structure can only be defined essentially in terms of a "unit cell" containing an infinitely large number of atoms means that a statistical description of the structure is unavoidable. Second, the absence of translational periodicity means that many simplifying features associated with the mathematical treatment of, say, diffraction are inappropriate. Finally, resulting from the above considerations, the structure of an amorphous solid can never be determined unambiguously, a situation reinforced by the fact that, in many cases, the structure of a noncrystalline material, at both microscopic and macroscopic levels, depends on details of the method of preparation.

In the light of the above problems, the use of a *single* experimental technique is insufficient to determine the structure of amorphous solids; rather a number of complementary structural probes must be employed in order to obtain as much experimental information as possible, before recourse is made to theoretical structure modeling studies with which the structural features present in the experimental data may be interpreted.

1. DEFINITIONS

1.1 The Amorphous State

We commence with a definition of amorphous materials (Elliott, 1984, 1990): *Amorphous materials are condensed phases which do not possess the long-range translational or orientational order (periodicity) characteristic of a crystal.*

The terms amorphous and noncrystalline are synonymous under this definition, and are used interchangeably in this article. Furthermore, no distinction is made between liquid and solid phases of matter, although here we will consider only the case of *solids* (having viscosities in excess of 10^{13} P at room temperature). Although the problems involved in the determination of the *average* structure are the same in both cases, additional complica-

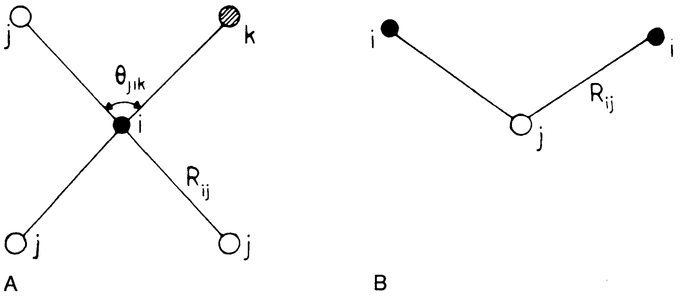

FIG. 1. Schematic illustration of the parameters describing short-range order in covalent amorphous materials.

tions exist in the case of the liquid state because of the dynamical disorder also present.

It should be stressed that here only *topological disorder* is considered, viz., aperiodic disorder in the atomic positions. Other types of disorder, which are associated with underlying *crystalline* lattices, are neglected, such as spin disorder (as in spin "glasses"), substitutional disorder (as in alloys), and either vibrational or orientational disorder, where dynamic vibrational or rotational disorder (which may be frozen in at sufficiently low temperatures in the latter case) may exist with respect to the equilibrium positions of a regular lattice.

Finally, we should emphasize that, with the definition given above, the terms amorphous and noncrystalline are the most general and all-embracing. In particular, we regard the term "glassy" to be a subcategory, with the following definition: *A glass is an amorphous solid which exhibits a glass transition.*

The glass transition is the phenomenon whereby a solid amorphous phase exhibits a more or less abrupt discontinuity in *derivative* thermodynamic properties (e.g., heat capacity or thermal expansivity) from crystal-like to liquidlike values with increasing temperature. Thus, glassy (or equivalently vitreous) materials are always amorphous, but conversely not all amorphous solids are glasses.

1.2 Structural Order

In order to proceed further with a description of the structure of amorphous solids and the techniques employed to determine it, it is convenient to consider the various types of structural order which can exist in such materials at various length scales. Such a categorization is convenient in two regards: the classification is hierarchical so that a particular type of order at one length scale can be dictated by order at a smaller scale (but not necessarily the converse); this division is also pragmatic in that different experimental structure probes are generally sensitive to structural correlations at various length scales.

1.3 Short-Range Order

We start with a discussion of covalent materials since the directed nature of the bonds characteristic of these systems considerably simplifies the picture. In such cases, the short-range order (SRO) is relatively easy to define in terms of well-defined local coordination polyhedra (see Fig. 1). Thus, the parameters which are sufficient to describe topological SRO are the number N_j of nearest neighbors j around an origin atom of type i, the nearest-neighbor bond length R_{ij}, the bond angle subtended at atom i, θ_{jik} (when the type of atom k is different from j), and the corresponding quantities when atom j is regarded as the origin, viz., N_i and θ_{ijk}. Note that in this description of SRO, nothing is said concerning the *connectivity* of the coordination polyhedra (e.g., corner-, edge-, or face-sharing); the form of connection of the polyhedra essentially determines the type and extent of the medium-range order (MRO), as will be seen in the next section.

An additional parameter is required if the degree of *chemical* SRO needs to be described as well, e.g., in the case when *different types* of atoms constitute the coordination polyhedron around a given origin atom. Thus, for nonstoichiometric compositions, for example, excess atoms must be accommodated by the introduction of "wrong" (i.e., homopolar) bonds (in the absence of coordination or valence changes), and the chemical order which might otherwise occur at the stoichiometric composition is thereby broken; the parameter of relevance here would then be the proportion of wrong bonds. Such considerations can also apply in the case of stoichiometric compositions, since chemical ordering may not exist even in that case.

A related type of chemical order is when the different types of atomic species in the coordination shell around a given origin atom are in fact the *same* element but each atom can have a different charge state, bonding connectivity, etc. An example of this is the case of nonbridging oxygens (NBOs) introduced in, say, silicate glasses by the incorporation of alkali modifier atoms, denoted Q_n species, where n (=0–4) is the number of *bridging* oxygens around a central Si atom. In fact, chemical ordering is often strong in such systems, and at the stoichiometric compositions only a *single* type of Q_n unit exists to a first approximation, whereas for compositions in between two stoichiometric compositions, the two species Q_{n+1}, Q_n, characteristic of the end-member compositions, coexist.

The question of chemical ordering in covalent systems is most simply discussed for the case of binary alloy systems, e.g., A_xB_{1-x}, where, if the elements A and B are in columns a and b of the Periodic Table, coordinations of $8-a$ and $8-b$, respectively, will occur, thereby satisfying their normal valence and the so-called "$8-N$" rule (strictly valid only for groups IV–VII). We neglect for the time being the effect of any coordination defects, such as dangling bonds. In general, A–A, A–B, and B–B bonds can coexist in an alloy of arbitrary composition, and two models can describe the distribution of such bond types (Lucovsky *et al.*, 1977).

The first is the *random covalent network* (RCN) model, in which the distribution of bond types is treated as being purely statistical, determined only by the local coordinations $N_a=8-a$ and $N_b=8-b$ and the concentration variable x. Thus, any effects leading to preferential ordering (e.g., arising from differences in bond energies) are neglected. The RCN model, therefore, admits A–A, A–B, and B–B bonds at *all* compositions except at $x=0$ and 1. The other model is the *chemically ordered network* (CON) model which assumes that heteropolar A–B bonds are favored; a completely chemically ordered phase thus occurs at the stoichiometric composition $x_c = N_a/(N_a + N_b)$ (e.g., As_2Se_3, $GeSe_2$). In contrast to the RCN model, only A–A and A–B bonds are allowed for A-rich compositions ($1 > x > x_c$), and conversely only B–B and A–B bonds for $1 < x < x_c$. Obviously the RCN and CON approaches are valid only for the case of covalent systems with well-defined directed bonds, i.e., not for metallic or ionic systems. Furthermore, they are appropriate only for glass-forming systems, i.e., excluding "modified" glasses in which network modifiers have either depolymerized the network, by introducing nonbridging anionic sites, or changed the coordination of the network-forming cation.

The above description of SRO in terms of rather well-defined coordination polyhedra is obviously inappropriate for those systems in which the bonding is nondirectional, e.g., in the case of metals or ionic systems in which the structure can be regarded simply in terms of a random packing of spheres. In such cases, a description of the local order is more difficult.

One particularly prevalent type of coordination polyhedron which can occur in randomly close-packed arrangements of spheres is the *icosahedron*. Thus, small neutral inert-gas clusters appear to exist comprised of "magic numbers" of atoms (13, 19, 23, 26, 29, etc.); all of these can be obtained by the serial addition of atoms to a starting 13-atom icosahedral cluster seed, giving so-called Mackay icosahedra. Moreover, it has long been asserted that supercooled liquid metals should contain icosahedral clusters (which cannot therefore subsequently act as nucleation centers for crystallization). It is consequently natural to consider the extent of local icosahedral order in solid materials rapidly quenched from the melt, viz., metallic glasses, and to do this some kind of order parameter is required.

One such concerns the so-called "Voronoi polyhedra" (or equivalently Wigner–Seitz cells) associated with such clusters. In three dimensions, the polyhedron is defined as the smallest convex polyhedron formed by the planes which bisect perpendicularly the "bonds" from a given origin atom to its nearest neighbors. The number of edges of a particular face of a Voronoi polyhedron is equal to the number of tetrahedra packed around the "bond" bisected by that face, i.e., pentagonal faces are a signature of icosahedral order.

Another monitor of local icosahedral order is associated with its *orientational* properties. Thus, Steinhardt *et al.* (1983) have proposed the following order parameter:

$$Q_{lm}(r)=Y_{lm}(\theta(r),\phi(r)), \tag{1}$$

where θ and ϕ are the polar angles of a "bond" between two nearest-neighbor atoms whose center is at r and $Y_{lm}(\theta,\phi)$ are the usual spherical harmonic functions. The particular direction of a bond is unimportant if only even-l spherical harmonics are considered, since these are inversion-invariant. Furthermore, rotationally invariant combinations are more discriminatory, such as

$$Q_l=\left[\frac{4\pi}{2l+1}\sum_{m=-l}^{l}|\overline{Q}_{lm}|^2\right]^{1/2}, \tag{2}$$

where $\overline{Q}_{lm}$ represents an average over a number of bonds in the structure. Clusters with icosahedral symmetry have nonzero spherical harmonics only for $l=6,10,12,\ldots$, etc., whereas various forms of cubic close packing, for example, have nonzero values of Q_l for $l=4$ as well. A dominant contribution to Q_l for $l=6$ can therefore signify local icosahedral order.

In the absence of reasonably well-defined coordination polyhedra, as discussed above, SRO can only be discussed in terms of averaged quantities; this is the case, for example, in glassy metal-metal alloys. An order parameter can be defined in terms of a function involving only the coordination numbers of the first shell (Sadoc and Wagner, 1983), viz.,

$$\alpha_1=1-\frac{N_{12}}{x_2(x_2N_1+x_1N_2)}, \tag{3}$$

where N_{ij} is the coordination number of atoms of type j surrounding atom i, and $N_i = \sum_{j=1}^{2} N_{ij}$. Negative values of α_1 indicate chemical ordering, i.e., the occurrence of unlike nearest neighbors. While Eq. (3) is strictly only valid for equally sized atoms, Cargill and Spaepen (1981) have also proposed an expression describing the extent of SRO in terms of nearest-neighbor coordination numbers, viz.,

$$\eta_{ij}=\frac{N_{ij}\overline{N}c}{x_jN_iN_j}-1, \tag{4}$$

where $\overline{N}$ is the average coordination number given by $\overline{N} = x_iN_i + x_jN_j$. For complete chemical disorder, $\eta_{ij} = 0$; otherwise, if chemical ordering exists (AB nearest neighbors favored), $\eta_{ij} > 0$, and in the other limit of chemical clustering (i.e., AA, BB pairs favored), $\eta_{ij} < 0$.

1.4 Medium-Range Order

Medium-range order (MRO) is less easy to define than SRO, and consequently several definitions exist in the literature. In this section we will adopt the following definition of MRO (Elliott, 1987): MRO can simply be regarded as constituting the next higher level of structural organization beyond that of SRO, existing on a length scale of, say, 5–50 Å. It is convenient in practice, particularly for covalent materials where MRO is more prevalent, to divide the types of MRO into three categories, corresponding to progressively increasing length scales.

1.4.1 Short-Range MRO. If SRO is defined in terms of well-defined coordination polyhedra, as above, short-range MRO (SRMRO) is therefore concerned with the type of connection of such polyhedra as well as their relative orientation. Thus, corner-, edge-, and face-sharing of polyhedra lead to very different ordering schemes at a local scale, as well as to pronounced differences at larger distances in terms of the network dimensionality (see Sec. 1.4.3).

MRO is most pronounced when the degrees of freedom associated with the relative orientation of neighboring polyhedra are restricted in some way, e.g., by the occurrence of edge-sharing connections. However, even in the case of corner-sharing units, where free rotation about the common bonds could occur in principle, certain orientations may be more probable than others. A structural parameter which is a measure of such orientational correlations for covalent systems (with well-defined bonds) is the "dihedral" (or torsion) angle, ϕ, characteristic of a four-body correlation function; it is the angle of rotation about a common bond required to bring into coincidence the projections, onto the plane perpendicular to this bond, of the other bonds in the connected units (Fig. 5). Departures from a uniform (i.e., random) distribution $P(\phi)$ are correspondingly a hallmark of MRO. Favored values of ϕ consequently are associated with features of MRO such as (small) rings. However, this need not necessarily always be the case: for example, it appears from structural modeling studies and considerations of features in the electronic density of states that the structure of *a*-Se is not representative of a freely rotating chain [with constant $P(\phi)$], but instead ϕ takes on more or less fixed values ($\sim 102°$, as in the crystal), with the sign of ϕ varying either alternately or randomly down a chain.

1.4.2 Intermediate-Range MRO. MRO at the next larger length scale, say $\geqslant 5$ Å, is obviously determined by the type and extent of SRMRO present. However, we make the distinction that intermediate-range MRO (IRMRO) is characterized by the presence of "superstructural" units (comprising several basic SRO units), e.g., rings or clusters of atoms of particular shapes or sizes, which occur in a considerably higher proportion than would be expected on a purely statistical (random) basis. In certain cases, such superstructural units can be regarded as forming the essential building blocks of the amorphous structure. Thus, IRMRO is characterized by correlation functions involving between, say, 6 and 12 atoms, and occurs if successive dihedral angles are themselves correlated.

1.4.3 Long-Range MRO. On a yet larger length scale, say greater than 10 Å, long-range MRO (LRMRO) can be regarded as being associated with the local dimensionality of a covalently bonded amorphous network, or the existence of domains in metallic systems.

A local dimensionality different from 3D can arise in a covalent network from two causes: either the type of connection between coordination polyhedra may impose such a reduced dimensionality, or it may result from network depolymerization resulting from the introduction of network modifiers.

It is often assumed that structural ordering at intermediate length scales is a *consequence* of a well-defined SRO. This picture is probably valid for the case of covalently bonded systems where the SRO is often extremely well-defined since it is determined by chemical bonding constraints. In the case of amorphous materials in which nondirectional bonding is predominant, e.g., metals, such constraints no longer apply, yet in some cases, e.g., in transition-metal metalloid (T-M) glasses, a well-defined topological and chemical SRO nevertheless still appears to be present. In such cases, it may be that the SRO itself is a *consequence* of the existence of a well-defined MRO, i.e., the converse of the case for covalent systems (Gaskell, 1987). An example of this in the crystalline state is the occurrence of tetrahedra and octahedra arising from ordered close-packed arrays of atoms. In a similar manner, the trigonal prismatic coordination of metalloid atoms in crystalline T-M materials can be regarded as arising from the introduction of "chemical twinning" planes containing the M atoms into close-packed crystalline arrangements of the metal atoms. Dubois *et al.* (1985) have proposed that similar considerations apply equally to the structure of *glassy* T-M alloys, in which the LRMRO is associated with domains of size 10–20 Å, within each of which more or less ordered arrays of chemical twinning planes exist, and along which are therefore located the trigonal prismatic units.

2. EXPERIMENTAL TECHNIQUES FOR STRUCTURE DETERMINATION

A variety of techniques can be used to investigate the structure of amorphous solids. Indeed, because of the limit on the amount of structural information obtainable from any one method, due to the aperiodicity of the structure, it is often necessary to employ a variety of complementary techniques in order to obtain the maximum amount of structural information. In this regard, the most useful structural techniques are those which are "atom-specific," viz., which probe the local structural environment around a given type of atom.

2.1 Diffraction

Diffraction, using x rays, neutrons, or electrons, is the technique most widely used to determine the structure of crystalline solids. However, for the case of amorphous materials, the absence of translational symmetry means that the diffraction theory must be developed from first principles without any of the simplifying features which can be employed in the case of crystalline materials. For the case of *monatomic* amorphous materials, diffraction provides the maximum amount of available structural information, whereas for the case of multicomponent systems the information is much less easily interpretable.

The scattering intensity from a sample is measured as a function of scattering angle 2θ, or equivalently the scattering vector (or momentum transfer)

$$k=\frac{4\pi}{\lambda}\sin\theta, \tag{5}$$

where λ is the wavelength of the radiation used. (k is conventionally used in x-ray applications and Q for neutron scattering.) For monatomic amorphous materials, the scattering intensity $I(k)$ is related to the structure factor $S(k)$ via

$$S(k)=I(k)/Nf^2, \tag{6}$$

where N is the number of scattering atoms and $f(k)$ is the k-dependent x-ray scattering factor (or equivalently b is the k-independent neutron scattering length). Thus, $S(k)$ is *independent* of the nature of the scattering radiation and is determined only by the atomic structure of the amorphous material. A reduced scattering factor can also be defined in terms of these two quantities, viz.,

$$F(k)=k[S(k)-1]. \tag{7}$$

$F(k)$ oscillates about an average value of zero, whereas $S(k)$ oscillates about unity and $I(k)$ about Nf^2.

It can be shown from first principles (see, e.g., Elliott, 1984, 1990) that, for isotropic amorphous materials, $F(k)$ is related to the real-space correlation function $G(r)$ (the reduced radial distribution function), via the expression

$$F(k)=\int_0^\infty G(r)\sin kr\,dr. \tag{8}$$

Correspondingly, there is an inverse relation through the Fourier transform:

$$G(r)=\frac{2}{\pi}\int_0^\infty F(k)\sin kr\,dk. \tag{9}$$

In practice, the scattering intensity cannot be measured over an infinite range of k values as required by Eq. (9); the maximum value is $k_{\max}=4\pi/\lambda$ from Eq. (5).

This cutoff in measured values of k leads to termination errors in the Fourier-transformed real-space correlation function: spurious small oscillations occur on either side of prominent peaks in the correlation function, and the resolution (i.e., width of peaks) is worsened.

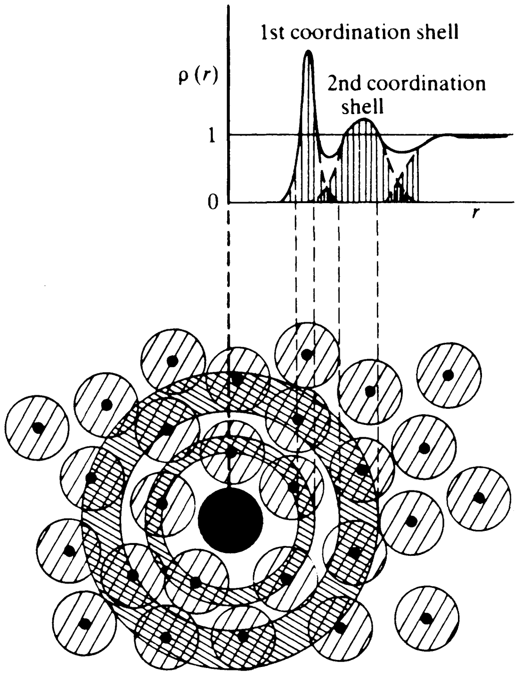

FIG. 2. Schematic illustration of the structural origin of features in the density function $\rho(r)$ for an amorphous solid.

The reduced radial distribution function (RDF) is related to the density correlation function $\rho(r)$ and the RDF itself $J(r)$ via the relations

$$\begin{aligned}G(r)&=4\pi r[\rho(r)-\rho_0]\\&=J(r)/r-4\pi r\rho_0,\end{aligned} \tag{10}$$

where ρ_0 is the average (macroscopic) atomic density. The RDF, defined as

$$J(r)=4\pi r^2\rho(r), \tag{11}$$

is the probability per unit length of finding an atom at a distance between r and $r+dr$ from a given origin atom. The structural origin of features in $\rho(r)$ [or $J(r)$] is illustrated in Fig. 2: it can be seen that the RDF is a one-dimensional representation of an (assumed isotropic) three-dimensional structure. Figure 3 shows various experimental correlation functions, in both real and reciprocal space,

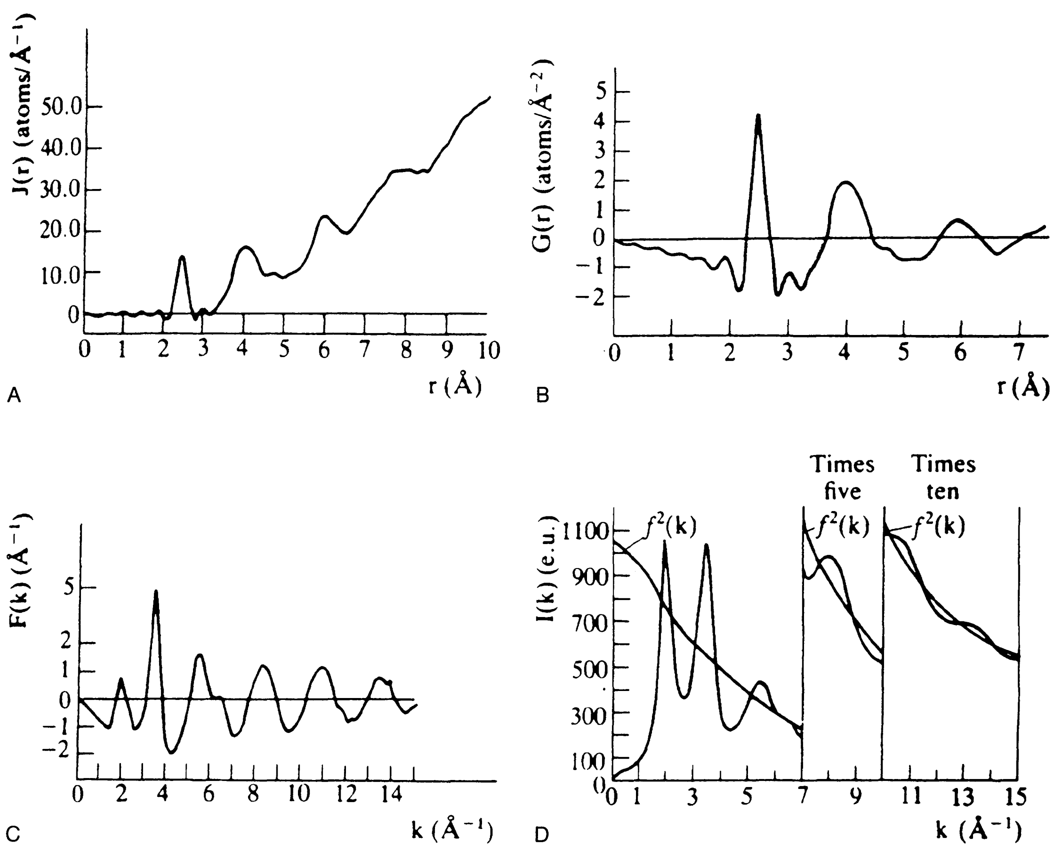

FIG 3. Structural correlation functions in real and reciprocal space obtained by x-ray diffraction for sputtered *a*-Ge films (Temkin *et al.*, 1973): (a) RDF; (b) reduced RDF; (c) reduced intensity; (d) scattering intensity.

for the case of the monatomic system *a*-Ge (Temkin *et al.*, 1973).

The more common situation involving multicomponent amorphous systems is considerably more complicated as far as diffraction is concerned. For a material containing n elements, a total of $n(n+1)/2$ distinct pair correlation functions are needed to describe the structure fully. The density function can now be defined, in terms of an origin atom i and surrounding atoms j, as

$$\rho(r)=\sum_{ij} W_{ij}\,\rho_{ij}(r)/x_j, \tag{12}$$

where the weighting factors (k-dependent for the case of x rays) are given by

$$W_{ij}=x_i\,x_j\,f_i\,f_j/\langle f\rangle^2, \tag{13}$$

and where $\langle f\rangle=\sum_{i=1}^{n} x_i\,f_i$. The reduced scattering intensity now becomes

$$F(k)=k\left[\frac{I/N-\langle f^2\rangle}{\langle f\rangle^2}\right]$$

$$=\int_0^\infty 4\pi r[\rho(r)-\rho_0]\sin kr\,dr \tag{14}$$

(where $\langle f^2\rangle=\sum_{i=1}^{n} x_i\,f_i^2$), which is superficially similar to Eqs. (8) and (10) for the case of monatomic systems.

The above treatment is developed in terms of atom-atom pair correlation functions (the so-called Faber–Ziman formulation). For the case of *binary* alloys, the expression for the scattering intensity can be reformulated in terms of number-number, number-concentration, and concentration-concentration correlation functions, $S_{NN}(k)$, $S_{NC}(k)$, and $S_{CC}(k)$, respectively (Bhatia and Thornton, 1970), where

$$S_{NN}(k)=x_1^2I_{11}(k)+x_2^2I_{22}(k)+2x_1x_2I_{12}(k), \tag{15a}$$

$$S_{\mathrm{NC}}(k)=x_1x_2\{[x_1I_{11}(k)+x_2I_{12}(k)] \\ -[x_1I_{21}(k)+x_2I_{22}(k)]\}, \qquad (15b)$$

$$S_{\mathrm{CC}}(k)=x_1x_2\{1+x_1x_2[I_{11}(k)+I_{22}(k) \\ -2I_{12}(k)]\}, \qquad (15c)$$

and where

$$I_{ij}(k)-1=\int_0^\infty 4\pi r^2\{[\rho_{ij}(r)/x_j]-\rho_0\} \\ \times\frac{\sin kr}{kr}\,dr. \qquad (16)$$

The overall scattering intensity in the Bhatia–Thornton formalism can then be written as

$$I/N=\langle f\rangle^2S_{\mathrm{NN}}(k)+2\langle f\rangle\Delta fS_{\mathrm{NC}}(k) \\ +\frac{[\langle f^2\rangle-\langle f\rangle^2]}{x_1x_2}\,S_{\mathrm{CC}}(k), \qquad (17)$$

where $\Delta f = f_1(k) - f_2(k)$. $S_{\mathrm{NN}}(k)$ represents the *topological* SRO, and it oscillates about unity and tends to that value as $k\rightarrow\infty$. $S_{\mathrm{CC}}(k)$ describes the *chemical* SRO, and for a random distribution of the two types of atoms in a binary alloy $S_{\mathrm{CC}}(k) = x_1x_2$; otherwise, it oscillates about this value and tends to it as $k\rightarrow\infty$. *Positive* values of $S_{\mathrm{CC}}(0) - x_1x_2$ indicate a preference for *like* nearest neighbors (or clustering), whereas *negative* values indicate a preference for unlike neighbors (or chemical SRO). Finally, $S_{\mathrm{NC}}(k)$ is zero for random mixtures; otherwise it oscillates about this value and vanishes as $k\rightarrow\infty$.

For the case of multicomponent amorphous systems, the maximum amount of structural information, viz., the partial pair correlation functions, is obtained, in principle, if as many scattering experiments are performed as there are distinct partial functions in each of which the weighting factor W_{ij} [Eq. (13)] is somehow varied. Since a change in composition (x_i or x_j) usually means a concomitant change in structure, this means that it is the scattering factors which must be varied, and at least five different methods for achieving this can be identified for the simplest case of binary systems where there are *three* distinct partial pair correlation functions.

The first is simply to use three different types of radiation, viz., neutrons, x rays, and electrons, although this method is often impractical in view of the disparate quantities of material required by each technique. The second method is that of isotopic substitution in neutron scattering, wherein the isotopic components of the elements involved are varied while keeping the overall composition unchanged (Neilson and Enderby, 1983). The largest changes in scattering factor arise when a particular element has a *negative* neutron scattering length, as is the case for the elements H, Li, Ti, and Ni, for which two special cases are possible: in the case of "null elements" (e.g., where $\bar{b}_1 = 0$), $I_{22}(k)$ or $G_{22}(r)$ is obtained directly from a neutron diffraction experiment; in the case of "zero alloys," i.e., where $\langle b\rangle = x_1b_1 + x_2b_2 = 0$, $S_{\mathrm{CC}}(k)$ is obtained directly, and if $b_1 = b_2$ (i.e., $\Delta f=0$), $S_{\mathrm{NN}}(k)$ is obtained directly [cf. Eq. (17)]. A third possibility of changing neutron scattering lengths is for the case of magnetic amorphous metals, where the scattering of *polarized* neutrons is different depending on whether the neutron spin polarization is parallel or antiparallel to the magnetization direction of the amorphous metal (Sadoc and Dixmier, 1976). A fourth technique, applicable to x-ray scattering, is isomorphous substitution, wherein one of the elements in a binary (usually metallic) alloy is partially replaced by a third element having the *same* size and chemical characteristics as that being replaced (so that the structure is unperturbed), but because of the difference in atomic number, the x-ray scattering factors can vary significantly. Finally, the method of anomalous scattering can be used to vary the scattering factors systematically in certain cases. The technique utilizes the fact that near an absorption edge for the scattering radiation involved, the scattering factor is modified by the dispersion correction which is complex, viz.,

$$f(k,\omega)=f^0(k)+f'(k,\omega)+if''(k,\omega). \qquad (18)$$

The first term in Eq. (18) is the normal scattering factor, which for the case of x rays is simply the Fourier transform of electronic charge density of the atom. The imaginary component of the dispersion correction is proportional to the absorption coefficient $\alpha(\omega)$, viz., $f''(\omega) \propto \omega\alpha(\omega)$, and f' and f'' are related via Kramers–Kronig transformations. Although the method is more generally useful for the case of x-ray scattering, where every element has a series of x-ray absorption edges at different energies and these are accessible using a broadband tunable x-ray synchroton radiation source, it can also be employed for the case of neutron scattering in the rare cases where a thermal neutron undergoes capture by a nucleus (e.g., in ^{149}Sm).

In conclusion, diffraction techniques provide, through the RDF, the maximum amount of structural information for amorphous materials for the case of monatomic systems, and a similar situation prevails in the case of multicomponent systems if the partial correlation functions can be extracted. Structural information can be interpreted most easily from the RDF, particularly for the first two peaks which give SRO information. Higher-lying peaks are increasingly difficult to interpret unambiguously in the absence of structural modeling studies (see Sec. 3).

2.2 X-Ray Absorption Spectroscopy

The first of the atom-specific structural probes, complementary to diffraction, to be discussed is x-ray absorption spectroscopy (XAS). In this, the x-ray absorption coefficient is measured as a function of x-ray photon energy in the vicinity of an absorption edge of one of the elements in a multicomponent amorphous material, and three regions in the resulting spectrum can be distinguished, consisting of, respectively, pre-edge structure, just beyond the absorption edge, "x-ray absorption near-edge structure" (XANES) or equivalently "near-edge x-ray absorption fine structure" (NEXAFS), and at higher photon energies "extended x-ray absorption fine structure" (EXAFS). Figure 4(a) shows experimental x-ray absorption spectra exhibiting features in all three regions of energy.
